Connect the gastric aspiration port and the nasogastric tube to the suction source (**Figure 63-11**). Place the gastric aspiration port and the nasogastric tube on low intermittent suction. Unclamp the esophageal balloon port clamp. Attach the Y tubing, manometer, and pressure bulb (or 50 mL syringe) to the esophageal balloon port (**Figure 63-11**). Inflate the esophageal balloon to a pressure of 25 mmHg if bleeding continues through the gastric aspiration port or the nasogastric tube. If bleeding continues to persist, increase the esophageal balloon pressure in 5 mmHg increments until 45 mmHg is achieved or the bleeding stops. Double clamp the SB tube to prevent accidental deflation of the balloons. If bleeding continues despite maintaining the esophageal balloon pressure at 45 mmHg, this is suggestive of a gastric wall varix. In this case, check that the tube is snugged up on the nose firmly and taped securely. Finally, fill the gastric balloon with more air gradually up to a total volume of 300 mL of air.

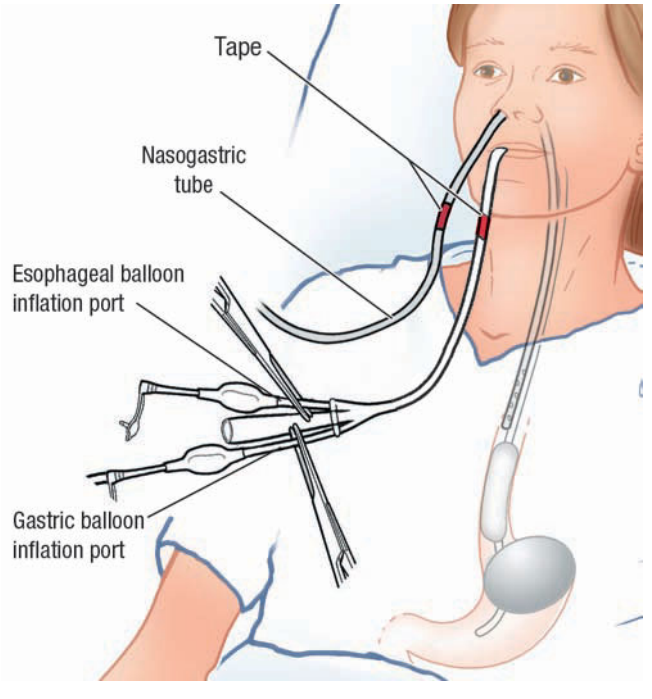

FIGURE 63-10. The nasogastric tube is inserted until the tape mark lines up with the tape mark on the SB tube. The football helmet/catcher's mask is omitted from this illustration for the sake of clarity.

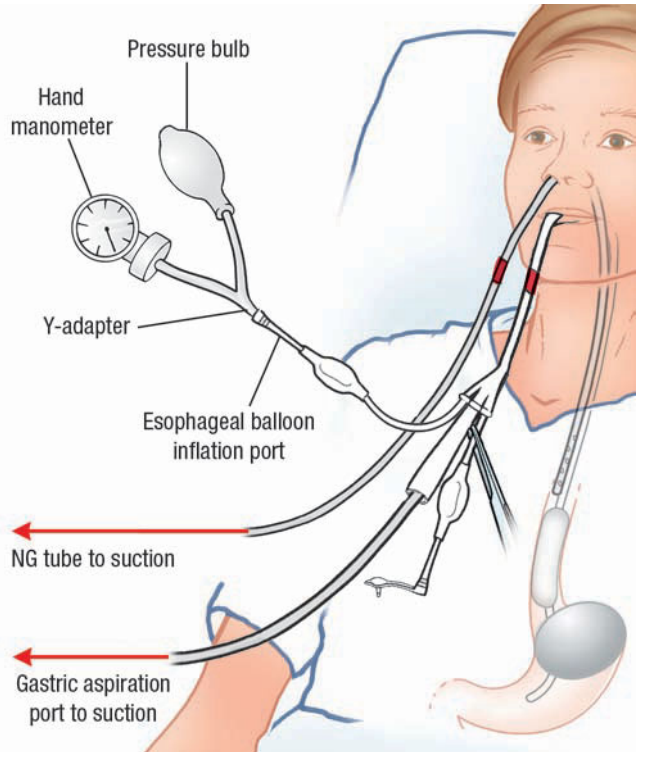

FIGURE 63-11. The esophageal balloon is inflated after the gastric aspiration port and the nasogastric tube have been attached to a suction source. The football helmet/catcher's mask is omitted from this illustration for the sake of clarity.

ALTERNATIVE TECHNIQUE

The above technique is also applicable to the four-lumen esophagogastric tamponade (Minnesota) tube. This tube is a modification of the triple-lumen SB tube that incorporates a separate esophageal suction port to the existing gastric suction port.[13,14] The design of the Minnesota tube may help prevent aspiration of esophageal contents.[15] Always check the manufacturer characteristics regarding the maximum inflation volume of both the gastric and esophageal balloons, as these are dependent upon the tube manufacturers.

Recently proposed is an effective methodology for placement of the SB tube endoscopically.[16] This method will avoid the need to obtain radiologic confirmation of the gastric balloon within the stomach.[16] Delay in treatment while waiting for a radiologic confirmation may put patients at risk, as they are almost always in critical condition and require immediate attention.[4–6] If endoscopic intervention is not successful, pass an SB tube and confirm the position of the gastric balloon under direct visualization through the endoscope. The balloons are inflated and secured in the usual fashion.[16]

ASSESSMENT

Check the pressure in the balloons periodically with the mercury manometer or keep the manometer attached for constant monitoring. Obtain a portable radiograph to confirm proper placement of the SB tube and the inflated balloons. The patient may be reclined, but always maintain at least 6 to 10 in. of head elevation on the bed to prevent aspiration in the awake patient. Tape a scissors to the head of the bed for quick access in case the balloon requires emergent deflation (**Figure 63-12**).

AFTERCARE

If the bleeding is controlled, reduce the esophageal balloon pressure by 5 mmHg every 3 hours until 25 mmHg is reached without bleeding from the nasogastric tube in the esophagus or the gastric aspiration port. Deflate the esophageal balloon for 5 minutes every 6 hours to avoid esophageal pressure necrosis. Give the patient nothing by mouth. Oral medications, if required, may be administered through the gastric aspiration port. Check the tension on the SB tube every 3 hours and adjust it as necessary. Verify patency of the SB and nasogastric tubes by checking the gastric and esophageal return regularly and periodically flushing both lumens.

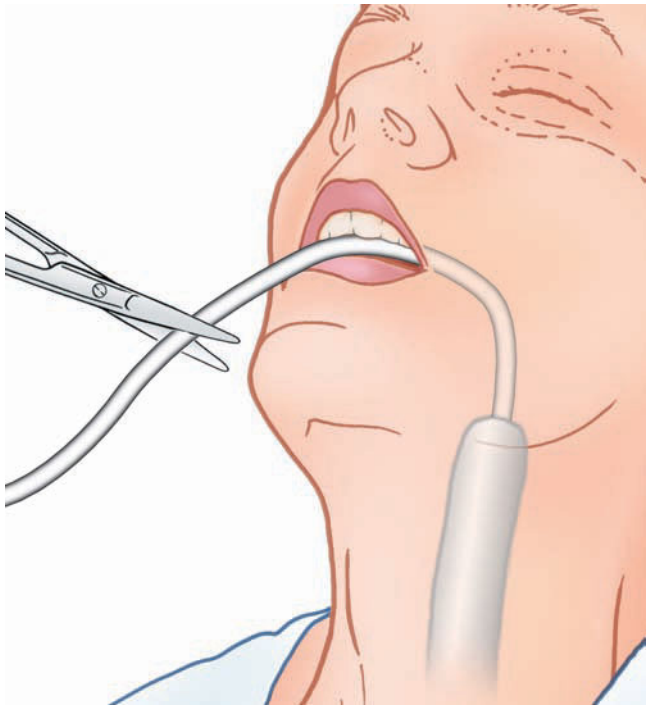

FIGURE 63-12. Emergent removal of the SB tube. Cut the SB tube between the ports and the patient to deflate both balloons rapidly.

Monitor the patient continuously for signs of chest pain, respiratory distress, and aspiration. Migration of the esophageal balloon into the hypopharynx of an awake patient will result in respiratory distress. **This situation is a true emergency and the tube should be removed immediately.** Cut the SB tube between the ports and the patient with a scissors (**Figure 63-12**). The balloons will immediately deflate and allow the removal of the SB tube.

The esophageal balloon should not remain inflated for more than 24 hours to avoid mucosal necrosis. The SB tube is usually left in place with the gastric or gastric and esophageal balloons inflated for 24 hours if variceal bleeding is controlled. If there is no bleeding after 24 hours, deflate the esophageal balloon and leave the gastric balloon inflated for an additional 24 hours. The SB tube may be left in place for an additional 24 hours after both balloons are deflated. If variceal hemorrhage recurs, the appropriate balloons should be reinflated while alternative therapy to control bleeding is sought. Patients who rebleed have a higher mortality rate. Therefore, other therapeutic interventions—such as rubber banding, sclerotherapy, transjugular intrahepatic portocaval shunt, or surgery—should be considered. Remove the SB tube if hemostasis persists for 24 hours after deflation of both balloons. Control of esophageal variceal bleeding can be achieved by balloon tamponade in 50% to 94% of patients.[18–22] However, rebleeding occurs in 38%.

COMPLICATIONS

Major complications occur in up to 15% of patients and lethal complications have been described in up to 6.5% of patients.[18–22] **Complications associated with the SB tube are often life-threatening.** The airway may become occluded due to proximal migration of the esophageal balloon into the hypopharynx of the awake patient from traction on the SB tube.[17] The patient will begin choking and gagging if not intubated. Cut the SB tube distal to the ports to immediately deflate the balloons and allow the SB tube to be removed. Pulmonary aspiration, and subsequent pneumonia, may occur during SB tube insertion. Airway protection by endotracheal intubation should be considered in all patients prior to insertion of the SB tube.[18]

Despite endotracheal intubation, the SB tube may still become malpositioned and end up in the airway.[27] Inflation of the balloons in the airway can result in respiratory distress, respiratory tract obstruction, tracheal or bronchial rupture, or tracheoesophageal fistulas from pressure necrosis. **This is why it is essential to confirm proper placement prior to inflating the balloons.**

Excessive balloon pressure or prolonged balloon inflation may lead to pressure necrosis and ulcerations of the esophagus, gastroesophageal junction, and/or stomach. Periodic deflation of the esophageal balloon every 6 hours will help prevent this. Rupture or lacerations of the esophagus, stomach, or small intestine may occur.[19] Esophageal rupture can result in mediastinitis, abscess formation, and sepsis. These can be prevented by adhering to proper balloon inflation techniques with pressure monitoring. Cardiac arrhythmias and pulmonary edema can occur and require continuous monitoring in the setting of an intensive care unit. Pulmonary edema is often due to pressure from the esophageal balloon on mediastinal structures.

Numerous other complications are associated with the use of the SB or Minnesota tube. Unintentional deflation of the balloons can

be prevented by the application of rubber shod clamps or hemostats to the balloon inflation ports after the balloons are inflated. Cut the SB tube distal to the ports if the balloons will not deflate. The patient may become agitated from the discomfort of the tube, migration of the tube into the hypopharynx resulting in hypoxemia and asphyxiation, or as chest and back pain is experienced from a misplaced or overdistended balloon. Hiccoughs are due to pressure on the diaphragm by the balloons. Excessive traction on the tube can result in epistaxis or pressure necrosis of the lips, nose, or tongue. Use air and not a liquid to inflate the balloons. Liquid in the balloons causes them to be heavy, increases the risk of pressure necrosis, and makes them hard to deflate.

SUMMARY

Balloon tamponade of variceal bleeding is an uncommonly performed procedure in the Emergency Department. The SB tube plays an important role in the temporary control of hemorrhage from esophageal or gastric varices.[20–22] It is used in cases of variceal bleeding, usually documented by endoscopy, that continues despite aggressive medical management including lavage, correction of blood clotting abnormalities, intravenous somatostatin or vasopressin infusion, rubber banding, and emergent sclerotherapy.[16,23–25] The SB tube can also be placed if these methods are contraindicated or unavailable. Despite the initial success of balloon tamponade in the control of variceal hemorrhage, sustained control of bleeding occurs in only 40% to 50% of patients.[26] Balloon tamponade has been shown to be as effective as intravenous vasopressin in controlling esophageal variceal bleeding. Only 25% of patients with ascites, jaundice, and encephalopathy achieve lasting hemostasis with balloon tamponade. Long-term efficacy in terms of rebleeding depends in part on the patient's underlying liver disease.[16] Maintain a low threshold to intubate the patient endotracheally in order to prevent aspiration, protect the airway, and prevent airway occlusion from migration of the esophageal balloon.

64 Gastrostomy Tube Replacement

Maggie Ferng and Ryan C. Headley

INTRODUCTION

Gastrostomy tubes are commonly used devices that provide prolonged enteral support in patients who are unable to obtain sufficient nutrition orally. Simplified techniques for their placement and improved materials have made gastrostomies common in the outpatient setting. Emergency Physicians fill a valuable role in solving gastrostomy tube problems as many patients present to Emergency Departments with various gastrostomy tube complaints. This chapter reviews the methods and materials used in gastrostomies and the approaches to replacing displaced or malfunctioning gastrostomy tubes.

ANATOMY AND PATHOPHYSIOLOGY

Familiarity with the basic techniques used to create gastrostomies and the characteristics of common gastrostomy tubes is helpful in solving problems with their function and replacing tubes when appropriate.

PLACEMENT OF GASTROSTOMY TUBES

Feeding tubes have been surgically placed in patients for more than a century. Three main procedures that remain in use today are the Stamm (described in 1894), the Witzel (described in 1891), and the Dupage and Janeway (described in 1913)[1–6] (**Figure 64-1**). They all require a laparotomy under general anesthesia and provide long-term access to the stomach for feedings or decompression while attempting to minimize the potential for gastric leakage.

Each of the techniques attempts to create a leakproof interface between the stomach, the feeding tube, and the anterior abdominal wall. The Stamm gastrostomy secures the stomach to a gastrostomy tube using a double purse-string suture to invaginate the stomach about the feeding tube (**Figure 64-1A**). The Witzel technique places the gastrostomy tube through a seromuscular tunnel in the stomach wall (**Figure 64-1B**). The Janeway technique creates a formal tunnel from a gastric flap to envelop the gastrostomy tube and form a gastrocutaneous stoma (**Figure 64-1C**). Importantly, all three techniques involve suturing the stomach wall to the undersurface of the abdominal wall. This is significant because if a surgically placed gastrostomy tube is accidentally dislodged in the early postoperative period, the stomach wall remains attached to the abdominal wall and the chance of intraperitoneal contamination is decreased. These surgical gastrostomies are considered long-term, semipermanent stomas.

Modern endoscopic techniques have provided a less invasive option for the placement of percutaneous feeding tubes (also known as gastrostomy tubes, percutaneous endoscopic gastrostomies, or PEGs).[7] Distinct advantages of endoscopically placed gastrostomy tubes over surgically placed tubes include relative ease of placement, avoidance of general anesthesia, smaller incision, and a lower morbidity rate.[2,7,8] The disadvantages of endoscopic techniques include the inability to place tubes in patients with thick abdominal walls, a history of multiple previous operations, and the presence of abdominal wall hernias, as well as an increased risk of injuring overlying viscera during the "blind" placement of the PEG tube. Another disadvantage is the unique danger of accidental dislodgement of a newly placed PEG tube. If a new PEG tube is dislodged, the stomach wall gastrotomy can pull away from the abdominal wall allowing the escape of gastric secretions and feedings with resultant peritonitis.

Popular endoscopic techniques in use today require two persons—an endoscopist and an operator at skin level. An endoscope is first advanced into the stomach (**Figure 64-2A**). The stomach is then insufflated with air to displace adjacent or overlying loops of bowel and appose the stomach wall to the anterior abdominal wall (**Figure 64-2B**). The endoscopist then visualizes the light of the endoscope as it transilluminates the abdominal wall. They then pierce the anterior abdominal wall with a hollow-bore needle (**Figure 64-2C**). The endoscopist confirms placement of the device into the gastric lumen (**Figure 64-2C**).

The gastrostomy tube is then placed. A guidewire is fed into the stomach through the needle, grasped with an endoscopic snare, and pulled out of the patient's mouth (**Figure 64-2C**). The "Ponsky pull" technique uses this guidewire as a means for pulling the gastrostomy tube into position through the patient's mouth (**Figure 64-3A**). The guidewire is secured around a gastrostomy tube and pulled retrograde from the mouth to the exit site on the anterior abdominal wall. The "Ponsky push" technique involves pushing the tube down and over the guidewire toward the gastrostomy site[9] (**Figure 64-3B**). A third technique, the "Russell poke" eliminates the need to direct the gastrostomy tube through the mouth.[10] Under direct visualization, a dilator is used to enlarge the skin puncture site. An introducer and a peel-away sheath are then used to place the gastrostomy

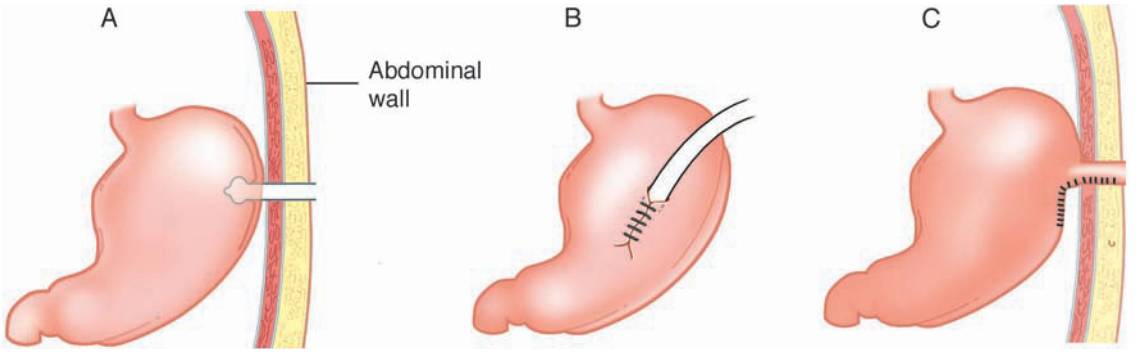

FIGURE 64-1. Surgical gastrostomies. **A.** The Stamm technique. **B.** The Witzel technique. **C.** The Janeway technique.

tube directly through the anterior abdominal wall (**Figure 64-3C**). **Regardless of which technique is used to establish the gastrostomy, the stomach is not sutured to the abdominal wall.** Instead, a fibrous tract eventually forms between the anterior abdominal wall and the stomach. **The maturation of this tract is an important consideration in assessing gastrostomy tubes.**

TYPES OF GASTROSTOMY TUBES

Although there are many types available, a basic understanding of gastrostomy tubes is all that is needed to diagnose and treat most problems. Familiarity with the characteristics of gastrostomy tubes is helpful in assessing tube function and determining appropriate replacements.

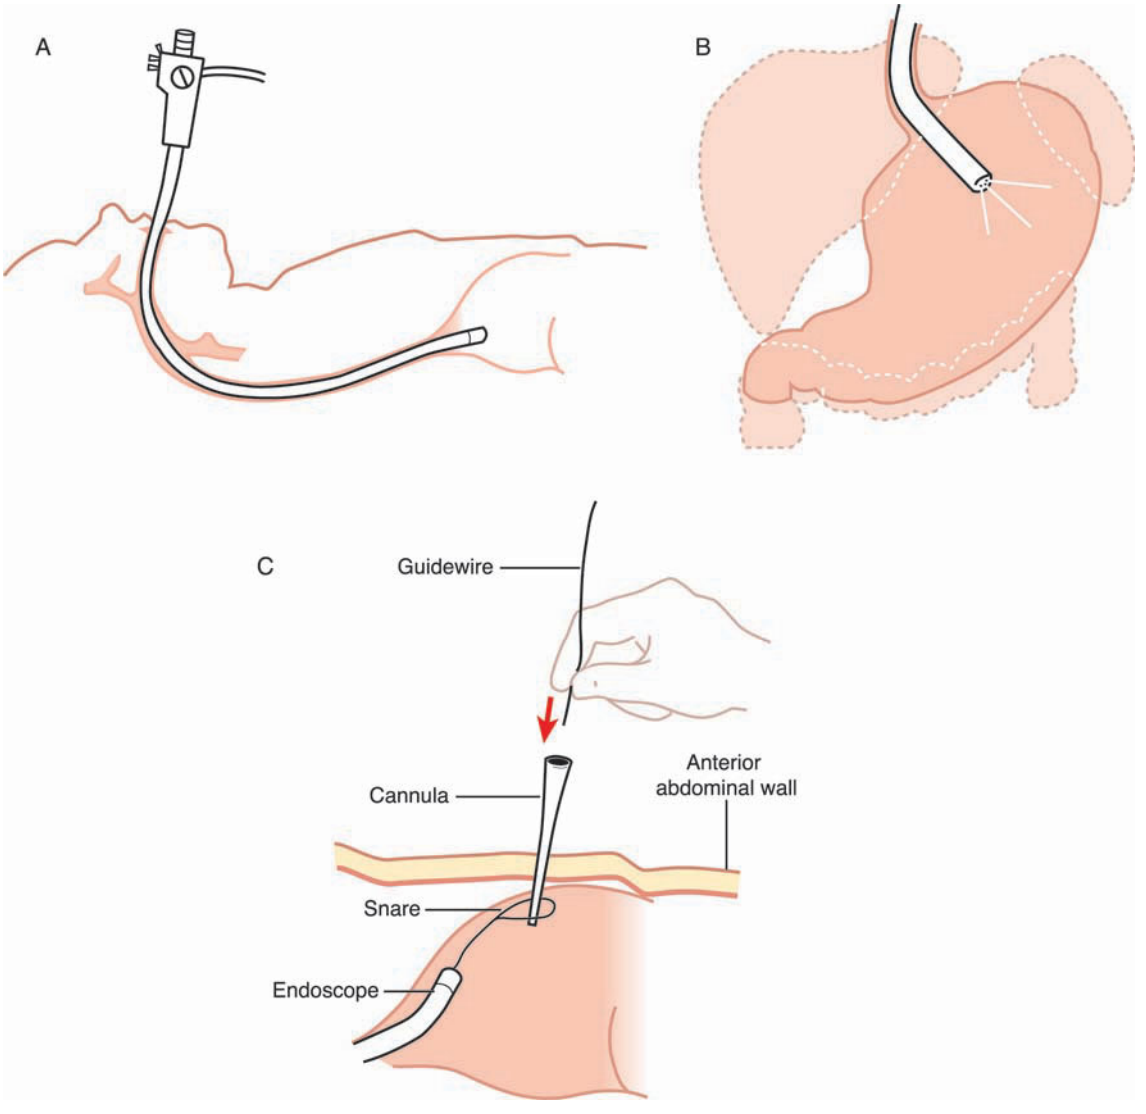

FIGURE 64-2. Endoscopic gastrostomy tube placement. **A.** The endoscope is inserted. **B.** The stomach is inflated with air and transilluminated. **C.** The anterior abdominal wall is pierced with a cannula or needle under endoscopic guidance. A suture or guidewire is then introduced into the gastric lumen and grasped with a snare.

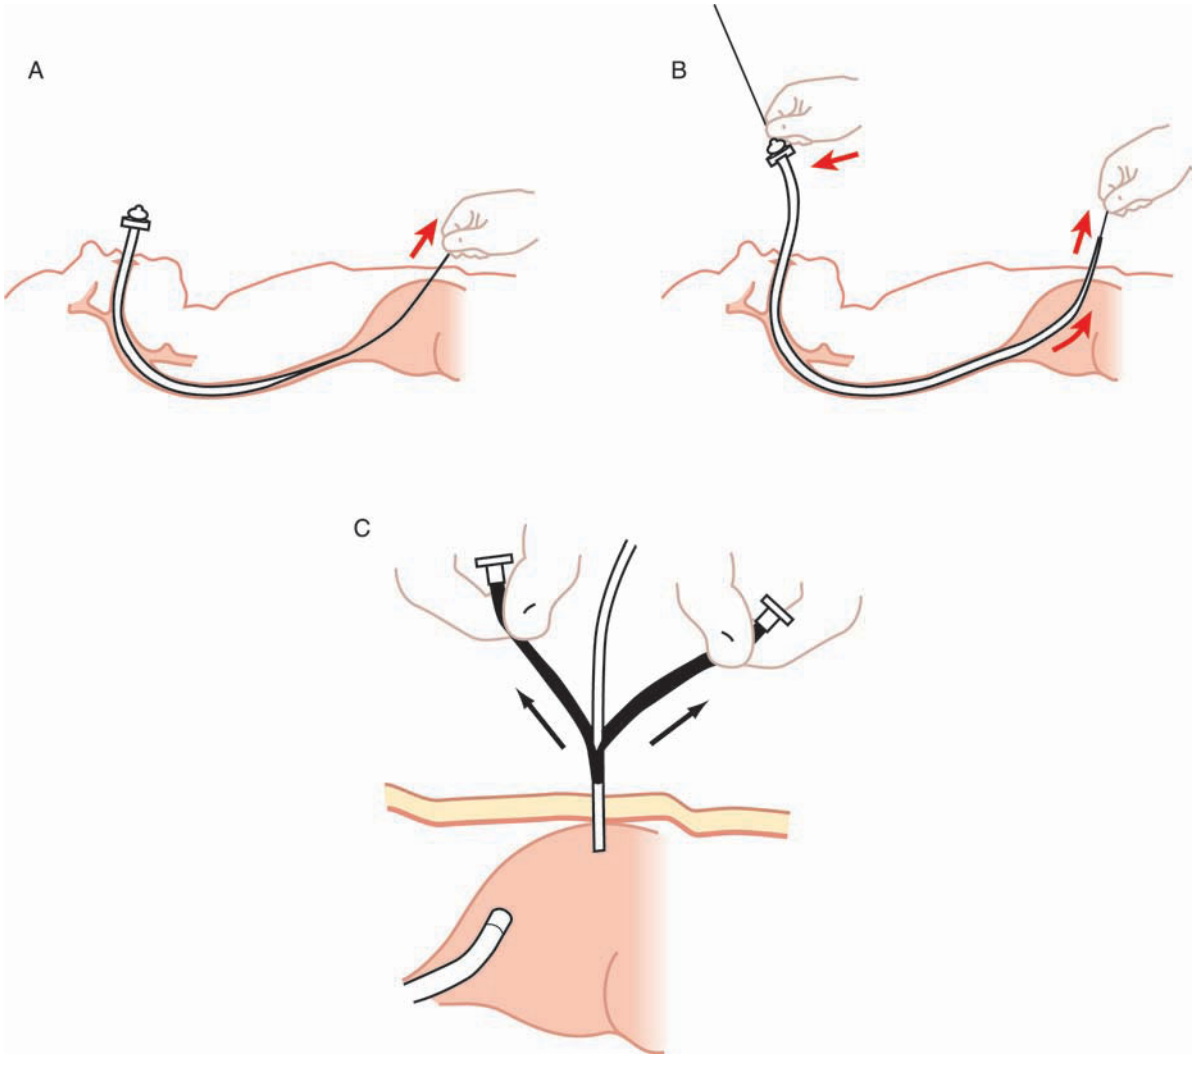

FIGURE 64-3. Endoscopic gastrostomy tube placement. **A.** The "Ponsky pull." A suture is attached to a modified gastrostomy tube and pulled in a retrograde direction through the anterior abdominal wall. **B.** The "Ponsky push." A guidewire serves as a trolley for the gastrostomy tube to be pushed over. **C.** The "Russell poke." The gastrostomy tube is inserted through a peel-away sheath.

The gastrostomy tube is simply a conduit for enteral feedings. The essential features of the gastrostomy tube include four components: the tube itself, an internal bolster, an external fixation (bolster or retention) device, and the ports (**Figure 64-4**). The main body of the gastrostomy tube is made of silicone or polyurethane. It is designed to minimize tissue reactions and optimize patient comfort. Gastrostomy tubes come in a variety of sizes ranging from 12 to 24 French. Some are reinforced with an inner steel wire. Many come with external identification marks to denote caliber, commercial brand name, centimeter markings to aid in positioning, and radiopaque lines to aid in radiographic identification (**Figure 64-4**).

The internal bolster fixes the gastrostomy tube within the lumen of the stomach and creates a seal to discourage leaking (**Figure 64-4**). Commercially available PEG catheters come with a variety of choices for internal bolsters including balloons, crossbars, T-bars, flanges, round disks, three-leaf retainers, soft domes, and others (**Figure 64-5**). The most basic tubes use a balloon as an internal bolster. Surgical gastrostomies commonly use Foley balloon catheters, mushroom-tip de Pezzer catheters, or Malecot catheters. Some internal bolsters are deformable and allow removal with gentle traction on the external tube. Others are not intended to give way with traction and require more invasive techniques for removal. The nature of the internal bolster will determine if a gastrostomy tube can be removed at the bedside or requires endoscopic removal.

External bolsters are devices at the skin exit site that secure the gastrostomy tube to the abdominal wall and prevent its inward migration (**Figure 64-4**). Surgical gastrostomies frequently rely on only a silk suture. PEGs typically use a T-bar or retention disk. The external bolster has little impact on the function of the gastrostomy tube or the technique used to place it. The external bolster may cause the gastrostomy tube to kink, fracture, or clog if it is too tight. Additionally, an external bolster that pulls the internal bolster too tightly toward itself may cause stomach wall and/or abdominal wall necrosis. Conversely, the gastrostomy tube may migrate inward with peristalsis and cause a bowel obstruction if the external bolster is too loose. Inappropriate care of the external bolster may lead to problems that contribute to the need for replacement, although it does not affect the ability to remove the gastrostomy tube. Identification and correction of problems with the external bolster can prevent unnecessary damage to the gastrostomy tube.

The external end of the gastrostomy tube contains the port(s) to access the lumen(s). Many tubes have a Y port, with one port for enteral feedings and a pop-off valve port to access a balloon (**Figure 64-4**). Some tubes have multiple ports to access each

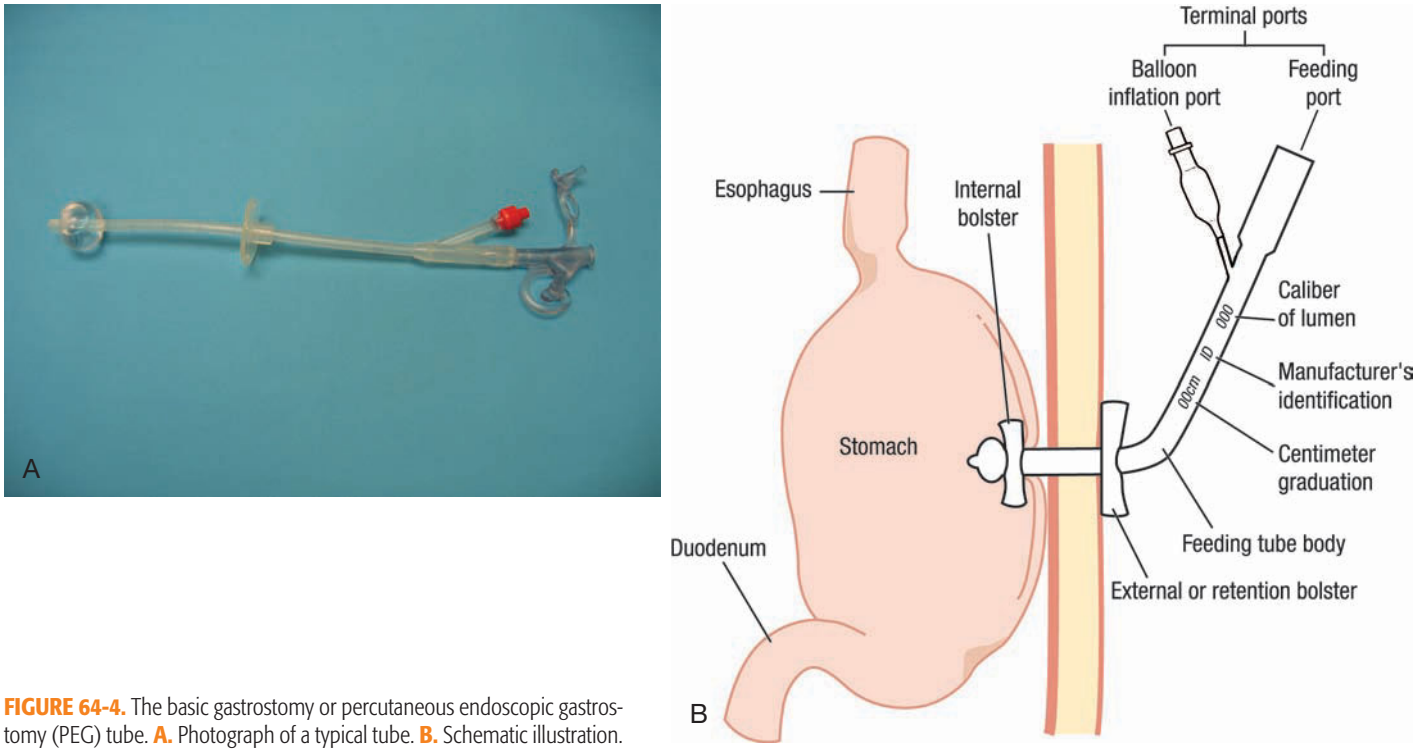

FIGURE 64-4. The basic gastrostomy or percutaneous endoscopic gastrostomy (PEG) tube. **A.** Photograph of a typical tube. **B.** Schematic illustration.

separate lumen that is designated for a specific purpose, such as medication administration. Others have a suction port for gastric suctioning and a port for distal feeding.

In an effort to improve patient comfort and acceptance, some manufacturers now supply skin-level devices. These are also referred to as low-profile systems or buttons. These tubes combine the external access port and the external bolster to provide a more cosmetically appealing look without a dangling tube.

INDICATIONS

There is no need for routine removal or replacement of gastrostomy tubes. The most common indication for gastrostomy tube replacement is accidental removal. Occasionally, gastrostomy tubes require replacement because they wear out, kink, or fracture. They should be replaced if the lumen becomes clogged with precipitate and cannot be unclogged. Most of these problems can be avoided with diligent care of the gastrostomy tube. Feedings should never be forced—a common error that can weaken the tube. The feeding tube should be flushed with water after each use. Medications should never be mixed with enteral feeding solutions. Proper care of the gastrostomy tube should prevent premature loss. Family members and healthcare providers should receive detailed instructions regarding gastrostomy tube management so as to avoid common problems.

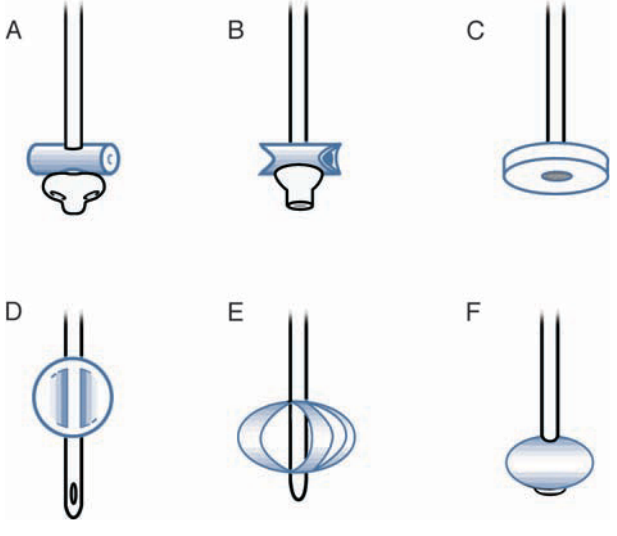

FIGURE 64-5. Examples of internal bolsters used in PEGs. **A.** Mushroom tip with de Pezzer flange. **B.** Crossbar. **C.** Round disk. **D.** Balloon tip. **E.** Malecot. **F.** Soft dome.

CONTRAINDICATIONS

A damaged, malfunctioning, or displaced gastrostomy tube should be replaced as soon as possible, with a few exceptions. **The existing tube should be left in place if the tract is immature. Premature removal of a tube in an immature tract, particularly if it is endoscopically placed, can lead to gastric spillage and peritonitis.** The exact time for a tract to mature depends upon the procedure used and the patient's nutritional status. A conservative approach is to consider any tract less than 4 weeks old to be immature. The specialist who performed the original procedure should be consulted prior to any manipulation of the immature tract. The gastrostomy tube and tract should be left alone and a Surgeon consulted if a patient has peritonitis at the time of presentation. If the patient has acute abdominal pain after manipulation of a gastrostomy site, feedings should be withheld until an investigation determines the source of the problem. Do not manipulate or change the gastrostomy tube if the patient has pain at the skin entry site or with movement of the tube. This may alert the clinician to an underlying abscess, infection, or intraabdominal pathology.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Commercial replacement gastrostomy tube kits
- Foley catheter of a similar caliber as the original tube

- 20 mL syringe with saline to fill the Foley balloon
- Water-soluble lubricant
- Toomey syringe or bulb syringe to aspirate gastric contents
- Some form of external bolster (see the text below)
- Adapter to cap off Foley catheter or attach it to feeding assembly
- Gloves

PATIENT PREPARATION

Explain the procedure to the patient and/or their representative. Gastrostomy tube replacement can usually be accomplished with little preparation or anesthesia. Place the patient supine. Clean the skin surrounding the entry site of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry. Anesthesia should not be necessary, as the gastrostomy site should not be tender. Significant pain at the site should alert the clinician to an infection, abscess, or intraabdominal pathology. **If anything more than minor discomfort occurs, the gastrostomy should not be manipulated.** Small children or anxious patients may benefit from mild sedation.

TECHNIQUES

The technique for replacing a gastrostomy tube will depend upon the original procedure used to place the tube, the maturity of the tract, and the nature of the internal bolster. Obtain as much information as possible about the age and nature of the existing tube. The following discussion reviews the procedure for replacing gastrostomy tubes in mature tracts, factors to consider prior to removing an existing but dysfunctional tube, and techniques to employ in fashioning replacement systems.

REPLACING A DISLODGED GASTROSTOMY TUBE

Every effort should be made to replace a dislodged gastrostomy tube as soon as possible. Gastrostomy sites begin to close as soon as the tube is removed. The tract will close within hours to days depending on its age, maturation, and size of the tube. If the original tube is in good condition, it can simply be reinserted to stent the tract until a permanent replacement is found. A commercially available replacement that is compatible with the original tube may be used. Foley catheters are simple to use, are widely available, and function well as temporary replacements.[8,11–13]

Select a tube of similar caliber to the patient's gastrostomy tube. Most commonly, a Foley catheter is used. A decision regarding the choice of external fixation should be made, and the tube adapted appropriately prior to its insertion (see discussion below). Lubricate the replacement tube liberally. Gently insert the replacement tube through the tract. **Do not advance the tube against any significant resistance. Advancement against more than mild resistance can result in complications.** Aspirate gastric contents to confirm proper placement. Inflate the Foley catheter balloon with saline. Pull the Foley catheter snug to lodge the balloon immediately behind the anterior abdominal wall. **The entire process should be painless and should not require dissection or force.** Inject the feeding port with water-soluble contrast and obtain a KUB to confirm proper placement

A few types of feeding tubes merit special attention. While many gastrostomies have a short, direct route to the stomach, the Witzel uses a more circuitous tunnel and a smaller tube. The tract may be difficult to maneuver. When problems replacing a surgical gastrostomy tube arise, obtain surgical consultation.

Not all feeding tubes terminate in the stomach. In some cases, the feeding tube enters the stomach, travels through the pylorus and duodenum, then terminates in the proximal jejunum. If a patient is known to have a jejunostomy (sometimes referred to as a percutaneous endoscopic jejunostomy, or PEJ), the tract may be stented with a replacement gastrostomy tube. More information should be obtained prior to resuming feedings.

Some catheters are not intended to be replaceable. Small needle jejunostomies may use 5 to 7 French catheters. Should such a catheter become disrupted or occluded, there is little one can do to correct it. Consult with the patient's primary care provider to discuss the variable options for management and follow-up.

PLACING AN EXTERNAL BOLSTER

After the successful insertion of a replacement tube, it needs to be secured in place. The tube should be kept 90° relative to the skin and fixed in some way to prevent migration into the distal bowel. A short-term solution is to dress the site with 4 × 4 gauze squares, building them up along the exit site to create a pyramid-shaped dressing several inches high. A strip of urethane foam can be used to bolster the tube[14] (**Figure 64-6A**). A 3 cm section of latex tubing can be wrapped about the base of the gastrostomy tube and secured with a plastic cable tie[15] (**Figure 64-6B**). A modification to a Foley catheter uses a retention disk and a plastic ring from a nasogastric tube to secure the Foley catheter (**Figure 64-6C**).[13]

Another option is to secure and bolster the tube with a suture (**Figure 64-7**). Some prefer to inject local anesthetic solution subcutaneously to minimize the discomfort of placing the single suture. Others believe placing the one suture is equal to the pain of injection of the local anesthetic agent and do not use it. This decision should be decided on a case-by-case basis after a discussion with the patient and/or their representative. Place a suture using a large bite of tissue near the skin exit site. This serves as a retention suture. Leave an open loop of 1 to 2 cm between the skin and the knot to avoid unnecessary traction on the skin. Wrap the ends of the suture up the gastrostomy tube in a laddered fashion and tie them securely. This method allows some room for the gastrostomy

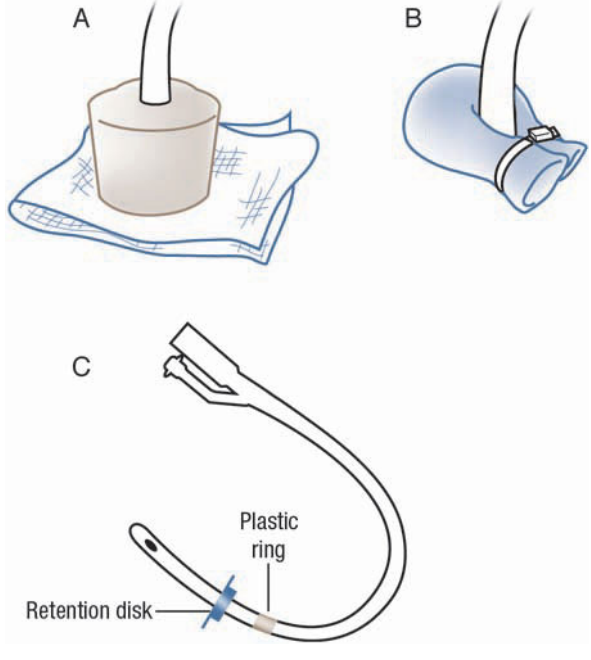

FIGURE 64-6. Types of external bolsters. **A.** Urethane foam dressing. **B.** Latex tubing wrapped about the base of the tube and secured with a plastic cable tie. **C.** A Foley catheter modified with a retention disk and plastic ring.

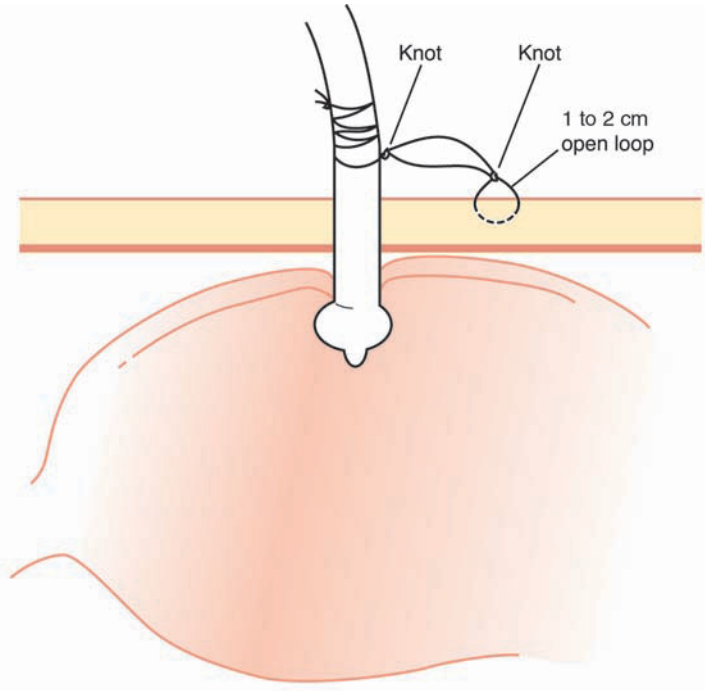

FIGURE 64-7. Simple external fixation using a silk suture laddered up the gastrostomy tube.

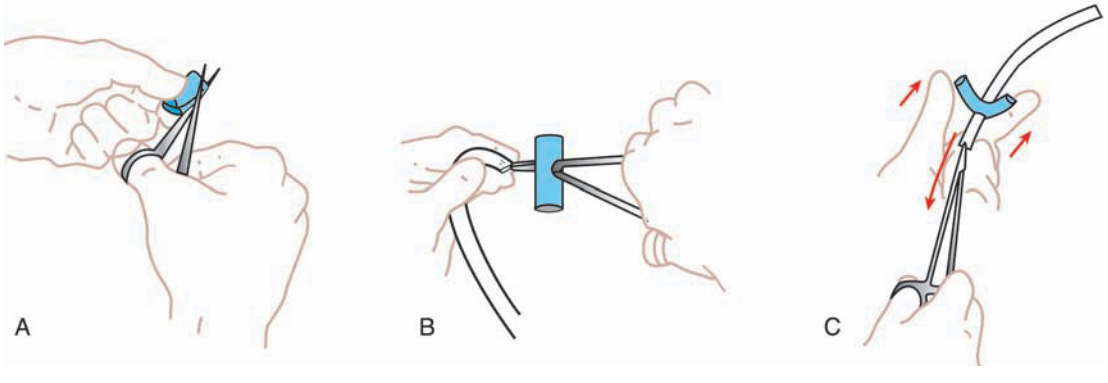
tube to move while preventing inward migration as the patient changes position.



These techniques are adequate for short-term use, but a more permanent form of external fixation is desirable. A number of external bolsters have been described that can be fashioned from materials available in most healthcare facilities. A T-bar external bolster can be made by cutting a 3 cm piece of tubing from a latex or silicone Foley catheter or feeding tube[11] (**Figure 64-8**). Fold the piece of tubing in half. Make two diamond-shaped cuts placed on the sides of the fold and opposite each other (**Figure 64-8A**). Insert a hemostat through the holes and grasp the replacement Foley catheter (**Figure 64-8B**). Slide the latex T-bar along the catheter (**Figures 64-8C & D**). In order to function satisfactorily, the latex T-bar must be snug enough to prevent migration but not so snug as to compress the Foley catheter lumen. After placement of the Foley catheter, position the latex T-bar so that it is about 0.5 to 1.0 cm from the skin surface.

There are several commercially available products designed specifically for replacement gastrostomies. They are convenient. Unfortunately, they are expensive, may not be compatible with the original tube, and may not be on hand at the moment they are needed.

Once the replacement tube's position is confirmed and secured, the end of the tube should be clamped or fitted with an appropriate feeding adapter.

NONFUNCTIONING GASTROSTOMY TUBES

A patient may present with a clogged, leaking, cracked, or fractured gastrostomy tube. A number of factors should be considered prior to removing any existing tube. Is the tract mature? Is replacement actually necessary or can other measures remedy the problem? What is the type of internal bolster and can it be removed by external traction? **The most important factor is the age and maturity of the tract. Premature removal of the gastrostomy tube from a fresh tract may lead to peritoneal contamination with gastric contents and peritonitis. A new gastrostomy site should not be manipulated without consultation with the specialist who placed**

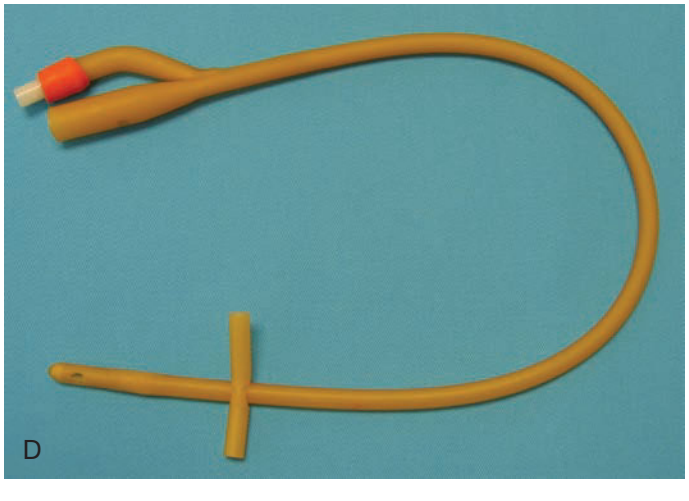


FIGURE 64-8. Fashioning an external bolster from a latex tube and a Foley catheter. **A.** The 3 cm piece of latex tube is folded and cut. **B.** A hemostat is inserted through the latex T-bar and grasps the distal end of the Foley catheter. **C.** The latex tube T-bar is advanced onto the catheter and pulled into position. **D.** The modified Foley catheter with a latex T-bar.

the original tube. A malfunctioning tube may have to remain in place to stent a fresh tract while alternative methods of nutritional support are provided to the patient.

The underlying problem with a nonfunctioning gastrostomy tube should be investigated prior to its removal and replacement. A fractured tube or a tube with a ruptured balloon will need replacement. A kinked tube may only need revision of the external bolster. A clogged tube should first be irrigated with warm tap water, saline, or a carbonated beverage in an attempt to open the lumen. **Do not force the irrigation fluid into the gastrostomy tube, as it may then rupture and injure the patient.** A variety of other options may be tried to open a clogged gastrostomy tube. These include the instillation of enzymes to break up or dislodge the clog with an endoscopic snare, biopsy forceps, or Fogarty catheter.[16,17] The latter methods are usually performed by a consultant and not the Emergency Physician.

A simple, quick, inexpensive, and easy to use device has been developed to declog a gastrostomy tube (Feeding Tube DeClogger®, Bionix Medical Technologies, Toledo, OH). These are flexible plastic wands with a basic screw thread. They come in lengths for gastrostomy and jejunostomy tubes, and various sizes (12 to 24 French). Insert the DeClogger® into the feeding port (**Figure 64-9**). Slowly advance it while rotating it clockwise. Once fully inserted, slowly remove the device from the feeding port. Aspirate and insufflate air to confirm the gastrostomy tube patency. This device may prevent the time and expense of replacing a clogged feeding tube. The patient and/or their caretaker can be taught how to use this device at home, which may prevent a trip to the physician or Emergency Department.

Once the decision has been made to replace a gastrostomy tube, information should be obtained regarding the type of tube in place. Many are removable by gentle external traction. **Never apply more than gentle traction when removing a gastrostomy tube.** If the internal bolster is a balloon, simply deflating the balloon will allow the tube to be removed. Other bolsters such as soft domes and T-bars may deform easily with gentle constant traction. If gentle traction is not sufficient to remove the gastrostomy tube, either the internal bolster is not intended to be removed externally or it may have become embedded within the gastric wall. When difficulty occurs trying to remove a gastrostomy tube, consult the physician who placed the tube. The most likely problems and alternate solutions are discussed below.

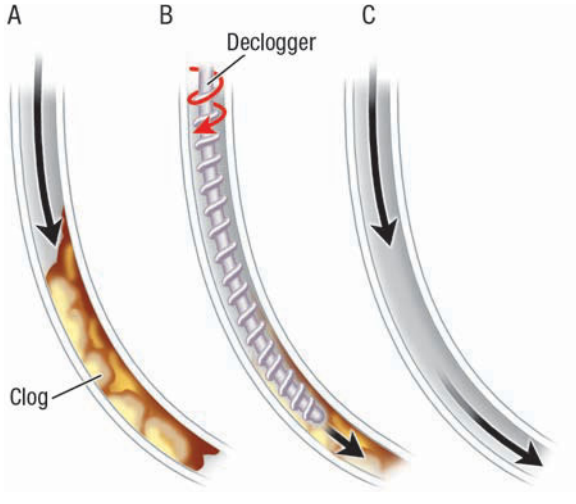

FIGURE 64-9. Using the Bionix Feeding Tube DeClogger. **A.** The clogged gastrostomy tube. **B.** The DeClogger is slowly advanced through the clog while being rotated clockwise. **C.** The clog has been removed and free flow reestablished.

THE BALLOON DOES NOT DEFLATE

The balloon may not deflate if the balloon inflation port is clogged or damaged. There are four options to remedy this situation. Simply cutting the gastrostomy tube may allow the balloon to deflate on its own. Cut the gastrostomy tube close to the ports. Maintain a firm hold, manually or with a hemostat, so that the cut tube does not migrate inside the patient and require endoscopic removal. The gastrostomy tube can be pulled taut to the skin and a needle advanced into the tract to puncture the balloon.[18–20] Alternatively, a guidewire may be advanced through the balloon port to puncture and deflate the balloon.[21] If these fail, the balloon may have to be ruptured internally with an endoscopic snare.

THE TUBE DOES NOT WITHDRAW WITH EASE

Although not universally recommended, one may simply cut the feeding tube at the skin level and push the remaining tube through the tract and into the stomach. This will allow the internal components to pass through the patient's gastrointestinal tract. Retained gastrostomy tube components have been known to cause bowel obstructions and perforations; however, the majority pass without incident.[22] This procedure works for many types of gastrostomy tubes, but it is not clear that this is a safe option for balloon bolsters that have not been deflated. **This option should be used only if a Primary Care Provider agrees with that choice and is available to follow the patient until the contents have passed.** Radiopaque components can be followed by plain radiographs at 24 to 48 hour intervals. The gastrostomy "hardware" may have to be retrieved endoscopically or surgically if it fails to pass within 2 to 3 weeks or the patient experiences obstructive symptoms. This option is not recommended for small children under the age of 6 years or weighing less than 20 kg.[23] These patients have a greater risk for complications.[23]

INADVERTENT REMOVAL OF THE TUBE FROM A FRESH OR IMMATURE TRACT

Whenever a fresh tract is disrupted, there is the possibility of gastric spillage and peritonitis. In such an event, all enteral feedings should be discontinued and the patient observed for the development of peritonitis. A number of replacement options have been described. The tract may be allowed to close spontaneously and a replacement PEG placed in 7 to 10 days if the patient remains well.[24] Alternatively, endoscopy can attempt to reintroduce a replacement tube under direct visualization through the original tract.[25] A General Surgeon should be consulted and laparotomy considered if peritonitis develops. Under these circumstances, the Surgeon may choose to place a surgical gastrostomy.

THE TRACT IS CLOSED

A gastrostomy tract that is not stented will begin to close within hours. A lost tract may require a repeat procedure. This problem requires consultation with an Endoscopist. Dilation of a closing gastrostomy site has been described using filiform catheters and followers or urethral sounds, a procedure adapted from Urology.[26] **This procedure should be performed with caution as it can result in numerous complications.** Interventional Radiologists can often replace dislodged tubes using special techniques.

EARLY BALLOON RUPTURE IN AN INTACT TUBE IN AN IMMATURE TRACT

In this instance, the tract is stented but there is the risk of gastric leakage about a deflated balloon. Esker and Hall report successful replacement using a guidewire to exchange the gastrostomy tube.[27] This technique is performed using endoscopic guidance to snare the guidewire and withdraw the original gastrostomy tube.

ASSESSMENT

The replacement gastrostomy tube should be placed to gravity drainage or the stomach contents should be aspirated. Use of the gastrostomy tube can be resumed if there is free flow of gastric contents. If there was any difficulty with placement of the gastrostomy tube or if the return is equivocal, its position should be confirmed radiographically. A small amount of water-soluble radiopaque contrast should be administered through the gastrostomy tube and a KUB should be obtained. Normal gastrostomy tube placement will show intraluminal contrast. Any extravasation of contrast is abnormal and requires enteral feedings to be withheld and a General Surgeon to be consulted. In most instances, the patient will require hospitalization for parenteral antibiotics, observation, and bowel rest until the tract heals. Some physicians elect to evaluate all replaced gastrostomy tubes radiographically prior to their use. While doing so is harmless to the patient and causes no complications, this process cannot be routinely recommended, as it is time-consuming and expensive.[29,30]

AFTERCARE

Routine maintenance can resume after successful replacement of the gastrostomy tube. Any factors that contributed to the malfunction should be addressed to prevent a recurrence. The patient and/or their caregivers should be taught the proper care and maintenance of a gastrostomy tube. The patient should follow up with their primary physician in 24 to 48 hours for evaluation, removal of the temporary tube, and placement of a gastrostomy tube. Instruct the patient to immediately return to the Emergency Department if they develop a fever, abdominal pain, nausea, or vomiting.

COMPLICATIONS

A variety of complications may accompany the initial insertion of a gastrostomy tube.[2,6,31] However, replacement at a mature site should be relatively free of problems. Excessive force during replacement can disrupt the tract. A misdirected tube may end in a blind pouch or the peritoneal cavity if the stomach separates from the anterior abdominal wall. Installation of enteral feedings intraperitoneally will cause a chemical peritonitis. This should be suspected if there is poor return from the replaced gastrostomy tube, difficulty installing feedings, or the patient develops pain or fever after the procedure. Peritonitis is preventable if proper positioning is confirmed prior to using the replacement tube.[28]

A replacement gastrostomy tube must be sufficiently secured externally so that the effect of peristalsis does not carry it distally. This is particularly true of balloon-tipped tubes. Once the tube migrates past the pylorus, it can cause bowel obstructions and perforations.[2,6] This can be avoided by carefully securing the replacement gastrostomy tube with an external device or suturing it securely to the skin.

Always advance the Foley catheter into the stomach before carefully and slowly inflating the balloon. Inflation of the balloon within the gastrocutaneous tract can result in hemorrhage, pain, and rupture of the tract. Overinsertion of the catheter can cause the balloon to enter the esophagus, duodenum, or gastroesophageal junction. These structures can rupture when the balloon is inflated. These complications can be avoided by inserting the Foley catheter 8 to 10 cm, slowly inflating the balloon, and not inflating the balloon to its maximal volume.

A mature gastrostomy tract begins to close as soon as the tube is removed. The tract narrows without the presence of the gastrostomy tube to keep it patent. Replace the gastrostomy tube as soon as possible. **Never force a tube through the tract.** This can result in bleeding, gastric perforation, intraperitoneal penetration, pain, and the formation of a false passage. Pass a smaller-size tube if necessary to reestablish the tract and maintain its patency.

An indwelling or replacement gastrostomy tube may result in a gastric outlet obstruction. The patient usually presents with distention of the stomach and vomiting. Immediately and gently, pull back on the gastrostomy tube until it is snug against the abdominal wall. Secure the gastrostomy tube with an external bolster. Observe the patient for resolution of their symptoms and any complications.

The skin exit site may become edematous, erythematous, and tender. A simple cellulitis should be managed with oral antibiotics and local wound care. Failure to resolve with antibiotics alone may suggest the presence of an abscess and further imaging or drainage may be required. A dermatitis can result from leakage of gastric contents around the gastrostomy tube. Ensure that the internal bolster is secured against the anterior abdominal wall. If the leakage persists, replace the gastrostomy tube with a larger one that occludes the tract. Local wound care is all that is necessary once the problem with the gastrostomy tube is corrected. Occasionally, hypersensitivity to the adhesive, cleansing solutions, or the gastrostomy tube itself may develop. The use of different materials and topical corticosteroids will correct this problem. A yeast infection (*Candida albicans*) appears erythematous and moist, with satellite lesions. Topical antifungal creams and local wound care will alleviate the yeast infection. Granulation tissue around the stoma can be eliminated by coagulation with silver nitrate sticks. The patient should follow up with their primary physician in 24 to 48 hours for a reevaluation of all these clinical entities.

SUMMARY

Both surgical and endoscopically placed gastrostomy tubes result in a simple fibrous tract connecting a feeding tube to the stomach. A mature tract can be safely and easily manipulated. Problems with an immature tract should prompt consultation. Techniques for the basic maintenance and repair of gastrostomy tubes are straightforward. Familiarity with the procedures and equipment used to establish gastrostomies will help the Emergency Physician solve common gastrostomy tube problems and intervene in an appropriate and timely manner.

65 Paracentesis

Susan B. Promes, Elizabeth M. Datner, and Sam Hsu

INTRODUCTION

The word *ascites* is derived from the Greek *askos* meaning "bag" or "sac." Ascites, an abnormal accumulation of fluid in the abdominal cavity, has important implications diagnostically, therapeutically, and prognostically. Cirrhosis of the liver, which is usually related to alcoholism, accounts for 75% of cases of ascites; malignancy accounts for an additional 10% to 12%, and cardiac failure for another 5%. The remaining cases have a variety of etiologies.[1] Unfortunately, the physical examination is not very reliable when it comes to detecting ascites, making paracentesis and ultrasound (US) important clinical tools.[2] US-guided paracentesis has two key benefits. It not only facilitates performance of the procedure, but it also identifies patients in whom the procedure is not warranted or could potentially be harmful.[3]

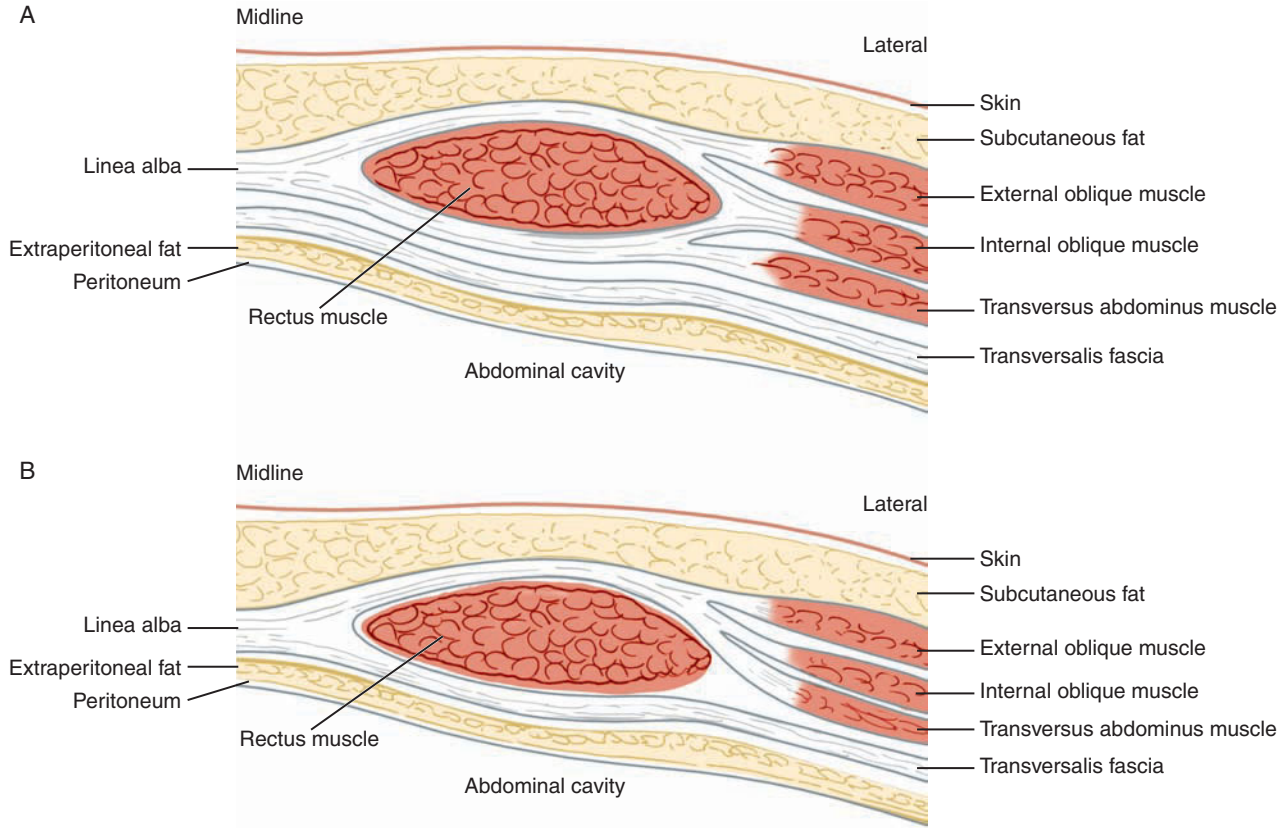

FIGURE 65-1. The layers of the anterior abdominal wall vary above (**A**) and below (**B**) the level of the anterior superior iliac spine.

Peritoneal aspiration of ascitic fluid or paracentesis was first described by Saloman in the early twentieth century.[4] With the introduction of diuretics as well as a fear of procedure-related complications, paracentesis fell out of favor in the 1950s, being replaced by medical management. At that time, large-bore needles were being used and complication rates were significant. Clinical studies published in the late 1980s demonstrated that performing a paracentesis was, in fact, a safe procedure.[5,6] Nowadays, the procedure is commonplace in Emergency Departments.

Paracentesis is an important diagnostic tool for patients with new-onset ascites to determine its etiology and in those patients with long-standing ascites to detect the presence of infection. Spontaneous bacterial peritonitis can be a very subtle disease. Infection occurs in as many as 27% of cirrhosis patients admitted for evaluation of symptoms associated with their ascites.[7] It is well known that some patients with spontaneous bacterial peritonitis are asymptomatic, making peritoneal fluid aspiration, analysis, and cultures imperative.[8] In addition to the diagnostic usefulness of paracentesis, large volumes of ascitic fluid can be removed therapeutically by this procedure in order to improve a patient's respiratory status and comfort level from the pressure of tense ascites. This often occurs in patients with end-stage liver disease as well as in some cases of malignancy. Malignant ascites may occur with carcinoma of the ovary, pancreas, stomach, colon, breast, testes, and a variety of sarcomas and lymphomas.

ANATOMY AND PATHOPHYSIOLOGY

The gross anatomy of the abdomen is well known to the Emergency Physician and is important to review in preparing for a paracentesis. The abdominal cavity is lined by the peritoneum and is protected from the environment by the abdominal wall musculature, fat, and skin. The right and left rectus muscles, which are nourished by the epigastric vessels, meet in the midline at the avascular linea alba. The umbilicus is located along the lower portion of the linea alba. The layers of the anterior abdominal wall structures vary above and below the level of the anterior superior iliac spine (**Figure 65-1**).

The liver sits in the upper right quadrant; when enlarged, it can be palpated in the lower right quadrant. The spleen is normally contained in the upper left quadrant, but when it is enlarged, it can extend into the left lower quadrant (LLQ) of the abdomen. The intestines occupy most of the abdominal cavity and are not rigidly adherent, allowing them to move about in the abdominal cavity. The bladder sits in the pelvis but can enter the abdominal cavity when it is distended with urine.

The abdominal cavity is divided into compartments according to mesenteric attachments. Ascitic fluid can be found anywhere in the peritoneal cavity. The location of the ascitic fluid depends primarily upon the amount of fluid present and the patient's position. Fluid follows the law of gravity. Small amounts of fluid generally accumulate in the cul-de-sac and pericolic gutters. Large amounts of fluid can be found bathing the intestines (**Figure 65-2**). There can also be distinct pockets of fluid in areas of bowel adhesions or scarring. These localized areas of fluid are typically found in those patients who have had previous surgery, trauma, or infection.

Although paracentesis is easily performed blindly, US can provide several benefits. US is diagnostically useful to ensure there is enough fluid to perform a paracentesis. It will identify and help avoid solid organs, masses, and vascular structures. If there are bowel adhesions, US will also identify areas where the bowel is adherent and puncture should not occur. In obese patients, US can measure the

FIGURE 65-2. US of the abdomen demonstrating loops of bowel floating in ascitic fluid (*black*).

soft tissue thickness to the peritoneum, locate the thinnest entry point, and determine the needle length required. US can be used to position the patient so that the maximum amount of fluid collects at the sampling site.

INDICATIONS

A paracentesis can be performed for diagnostic or therapeutic purposes. A paracentesis or "abdominal tap" is warranted in a patient with new-onset ascites to establish the etiology of the fluid. A patient with a history of ascites may need the procedure if they have associated signs and symptoms suggestive of infection such as fever, dyspnea, abdominal pain, encephalopathy, renal impairment, or peripheral leukocytosis.[9] A paracentesis can be performed therapeutically for patients in whom medical management with diuretics has not been successful. It is most commonly performed when an intraperitoneal infection is suspected. Clinical guidelines recommend that patients with ascites admitted to the hospital whether or not they have symptoms of spontaneous bacterial peritonitis should undergo a paracentesis.[9,10] Paracentesis has been used to aid in the diagnosis of ruptured ectopic pregnancy, bowel perforation, and hemoperitoneum due to trauma. More accurate diagnostic procedures should be used rather than a paracentesis for these conditions if they are available.

CONTRAINDICATIONS

There are no absolute contraindications to performing a paracentesis. The relative contraindications include pregnant patients or patients who have a history of abdominal surgery, a current bowel obstruction, a coagulopathy, or thrombocytopenia. Pregnancy is listed because the gravid uterus may fill the space where the procedure is normally performed. If a paracentesis is indicated, it should be performed superior to the uterine fundus. It is important to avoid sites of previous surgical incisions, because adhesions may fix the bowel wall to the abdominal wall, thus increasing the possibility of perforation. Many patients who are subjected to a paracentesis have underlying liver disease and resultant coagulopathies. Some advocate that patients with thrombocytopenia or an abnormal international normalized ratio (INR) should have platelet transfusions or factor replacement prior to performing a paracentesis. This practice is controversial and there are no controlled data to support these contentions.[11] Many, however, would suggest using an infraumbilical midline, also known as a linea alba, approach in coagulopathic patients. This area is free of any vasculature, thus reducing the possibility of bleeding complications. A recent study in which the majority of ascites patients had a paracentesis performed in the LLQ did not demonstrate any bleeding complications.[12] With this in mind, and given that the abdominal wall is thinner and ascitic fluid pools more in the LLQ, this location may be chosen over the infraumbilical approach when US is not being used to guide the procedure.[13]

EQUIPMENT

- Protective eyewear
- Sterile gloves and gown
- Cap and mask
- Povidone iodine or chlorhexidine solution
- Sterile 4 × 4 gauze
- Sterile drape
- Local anesthetic solution with epinephrine
- 25 or 27 gauge needle to anesthetize the skin
- 10 mL syringe for anesthetic
- Choice of needle options: 18 to 22 gauge needle, 3½ in. needle or spinal needle
- Seldinger-type guidewire kit
- Catheter-through-the-needle
- Catheter-over-the-needle—consider Caldwell needle
- Large syringe(s) for fluid collection (20 to 60 mL)
- Intravenous tubing or blood collection tubing if vacuum bottles are being used
- Collection bottles (vacuum) or collection bag
- Adhesive dressing
- Three-way stopcock
- Blood collection tubes for white blood cell (WBC) count, electrolytes, albumin, pH, etc.
- Blood culture bottles (aerobic and anaerobic)
- Sterile specimen container for cytology (optional)
- US machine and probe
- Sterile US gel
- Sterile US probe cover

Commercially available paracentesis kits are available. These contain all the required equipment except the collection bottles. They include the sterile drapes and local anesthetic solution. These are convenient and relatively inexpensive.

A general-purpose curvilinear or phased-array US probe provides the best combination of penetration and field of view into the abdomen. A linear probe can be used for thin, small adults, and children.

PATIENT PREPARATION

Explain the procedure, its risks, and its benefits to the patient and/or their representative. Obtain an informed consent for the procedure. The patient's bladder should be empty. Use an US machine to check for a full bladder or place a Foley catheter to decompress the bladder if the patient is unable to urinate voluntarily. Placement of a nasogastric tube is recommended, although not routine. It prevents an iatrogenic perforation if the stomach is dilated or if a concomitant bowel obstruction is present.

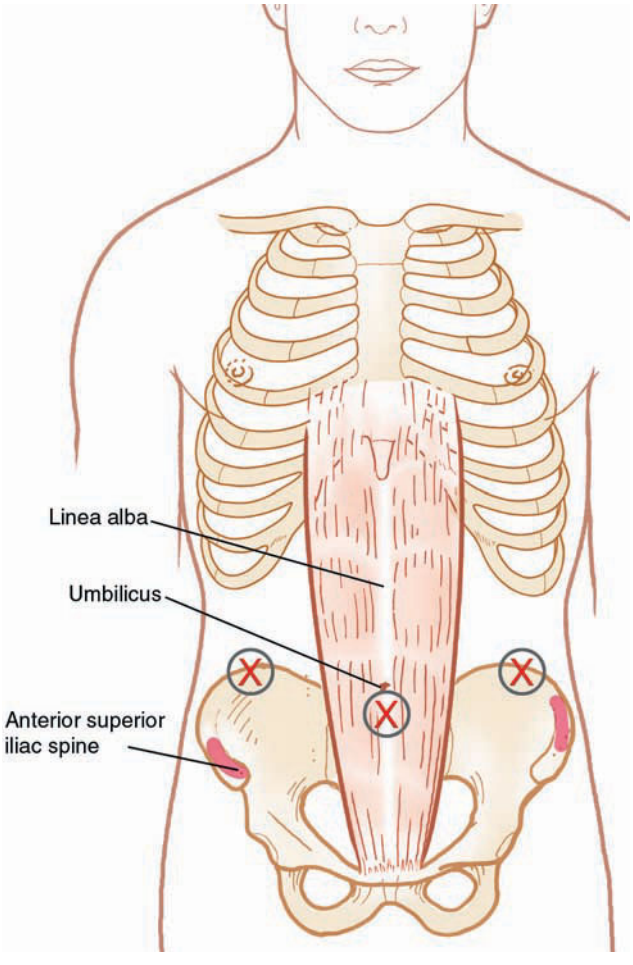

FIGURE 65-3. Needle insertion sites to perform a paracentesis (indicated by a red ⊗). The preferred site is in the midline and 2 cm below the umbilicus. Alternative sites are just medial and 4 to 5 cm above the anterior superior iliac spines.

There are two recommended areas of entry for the paracentesis needle (**Figure 65-3**). The first site is in the midline and 2 cm below the umbilicus. Alternatively, the region 4 to 5 cm superior and just medial to the anterior superior iliac spine in one of the lower quadrants may be used. Some physicians choose the right lower quadrant to avoid the sigmoid colon and spleen. Others choose the LLQ to avoid the cecum and liver. Remember to exercise caution in the region of a scar, prominent veins, caput medusa, or over an area of inflamed or infected skin to minimize complications. US-assisted paracentesis is recommended if an US machine is readily available. Not only can US assist in identifying the ideal fluid pocket but also hopefully avoid a "dry tap".[3]

Place the patient sitting upright for a midline or linea alba approach, lying in the right lateral decubitus position for a right lower quadrant approach, or lying in the left lateral decubitus position for a LLQ approach. Another position one might consider is having the patient assume a hand-knee or "crawling" position. This position, however, is awkward for the Emergency Physician performing the procedure. Remember that the fluid will pool in dependent areas and the bowel will float on top of it—barring any adhesions or masses.

Prepare the patient. Clean the skin around the chosen puncture site of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry. Apply sterile drapes to delineate a sterile field. Inject 2 to 5 mL of local anesthetic solution subcutaneously and along the needle insertion tract. Allow 3 to 5 minutes for the local anesthetic to take effect.

TECHNIQUES

Z-TRACT TECHNIQUE

A "Z-tract" is used to decrease the possibility of an ascitic fluid leak, especially in patients with tense ascites (**Figure 65-4**). This is the preferred method for inserting the needle. This technique should also be followed when using the other techniques described below. Apply traction on the skin cephalad or caudad to the needle insertion site so that the skin is pulled taut when the needle enters the peritoneum (**Figures 65-4A & B**). The idea is that when the skin tension is released, the skin returns to its normal position and seals off the pathway of the paracentesis needle.

Apply an 18 to 22 gauge, 3½-in needle or spinal needle to a 60 mL syringe. Slowly insert and advance the needle perpendicular to the skin (**Figure 65-4A**) or at 45° to the skin and aimed caudally (**Figure 65-4B**). Apply negative pressure to the syringe as it is being advanced. A loss of resistance should be felt as the needle enters the peritoneal cavity. Stop advancing the needle when ascitic fluid enters the syringe. Continue to aspirate until the syringe is one-half to three-fourths filled with fluid. Depending on the size of syringe consider using a three-way stop cock so syringes can be removed as they are filled.

The omentum, a loop of bowel, peritoneal fat, or other tissue may be occluding the needle tip if ascitic fluid suddenly stops flowing into the syringe. Release the plunger of the syringe. Reattempt to aspirate. If fluid still will not flow, inject 1 to 2 mL of ascitic fluid back into the peritoneal cavity and then reattempt to aspirate. Reposition the needle if ascitic fluid still does not flow into the syringe. **Never reposition the needle while the sharp tip is within the peritoneal cavity. The needle can lacerate the bowel, the omentum, or a blood vessel.** Withdraw the needle to the dermis, reposition it, and then readvance it into the peritoneal cavity. The Caldwell needle appears to be superior to a conventional angiocatheter needle when it comes to problems with fluid return. The Caldwell needle's unique design with fenestrations on the side is believed to allow for continued flow despite occlusion of the needle tip.[14,23]

Note the color and clarity of the ascitic fluid. Aspirate 30 to 50 mL if the procedure is being performed for diagnostic purposes. Withdraw the needle after obtaining the fluid. Immediately place the fluid into the appropriate collection tubes and culture bottles.[15] If the reason for the paracentesis is therapeutic and there is a large collection of fluid that must be drained, hold the needle or catheter securely and remove the syringe. An assistant can place the sample into laboratory containers. Connect the needle or catheter to intravenous tubing. Connect the other end of the intravenous tubing to a suction bottle or bag in order to drain off the desired amount of ascitic fluid. Remove the needle or catheter once the procedure has been completed. Removal results in the formation of the Z-tract, so that ascitic fluid will not leak from the skin (**Figure 65-4C**). Apply a bandage to the skin puncture site. Consider a compression dressing with an occlusive bandage if fluid is oozing from the puncture site.

SELDINGER TECHNIQUE

First described by Seldinger in 1953, this technique allows for the placement of a catheter over a wire (**Figure 65-5**). The wire used must be longer than the catheter. The needle used to insert the wire can be short and of a smaller gauge than the catheter. Materials needed for catheter insertion are commercially available in a prefabricated kit. The Seldinger technique is most commonly used for central venous catheter insertion.

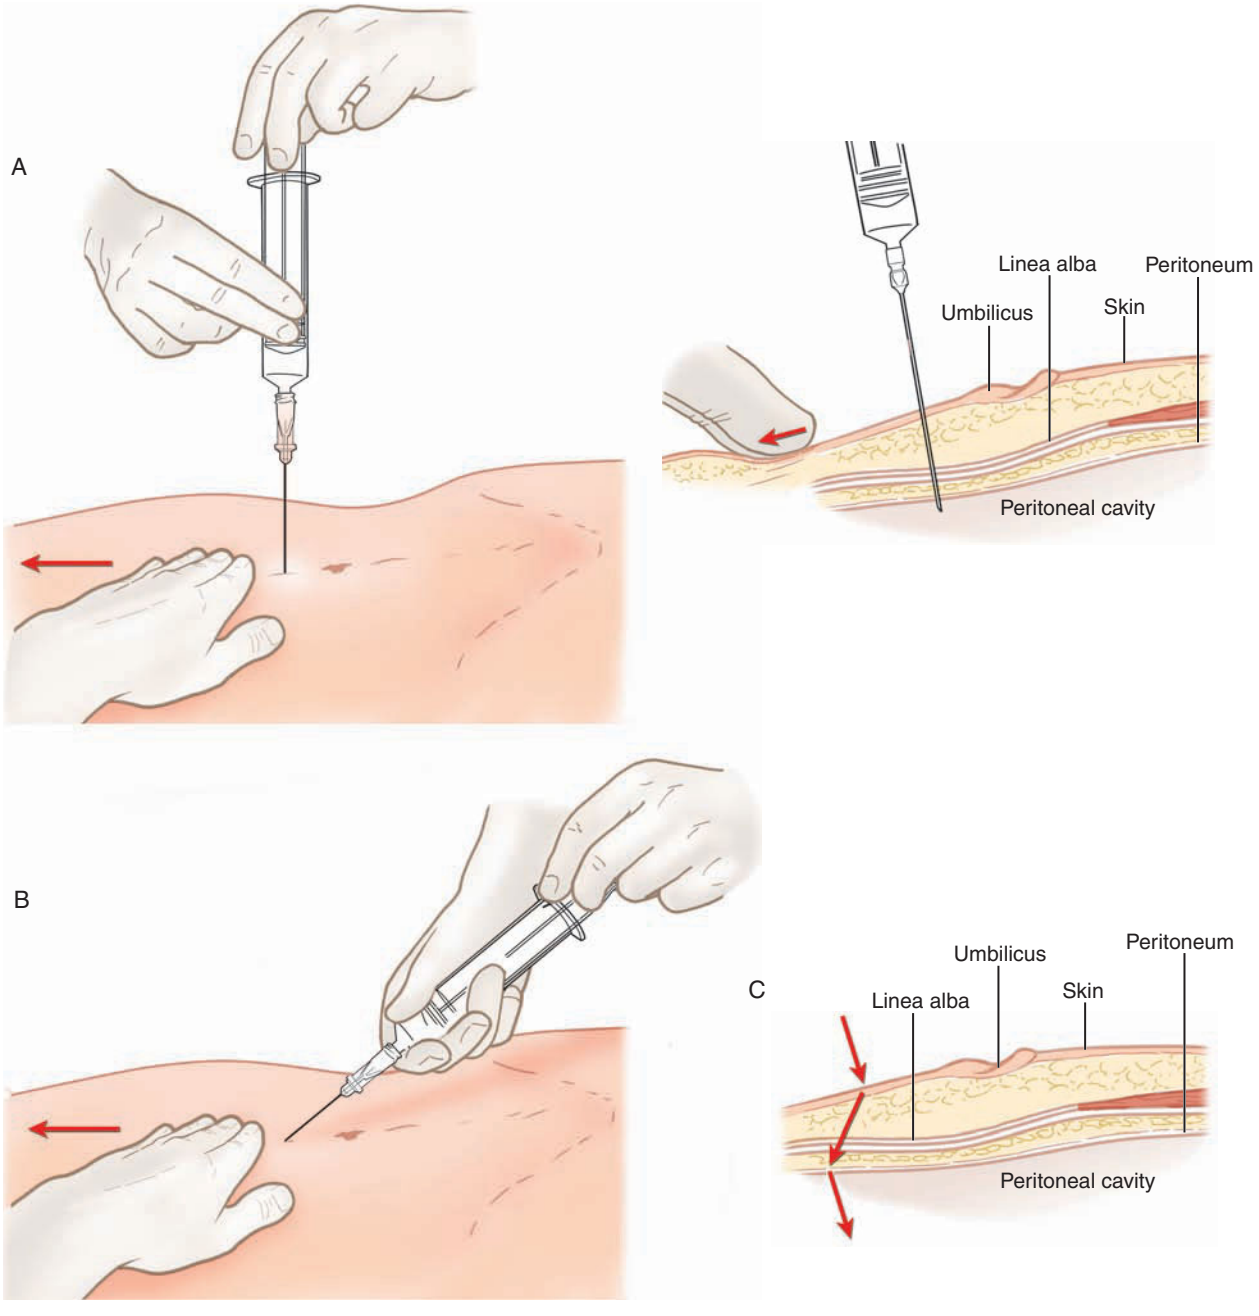

FIGURE 65-4. The Z-tract. **A.** The needle is inserted perpendicular to the skin while the skin is pulled taut. **B.** Alternatively, the needle can be inserted at 45° to the skin and aimed caudally. **C.** The resultant Z-tract (*arrows*).

Choose the puncture site and prepare the patient for the procedure. Insert the thin-walled introducer needle in a Z-tract manner while applying negative pressure to the syringe (**Figure 65-5A**). The introducer needle has a tapered hub on the proximal end to guide the wire into the needle lumen. Avoid using a standard hypodermic needle, as it will not allow for the passage of the guidewire. A flash of fluid in the needle hub signifies that the tip of the needle is within the peritoneal cavity (**Figure 65-5A**). Advance the needle an additional 2 to 3 mm. Hold the needle in place securely and remove the syringe.

Occlude the needle hub with a sterile gloved finger. This will prevent air from entering and ascitic fluid from exiting. Insert the guidewire through the hub of the needle (**Figure 65-5B**). Advance the guidewire to the desired depth, ensuring that it is at least several centimeters beyond the beveled end of the needle. **Always have at least one hand holding the guidewire at all times to prevent it from slipping completely into the peritoneal cavity.** Hold the guidewire securely in place. Remove the needle over the guidewire (**Figure 65-5C**). Make a small nick in the skin adjacent to the guidewire with the #11 scalpel blade included in the kit (**Figure 65-5D**). **Direct the sharp edge of the scalpel blade away from the guidewire to avoid nicking the guidewire.**

Place the dilator through the sheath (or catheter) to form a unit. Advance the dilator and sheath unit over the guidewire (**Figure 65-5E**). Continue to advance the dilator and sheath unit over the guidewire and into the peritoneal cavity (**Figure 65-5F**). A twisting motion may aid in its advancement through the skin and into the peritoneal cavity (**Figure 65-5F**). Advance the unit until the

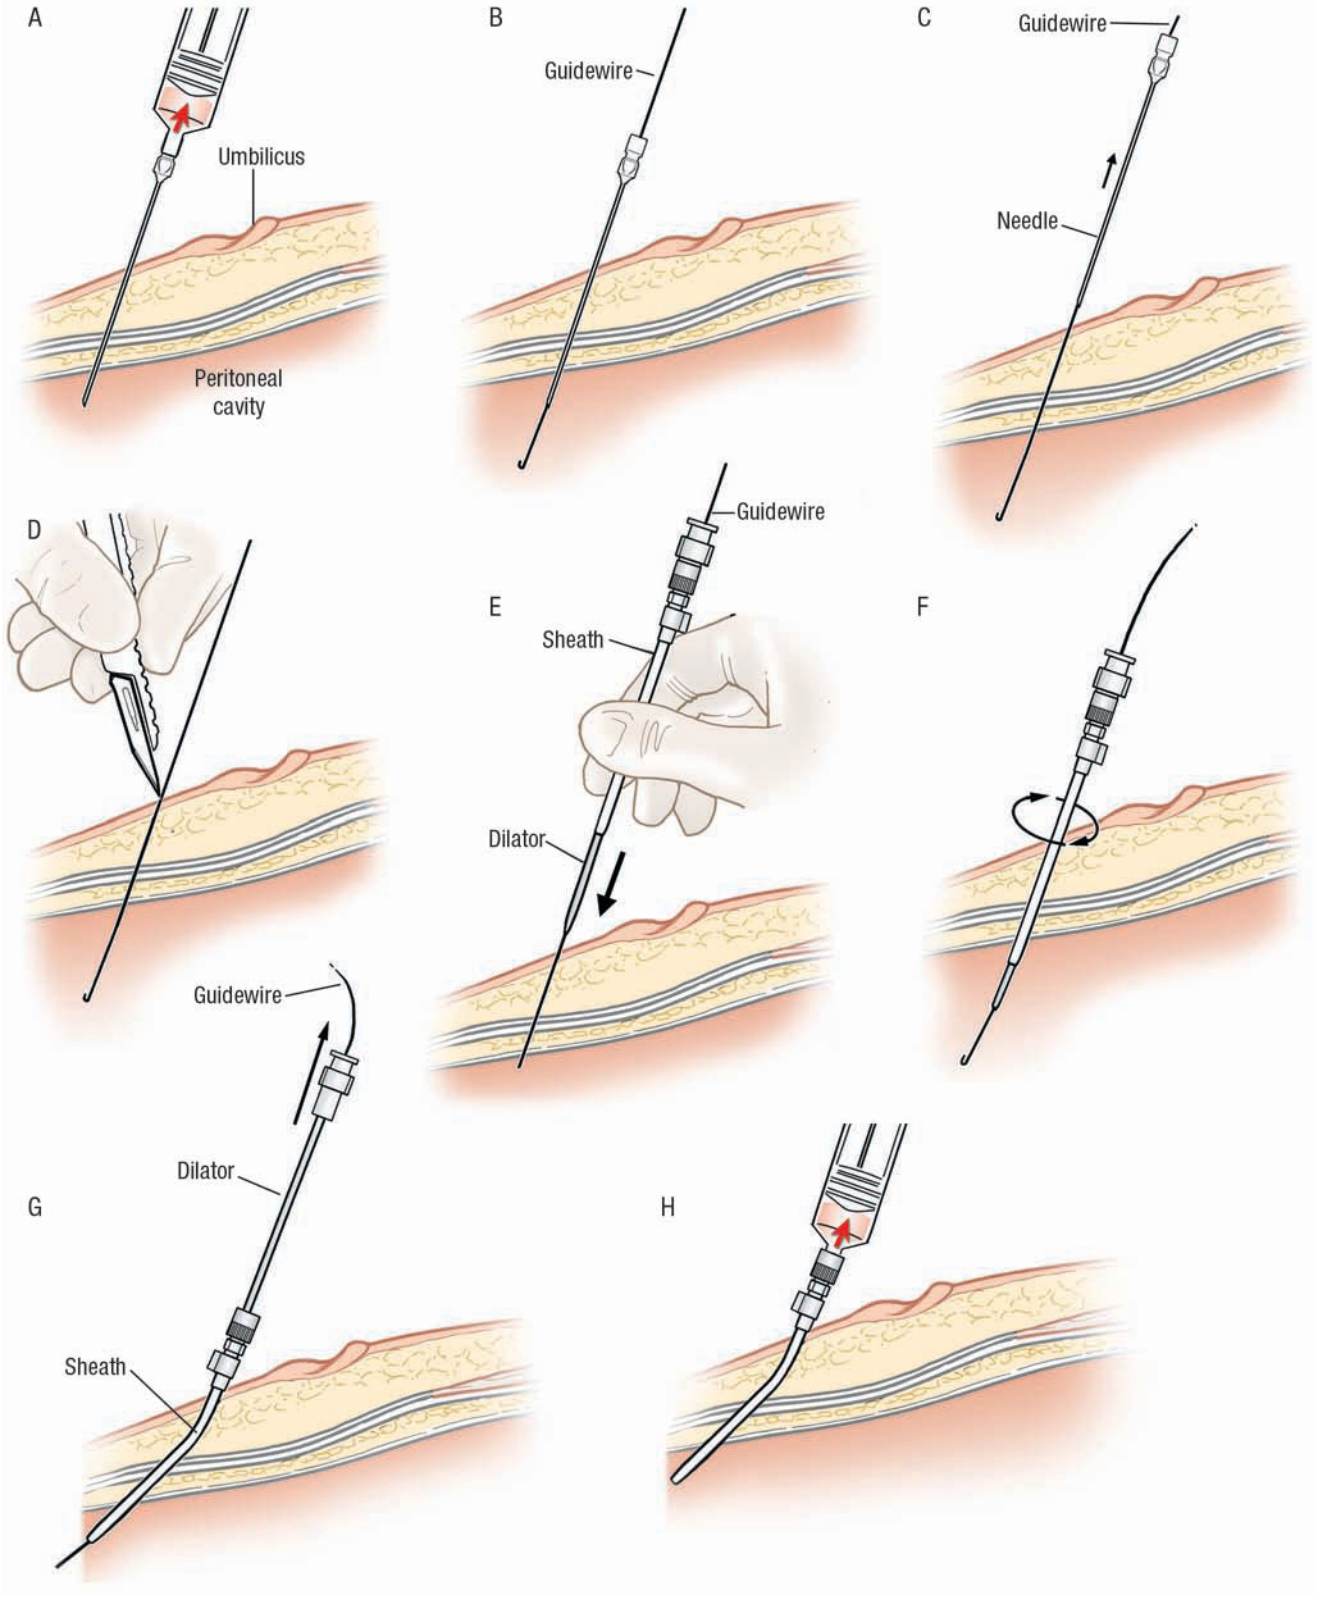

FIGURE 65-5. The Seldinger technique. **A.** The needle is advanced into the peritoneal cavity. **B.** The syringe is removed and a guidewire is inserted through the needle and into the peritoneal cavity. **C.** The needle is removed, leaving the guidewire in place. **D.** An incision is made where the guidewire enters the skin. **E.** The dilator and sheath are advanced as a unit over the guidewire. **F.** The dilator and sheath are advanced into the peritoneal cavity with a twisting motion. **G.** The guidewire and dilator are removed as a unit, leaving the sheath in place. **H.** A syringe is attached to the sheath. The aspiration of ascitic fluid confirms proper intraperitoneal placement of the sheath.

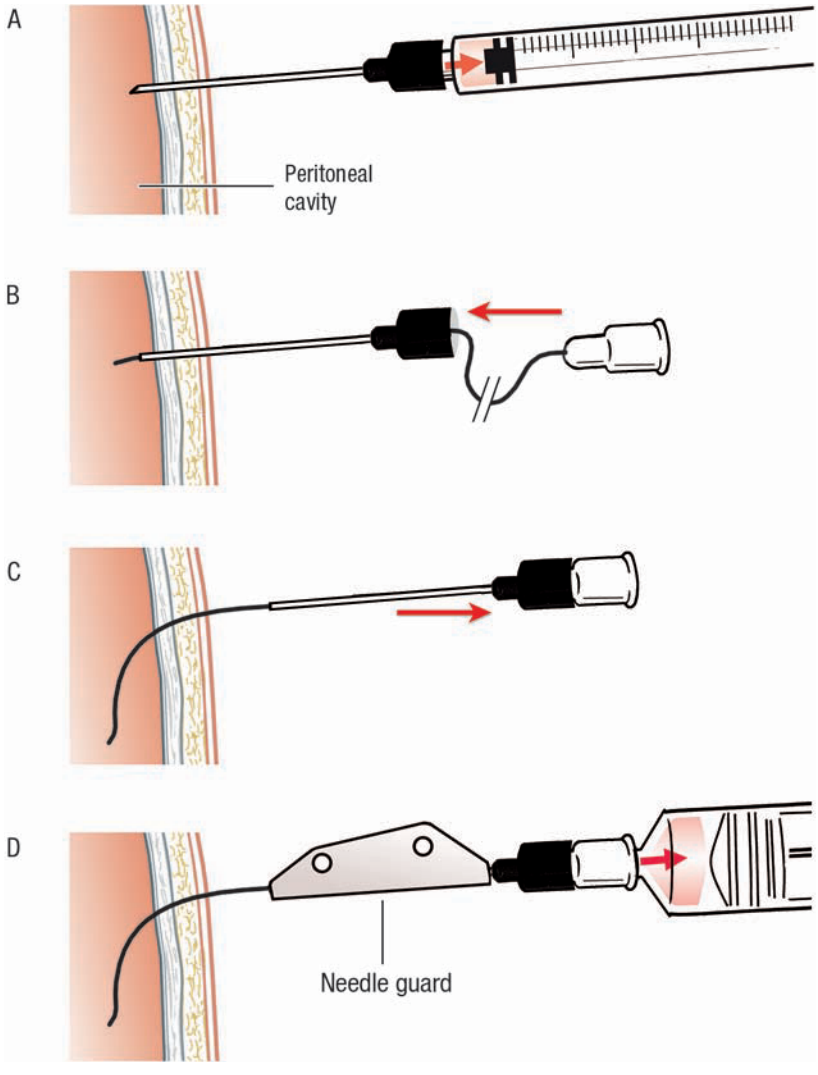

FIGURE 65-6. The catheter-through-the-needle technique. **A.** The needle is advanced into the peritoneal cavity while maintaining negative pressure on the syringe. **B.** The syringe has been removed. The catheter is inserted through the needle. **C.** The needle is withdrawn and the catheter is left within the peritoneal cavity. **D.** A syringe is attached to the catheter and the needle guard applied. The aspiration of ascitic fluid confirms proper intraperitoneal placement of the catheter.

hub of the sheath is against the skin. Hold the hub of the sheath securely. Remove the guidewire and dilator as a unit (**Figure 65-5G**). Attach a syringe to the hub of the sheath (**Figure 65-5H**).

Aspirate fluid from the sheath to confirm intraperitoneal placement. Hold the hub of the sheath securely and remove the syringe. Pass the syringe to an assistant to place the sample into laboratory containers. Connect the hub of the sheath to intravenous tubing. Connect the other end of the intravenous tubing to a suction bottle or bag in order to drain off the desired amount of fluid. An alternative is to attach a three-way stopcock to the distal end of the intravenous tubing. A syringe may then be attached to the stopcock to withdraw laboratory samples or "pump out" the ascitic fluid into a nonsterile container. Remove the sheath once the procedure is completed. Apply a bandage to the skin puncture site. While this technique seems complicated at first glance, it is easy to learn and can be performed in a few minutes by an experienced Emergency Physician.

CATHETER-THROUGH-THE-NEEDLE TECHNIQUE

This system is used most commonly for central venous access. Select a catheter size that is appropriate for the patient and the site of entry. Packaged with each catheter are a needle and a needle guard. The needle will have an inner diameter that is slightly larger than the outer diameter of the catheter. The needle guard has a beveled channel in which the needle can reside. The needle guard hinges closed over the needle to hold it securely and prevent the needle from shearing the catheter.

Choose the puncture site and prepare the patient for the procedure. Place the needle on a tuberculin syringe. Insert the needle through the skin in a Z-tract manner and into the peritoneal cavity while applying negative pressure to the syringe (**Figure 65-6A**). A flash of fluid in the syringe confirms that the tip of the needle is within the peritoneal cavity. Advance the needle an additional 2 to 3 mm to ensure that the tip of the needle is completely within the peritoneal cavity. Securely grasp and hold the needle with the nondominant hand. Remove the syringe with the dominant hand. Immediately place the nondominant thumb over the needle hub to prevent air from entering and fluid from exiting.

Insert the catheter through the hub of the needle (**Figure 65-6B**). Advance the catheter through the needle until the desired length of catheter is within the peritoneal cavity. **If the catheter will not advance, remove the catheter and needle as a unit. Never withdraw the catheter through the needle. The sharp bevel of the needle may cut the catheter as it is being withdrawn and result in a catheter embolism in the peritoneal cavity.**

Withdraw the needle over the catheter (**Figure 65-6C**). **Do not allow the catheter to be withdrawn through the needle.** Continue to withdraw the needle until the tip is completely outside the skin. Apply the needle guard over the needle (**Figure 65-6D**).

Attach a syringe onto the hub of the catheter. Aspirate fluid from the catheter to confirm intraperitoneal placement. Hold the hub of the catheter securely and remove the syringe. Pass the syringe to an assistant to place the sample into laboratory containers. Connect the catheter to intravenous tubing. Connect the other end of the tubing to a suction bottle or bag in order to drain off the desired amount of fluid. An alternative is to attach a three-way stopcock to the distal end of the tubing. A syringe may then be attached to the stopcock to withdraw laboratory samples or "pump out" the ascitic fluid into a nonsterile container. Remove the catheter once the procedure is completed. Apply a bandage to the skin puncture site.

The main disadvantage of this technique is the possibility of the needle tip shearing off the catheter and resulting in a catheter embolism. **This can be prevented by not withdrawing the catheter through the needle and applying the needle guard immediately after the needle is withdrawn from the skin.** Another disadvantage is that the contaminated needle must be handled to some extent, creating a potential risk for needle-stick injuries.

CATHETER-OVER-THE-NEEDLE TECHNIQUE

The catheter-over-the-needle systems are most commonly used for peripheral venous access. The infusion catheter fits closely over a hypodermic needle. The needle and the catheter are advanced as a unit into the peritoneal cavity. They are inexpensive, come in a variety of diameters and lengths, and are widely available. Versions designed to minimize accidental needle-stick injuries are available, and their use is encouraged (**Figure 47-7B**). Placement of these catheters is usually quick and simple. Consider using a Caldwell needle with fenestrations on the side to help minimize problems with the flow of fluid.

Choose the puncture site and prepare the patient for the procedure. Insert the catheter-over-the-needle through the skin in a Z-tract manner and into the peritoneal cavity (**Figure 65-7A**). A flash of fluid in the hub of the needle confirms that the tip of the needle is within the peritoneal cavity. Advance the catheter-over-the-needle an additional few millimeters to ensure that the catheter is within the peritoneal cavity. Hold the hub of the needle securely. Advance the catheter over the needle until its hub is against the skin (**Figure 65-7B**). Withdraw the needle and syringe as a unit. Attach a syringe onto the hub of the catheter (**Figure 65-7C**). Aspirate fluid from the catheter to confirm intraperitoneal placement. Hold the hub of the catheter securely and remove the syringe. Pass the syringe to an assistant to place the sample into laboratory containers. Connect the catheter to intravenous tubing. Connect the other end of the tubing to a suction bottle or bag in order to drain off the desired amount of fluid. An alternative is to attach a three-way stopcock to the distal end of the tubing. A syringe may then be attached to the stopcock to withdraw laboratory samples or "pump out" the ascitic fluid into a nonsterile container. Remove the catheter once the procedure is completed. Apply a bandage to the skin puncture site.

US ASSISTED AND GUIDED PARACENTESIS

The use of US increases the success rates for performing a paracentesis and decreases complications.[22] US may be used to assist or guide the paracentesis. A static technique is used to identify the skin puncture site and ascitic fluid location. The remainder of the procedure is "blind" using one of the above-described techniques. If ascites is not aspirated, the US probe can be placed back on the abdomen to locate the needle and determine if it is off target or not long enough to reach the peritoneal cavity. Occasionally, a dynamic technique is used and the needle inserted using real-time US.

Position the patient. Clean and prep the skin. Scan longitudinally and transversely with the US probe to survey each potential needle entry site (**Figure 65-8**). Ascites appears anechoic (black) and outlines the loops of bowel (**Figure 65-9**). The bowel may be seen

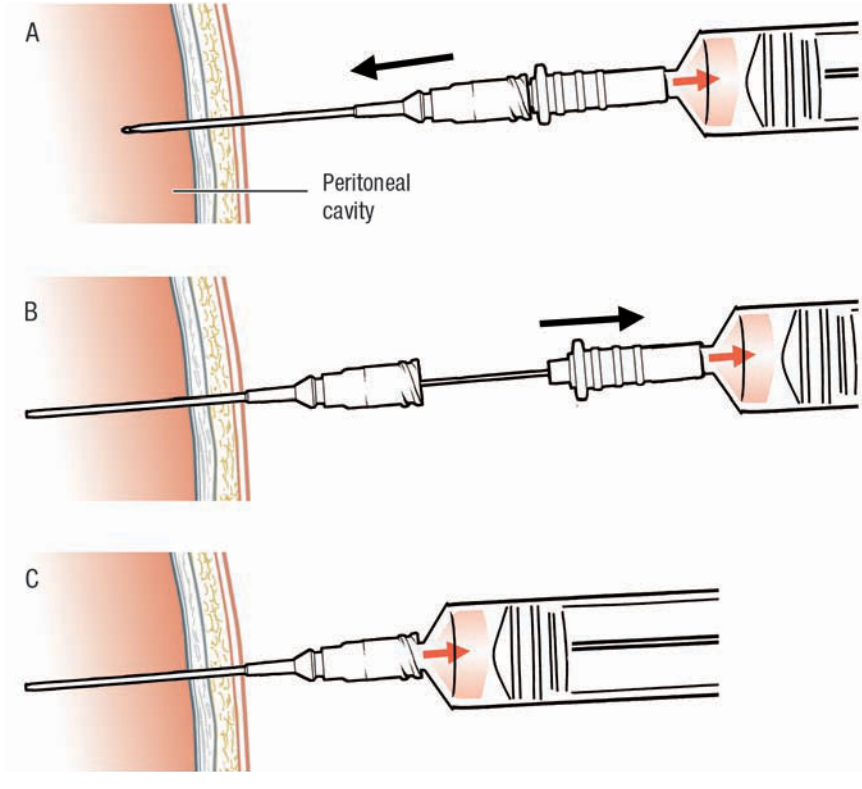

FIGURE 65-7. The catheter-over-the-needle technique. **A.** The catheter-over-the-needle is inserted into the peritoneal cavity while maintaining negative pressure on the syringe. **B.** The needle and syringe are removed. **C.** A syringe is attached to the catheter. The aspiration of ascitic fluid confirms proper intraperitoneal placement of the catheter.

FIGURE 65-8. The patient is positioned and being surveyed for the location of ascitic fluid.

undulating in the ascites as a result of peristalsis. Without ascites, individual loops of bowel cannot be visualized.

Note the amount of fluid and the presence of any structure that might make a particular site undesirable. If no site seems suitable, try repositioning the patient. Note the depth from the skin surface to the fluid. Choose a site with the most fluid at the least depth. Position the US probe so that the target is in the middle of the US view screen. The entry site will now be under the center of the probe. Mark the skin, wipe off the US gel, re-prep the area, and proceed with the procedure. If difficulties are encountered, use the probe to determine the needle's location (**Figure 65-10**).

Do not mistake a cystic fluid collection or the bladder for ascites. Ascites will outline individual bowel loops and appears in many places around the abdomen. Fluid in a cyst or the bladder has

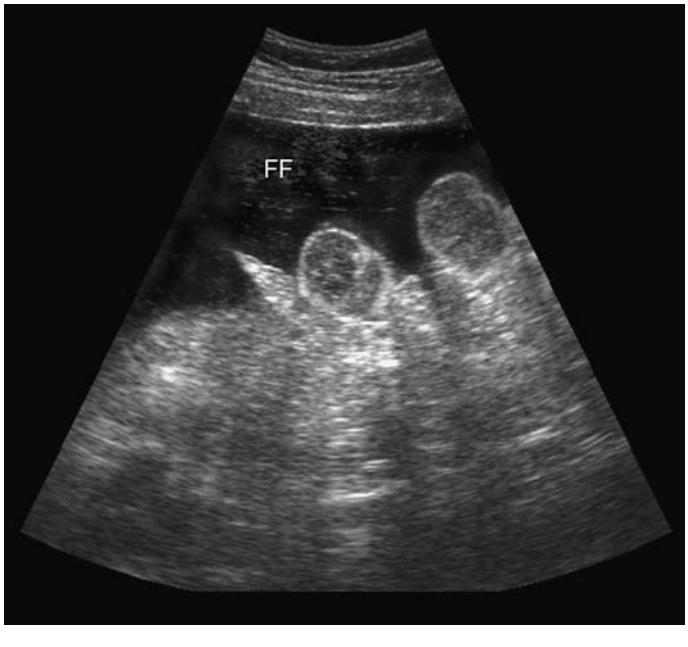

FIGURE 65-9. The presence of anechoic free fluid (FF) allows the individual bowel loops to be discerned.

FIGURE 65-10. The needle (*arrows*) is inserted through the abdominal wall and into the free fluid.

rounded borders and is localized. Loculated ascites will occasionally mimic a cyst but will still outline the bowel.

AFTERCARE

Once the procedure is completed, the puncture site should be bandaged. The site will occasionally ooze fluid in patients with tense ascites. These patients should be directed to change their dressings regularly. Occlusive tape can be helpful in preventing the fluid from leaking onto the patient's clothing and bedding. At times, a simple mattress or figure-of-eight suture is necessary to control the drainage. More recently, Emergency Physicians have used a tissue adhesive such as Dermabond, Indermil, or Histoacryl to help control a fluid leak. The patient may be discharged home if the purpose of the paracentesis was to relieve tense ascites and no signs or symptoms of spontaneous bacterial peritonitis exist and the fluid analysis is unremarkable. The patient should immediately return to the Emergency Department if they develop abdominal pain, nausea, vomiting, abdominal distention, or a fever.

The patient will require hospitalization and intravenous antibiotics if spontaneous bacterial peritonitis is suspected or diagnosed. Empiric antibiotics that cover gram-negative enterics (of which *Escherichia coli* is the most likely) and streptococcal species

(including *Enterococcus*) should be administered in the Emergency Department. A third-generation cephalosporin, such as cefotaxime, covers the most common causative agents in this disorder and should be administered.[9] Ampicillin may be added if *Enterococcus* is suspected. Check previous culture results for antibiotic sensitivities if the patient has a history of spontaneous bacterial peritonitis.

COMPLICATIONS

Complications from abdominal paracentesis are infrequent and rarely serious. However, known complications include shearing of the peritoneal catheter, abdominal wall hematoma, hemoperitoneum, bowel perforation, infection, persistent ascitic fluid leak, and systemic hemodynamic compromise.

Although bleeding is a potential complication of paracentesis, administration of prophylactic blood products such as fresh frozen plasma does not appear to be warranted.[16] Spontaneous hemoperitoneum secondary to mesenteric variceal bleeding has been reported to occur in patients receiving large-volume (i.e., >4000 mL) paracentesis.[17] Patients who developed this complication have had advanced cirrhosis with refractory ascites, previous large-volume paracentesis, and hemorrhagic shock without evidence of gastrointestinal bleeding. Mortality for this complication is exceedingly high. An additional vascular complication, an inferior epigastric artery pseudoaneurysm, has been described as a result of a therapeutic paracentesis.[18]

Perforation of the bowel during paracentesis is rare. Additionally, most of these injuries are self-sealing and develop no further problems. Generalized peritonitis and abdominal wall abscesses have also been reported and are exceedingly rare. Do not move the needle when it is within the peritoneal cavity in order to avoid lacerating the bowel wall.

Ascitic fluid may continue to leak from the site of paracentesis. A simple suture at the site may correct the problem. Patients with persistent leaks should also be evaluated for peritonitis.

Rapid removal of significant amounts of ascitic fluid has been found to cause hemodynamic compromise. Initially, removal of large amounts of ascites causes improvement in circulatory function, likely related to both mechanical (i.e., improved cardiac venous return) and neurohumoral factors. However, total paracentesis in cirrhotic patients may cause delayed (i.e., >12 to 24 hours postprocedure) effective hypovolemia by accentuation of baseline arteriolar vasodilation through neurohumoral mechanisms.[19] The literature suggests that some of the postparacentesis circulatory dysfunction may be avoided by pretreating patients with an intravenous colloid such as albumin.[20] This is not a universally accepted practice.

ASCITIC FLUID ANALYSIS

Normal ascitic fluid should appear clear with a yellow color. Increased turbidity may suggest infection, elevated triglyceride levels, or other particulate matter. Sanguinous fluid is present in patients with malignancy, intraperitoneal bleeding from the intraabdominal organs (spontaneous or iatrogenically introduced), or tuberculous peritonitis.

The specific analytical tests ordered on ascitic fluid should reflect the Emergency Physician's clinical suspicion (**Table 65-1**). Simple analysis of fluid with a cell count and differential, routine cultures, and albumin concentration are all that is necessary in patients with uncomplicated cirrhosis. These initial tests can be supplemented depending upon clinical suspicion. An ascitic fluid pH <7.35 and a blood–ascitic fluid pH gradient ≥0.10 can aid in the diagnosis of spontaneous bacterial peritonitis.[7] Total protein, glucose, LDH, amylase, triglyceride, and bilirubin levels are not helpful except in select circumstances and are not warranted on a routine basis.

TABLE 65-1 Laboratory Tests for Ascitic Fluid

Recommended	Optional	Unusual
Cell count	Total protein	Acid-fast smear and culture
Albumin	Glucose	Cytology
Cultures	LDH	Triglycerides
pH	Amylase	
	Gram's stain	

The serum-ascites albumin gradient is approximately 97% accurate in indicating portal hypertension.[5,21] The gradient is calculated by subtracting the ascitic fluid albumin concentration from the simultaneously measured serum albumin concentration. A gradient of ≥1.1 g/dL suggests portal hypertension as the etiology of the ascites (**Table 65-2**). A gradient of <1.1 g/dL suggests that the patient does not have portal hypertension and that the ascites has some other etiology (**Table 65-2**).

Peritoneal carcinomatosis should be suspected and cytology ordered in those patients with a history of breast cancer, colon cancer, gastric cancer, pancreatic cancer, or the suspicion of undiagnosed malignancy and ascites. Cultures for mycobacteria are approximately 50% sensitive. They should be ordered when the suspicion for tuberculous peritonitis is high, as in patients who have immigrated from endemic areas or have an immunocompromised status.

Patients with uncomplicated ascites secondary to cirrhosis should have an ascitic fluid WBC count < 500 cells/mm^3. The cells should be predominantly lymphocytes and there should be no clinical evidence of peritonitis. If an infection is suspected, a WBC count of >250 cells/mm^3 with greater than 50% polymorphonuclear leukocytes confirms spontaneous bacterial peritonitis. In order to adjust for significant blood in a specimen (RBC > 10,000 cells/mm^3), subtract one neutrophil per 250 RBC.[9] A Gram's stain is usually not helpful other than in the case of spontaneous bowel rupture. Otherwise, the concentration of bacteria is too low to justify utilization of a Gram's stain. All potentially infected ascitic fluid should be cultured by directly inoculating blood culture bottles at the bedside.[15,23]

SUMMARY

Paracentesis is a safe procedure that is common in the practice of Emergency Medicine. There are few relative contraindications to its performance. It is most commonly performed diagnostically to detect spontaneous bacterial peritonitis. It can also be performed therapeutically for symptomatic relief in patients with tense ascites. Complications, although they do occur, are rare.

TABLE 65-2 Classification of Ascites by the Serum to Ascites Albumin Concentration Gradient

High gradient (≥1.1 g/dL)	Low gradient (<1.1 g/dL)
Cirrhosis	Peritoneal carcinomatosis
Alcoholic hepatitis	Tuberculous peritonitis
Cardiac ascites	Pancreatic ascites
Massive liver metastases	Nephrotic syndrome
Fulminant hepatic failure	Serositis in connective tissue diseases
Budd–Chiari syndrome	
Portal vein thrombosis	
Venoocclusive disease	
Fatty liver of pregnancy	
Myxedema	
Mixed ascites	

66 Diagnostic Peritoneal Lavage

Sandeep Johar and Umashankar Lakshmanadoss

INTRODUCTION

The diagnostic peritoneal lavage (DPL) was first described in 1965 by Root who described a method for sampling the peritoneal cavity to determine more rapidly the presence of a hemoperitoneum after trauma.[1] The initial physical examination can be misleading in up to 45% of blunt trauma patients.[2] A DPL can be useful in diagnosing abdominal injury in a timely fashion.[2] It is performed less frequently today due to the use of focused abdominal sonography for trauma (FAST) bedside ultrasound scanning and helical computed tomography (CT). The DPL is the only invasive test of the three and remains the most sensitive test for mesenteric and hollow viscus injuries.[3,4]

Dr. Root's description of the DPL represented an improvement upon the use of paracentesis to identify a hemoperitoneum as described by Salomon in 1906.[5] His initial description of a DPL utilized a trocar placed into the peritoneal cavity to instill fluid. The fluid was visually inspected upon removal and the patient then underwent a laparotomy if it appeared bloody.

DPL has undergone several modifications since its initial description. The trochar technique was abandoned first in favor of the open technique, and later the Seldinger or closed technique.[7,8] A novel method which combines the use of diagnostic laparoscopy and DPL has been termed laparoscopic diagnostic peritoneal lavage (L-DPL).[6] This procedure combines the visual advantages of laparoscopy with the sensitivity and specificity of a DPL for the diagnosis of significant penetrating intraabdominal injury. While the DPL was first described for blunt abdominal trauma, it has found an indication in the patient with penetrating abdominal trauma.[2] Initial attempts to quantify the effluent based on its appearance have been replaced by the red blood cell (RBC) count, the white blood cell (WBC) count, and the measurement of various enzymes.[9–11] The debate still rages in the literature as to which criterion best determines the need for a laparotomy.

ANATOMY AND PATHOPHYSIOLOGY

The gross anatomy of the abdomen is well known to Emergency Physicians and is important to review when preparing for a DPL. The abdominal cavity is lined by the peritoneum and is protected from the environment by the abdominal wall musculature, fat, and skin. The right and left rectus muscles, which are nourished by the epigastric vessels, meet in the midline at the avascular linea alba. The umbilicus is located along the lower portion of the linea alba. The layers of the anterior abdominal wall structures vary above and below the level of the anterior superior iliac spine (**Figure 66-1**).

DPL, unlike a paracentesis, is always performed in the anterior midline of the abdomen (Figure 66-2). The linea alba is an avascular location through which the peritoneal cavity may be entered using either an open technique or a closed Seldinger type technique. This midline location minimizes the number of false-positive lavages that occur due to bleeding from the abdominal wall muscles or blood vessels. This also allows the Surgeon to perform a midline laparotomy, if necessary, through the lavage site and avoid the formation of an avascular skin bridge.

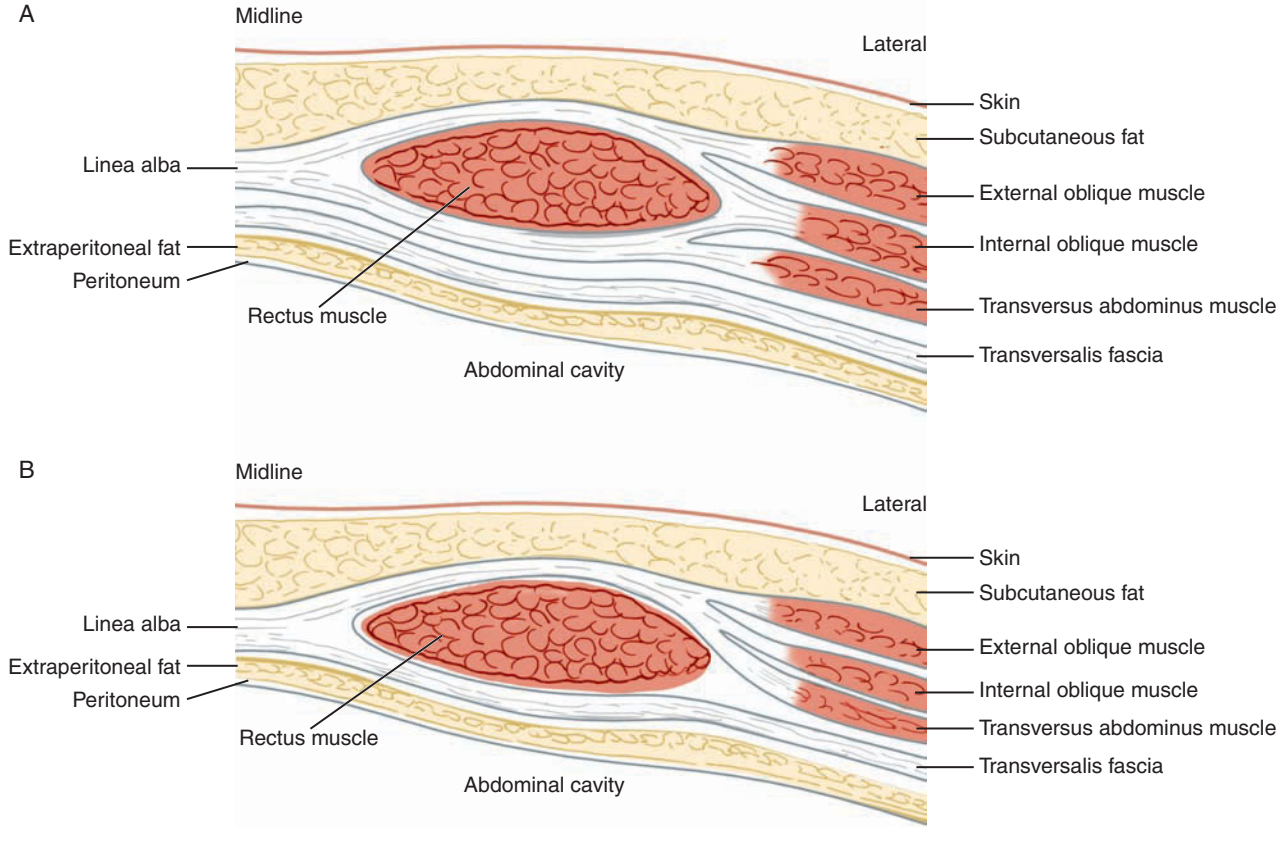

FIGURE 66-1. The layers of the anterior abdominal wall vary above (**A**) and below (**B**) the level of the anterior superior iliac spine.

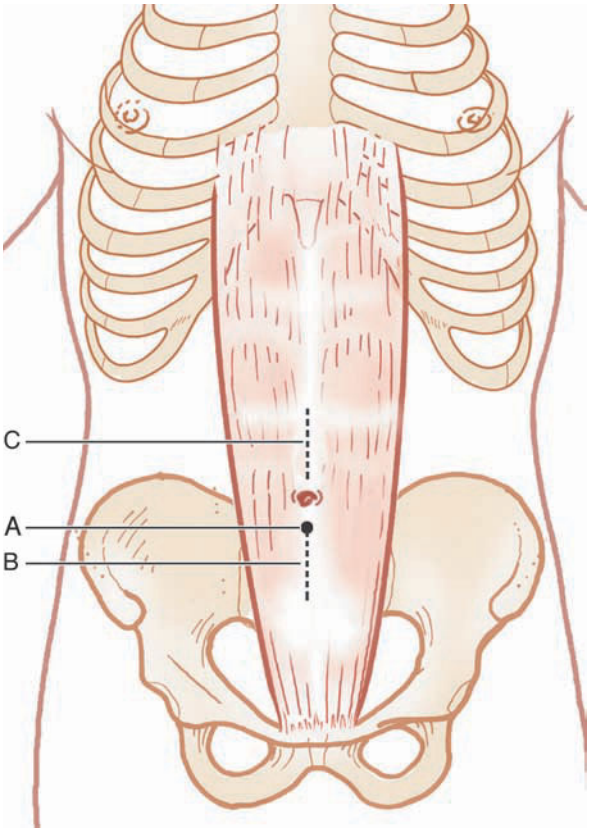

FIGURE 66-2. The preferred sites to perform a DPL. **A.** The midline and approximately 1 to 2 cm below the umbilicus is the location for a closed DPL. **B.** A midline incision beginning 1 to 2 cm below the umbilicus and extending inferiorly for 5 to 6 cm is the location for semi-open and select open DPLs. **C.** A midline incision beginning 2 cm above the umbilicus and extending superiorly for 5 to 6 cm is the location for most open DPLs.

Most DPLs may be safely performed 1 to 2 cm below the umbilicus (**Figures 66-2A & B**). This location allows the DPL catheter to be directed into the pelvis, minimizes the occurrence of inadvertent vascular injury, and increases the likelihood that fluid will be sampled from a dependent portion of the abdomen. It is more difficult to retrieve fluid if the DPL is performed above the umbilicus due to interference from the omentum. All closed and semi-open DPLs, as well as many open DPLs, are performed below the umbilicus.

The resultant retroperitoneal hematoma in patients with a pelvic fracture may extend anteriorly to the level of the linea semilunaris. **Therefore, it is important to perform the DPL in patients with a pelvic fracture using an open technique above the umbilicus (Figure 66-2C).** This will avoid a false-positive DPL and the inadvertent decompression of the hematoma.[12]

Another special situation occurs in the pregnant patient. **The DPL should be performed using an open technique superior to the uterine fundus.**[7] It may be performed below the umbilicus if the patient is in an early stage of pregnancy. The DPL should be performed more cephalad as the pregnancy progresses to minimize the chance of injuring the gravid uterus.

The third situation that may necessitate a change in the location to perform the DPL is in the patient with previous abdominal surgery. These patients must be individualized based upon the location of their scar. The DPL should be performed supraumbilically if the patient has a lower abdominal scar and infraumbilically if the patient has an upper abdominal scar.[1,9] In all cases of previous surgery, the DPL should be performed using an open technique to avoid any adhesions and minimize complications.[13]

INDICATIONS

A DPL is indicated in any patient with suspected abdominal trauma, blunt or penetrating, that does not have an obvious indication for a laparotomy and in whom serial physical examinations are not practical. It can be performed quickly, will reliably exclude significant intraabdominal trauma, and allow the diagnosis and treatment of associated injuries. It does not require transfer of the patient out of the monitored environment of the Emergency Department, as does a CT scan. It likewise does not require sophisticated equipment and extensive training comparable to those required to perform abdominal ultrasonography.

A DPL is especially useful in patients with an unreliable or equivocal abdominal examination and those who will be unavailable for serial physical examinations. The patient with an altered mental status (e.g., alcohol, drugs, head injury, etc.) or abnormal sensation due to a spinal cord injury is considered to have an unreliable physical examination.[7,11,14] Patients may have an equivocal examination due to tenderness from surrounding fractures of the ribs, spine, or pelvis.[11,13] They may also have tenderness over the wound or an area of injury that is difficult to distinguish from peritonitis. The third group of patients who may benefit are those that undergo surgery for another injury, such as a neurosurgical or an orthopedic procedure.[14] These patients are unavailable for serial examinations while in the operating room. Their examination may be altered postoperatively as well due to the analgesics that they receive.

DPL may be useful in the occasional circumstance when the patient presents in shock with other potential sources of hemorrhage, such as intrathoracic or retroperitoneal bleeding. It may confirm or rule out the abdomen as the source of the patient's bleeding and shock.[7] **It is important to remember that an injury confined to the retroperitoneum will not result in a positive DPL.**[15]

CONTRAINDICATIONS

The only absolute contraindication to performing a DPL is if the patient has an obvious indication for a laparotomy. Patients who present following abdominal trauma who are in shock, have peritonitis, pneumoperitoneum on chest radiography, evisceration, blood per orifice, or a retained stabbing implement have obvious indications for a laparotomy.

Several relative contraindications to DPL do exist. These actually represent contraindications to performing the closed technique. Patients with a pelvic fracture may have a large retroperitoneal hematoma that extends anteriorly to the linea semilunares. The DPL may be performed using the open technique above the umbilicus to avoid decompression of the hematoma.[12] Pregnant patients should not have a closed DPL performed because of the risk of injury to the uterus. It is safe, however, to perform an open DPL above the uterine fundus.[7] Patients with evidence of previous abdominal surgery may have adhesions of the viscera to the abdominal wall that make intraabdominal injury more likely to result when a closed DPL is performed.[1,9] An open technique may be performed in a location away from the scar.[13] One must recognize, however, that compartmentalization of the abdomen may have occurred due to intraperitoneal adhesions, thus making it more likely to have a falsely negative DPL result.

The DPL should be performed using the open technique in patients who are unable to have a Foley catheter placed due to urethral injury or stricture. This minimizes the chance of inadvertent injury to the bladder. Morbid obesity is a relative contraindication to closed DPL. This represents a difficulty in technically performing

the DPL when the abdominal wall is thicker than the 2.5 in. long locator needle. It is useful to perform the DPL in these patients using a semi-open technique.[16] Preexisting coagulopathy is also a relative contraindication.

EQUIPMENT

Closed Technique

- Povidone iodine or chlorhexidine solution
- Face mask
- Sterile gloves
- Sterile gown
- 4 × 4 gauze squares
- Local anesthetic solution
- Purple top blood collection tube
- 5 mL syringes
- 18 gauge needles
- 25 gauge needles
- Nasogastric tube
- Foley catheter
- 1 L of IV fluid to infuse, 0.9% NaCl or lactated Ringer solution
- Commercial Peritoneal Lavage Kit (e.g., Arrow AK-0900)

Semi-Open or Open Technique

- All items listed above
- Razor
- #10 scalpel blade on a handle
- Abdominal skin retractors, Weitlaner or skin rakes
- Two tissue forceps
- Two Allis clamps
- Four hemostats
- Needle driver
- Suture for vessel ligation (4-0 Vicryl, 4-0 Dexon, or 4-0 chromic)
- Suture for fascial closure (0 Vicryl, 0 Dexon, 0 Maxon, or 0 Prolene)
- 4-0 nylon suture or skin stapler for skin closure
- Suture scissors

A commercially available, disposable, and single-patient use peritoneal lavage kit is available from numerous manufacturers. The kit includes all the material required to perform a closed DPL except lavage fluid. An example is the Arrow kit (Arrow International, Reading, PA). It contains 10% povidone iodine swabs, gauze squares, a fenestrated drape, IV fluid administration tubing, 1% lidocaine, 5 mL syringes, 22 and 25 gauge needles, an 18 gauge × 2.5 in. introducer needle, an 0.89 mm × 45 cm J-tipped guidewire, an 8 French lavage catheter, and a #11 scalpel blade on a handle.

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. This should include the possible complications. Informed consent should be obtained from the patient or from the family if the patient is unable to consent due to age or mental status. **The consent process should not unduly delay the performance of the DPL in an unstable patient.**

Place the patient in the supine position. A distended stomach or bladder may be inadvertently perforated during the procedure.

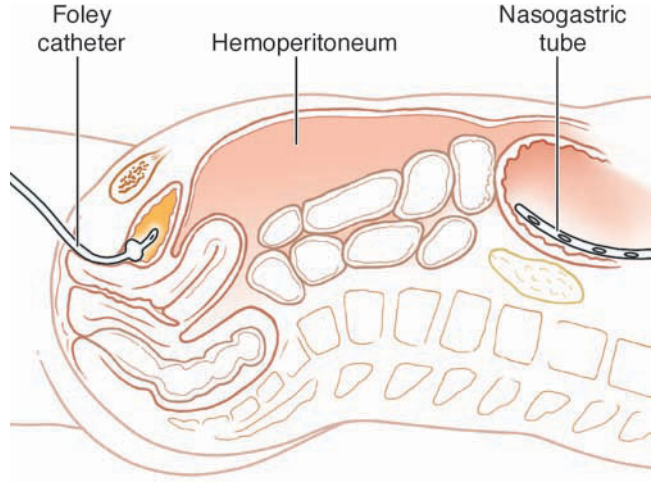

FIGURE 66-3. Midsagittal section through the abdomen and pelvis demonstrating decompression of the stomach with a nasogastric tube and decompression of the bladder with a Foley catheter.

These organs require decompression prior to performing a DPL (**Figure 66-3**). Decompress the stomach using a nasogastric or orogastric tube.[14,17] Refer to Chapter 58 regarding the details of nasogastric tube insertion. Decompress the bladder using a Foley catheter once a urethral injury has been ruled out.[7,8,14,17] Refer to Chapters 142 and 145 regarding the details of urethral catheterization and evaluation of a urethral injury.

Prepare the abdomen.[14] Shave the area surrounding the incision site if an open or semi-open DPL is to be performed. Clean the skin of any dirt, debris, and blood. Apply povidone iodine or chlorhexidine solution and allow it to dry. Apply sterile drapes to delineate a sterile field. Each healthcare provider who is involved in the procedure should don a face mask, a sterile gown, and sterile gloves.[14]

TECHNIQUES

A DPL is performed one of three different ways.[18,19] The open technique utilizes a vertical infraumbilical incision and direct visualization of the peritoneal cavity before inserting the catheter. The closed technique relies on percutaneous needle access to the peritoneal cavity, followed by the insertion of a catheter using the Seldinger technique. The semi-open technique follows the same principles of the open technique except that the midline fascia is penetrated with a needle and the catheter is advanced using the Seldinger technique. There is no difference in overall outcomes or rates of injury to visceral contents between the three techniques.[20–24]

PERCUTANEOUS (CLOSED) TECHNIQUE

The closed technique is the preferred method unless contraindications exist (**Figure 66-4**). The closed DPL can be performed in a significantly shorter time than the open technique.[23,24] There is no difference in the amount of fluid retrieved from the abdomen, the diagnostic accuracy, or the complication rate between the closed and open techniques.[23]

The closed DPL is performed in the midline and approximately 1 to 2 cm below the umbilicus (**Figure 66-2A**).[17] Prepare the patient as described previously. Infiltrate the skin, subcutaneous tissue, and fascia with local anesthetic solution. Place the 2.5 in. introducer needle onto a 5 mL syringe. Insert the needle in the midline and 1 to 2 cm below the umbilicus. Advance the needle at a 45° angle and

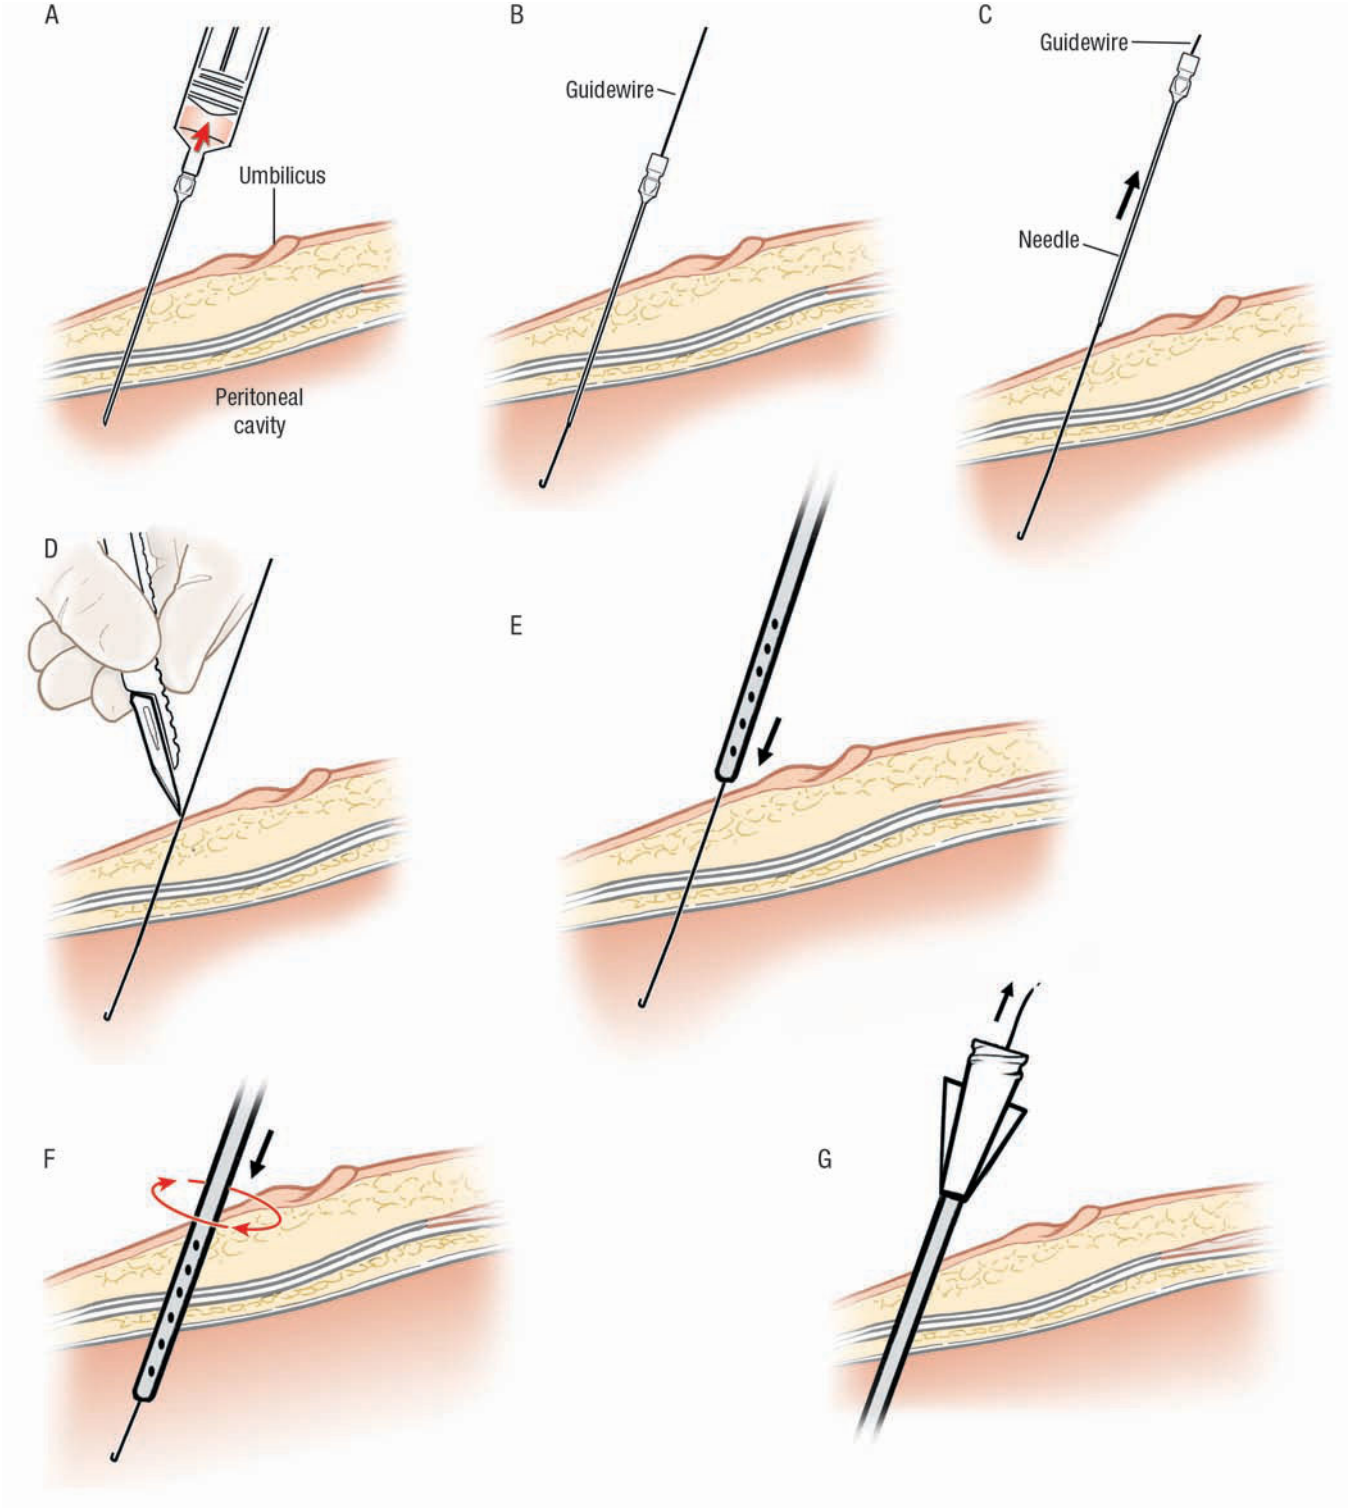

FIGURE 66-4. The percutaneous or closed DPL technique. **A.** The introducer needle is advanced caudally and at a 45° angle to the skin of the abdominal wall while negative pressure is applied to the syringe. **B.** The syringe has been removed and the guidewire is inserted through the introducer needle. **C.** The introducer needle is withdrawn over the guidewire, leaving the guidewire in place. **D.** A small nick is made in the skin and subcutaneous tissue adjacent to the guidewire using a #11 scalpel blade. **E.** The lavage catheter is placed over the guidewire. **F.** The lavage catheter is advanced over the guidewire and into the peritoneal cavity. A twisting motion may aid in the advancement of the catheter. **G.** The guidewire is removed, leaving the lavage catheter in place.

direct it into the pelvis (**Figure 66-4A**). Apply negative pressure to the syringe as it is advanced. Three "pops" are felt as the needle penetrates the skin, fascia, and peritoneum. After the third pop, slowly advance the needle another 2 to 3 mm while maintaining negative pressure on the syringe. A flash of blood will be seen in the syringe if the patient has a massive hemoperitoneum. This is considered a positive tap and concludes the procedure.

Continue the procedure if no blood is aspirated into the syringe. Stabilize the introducer needle with one hand at the level of the abdominal wall and remove the syringe. **Do not allow the**

introducer needle to move as it may lacerate the intraabdominal organs. Insert the guidewire through the introducer needle until only 7 to 10 cm of the guidewire remains outside of the hub of the needle (**Figure 66-4B**). The guidewire should advance through the needle easily with only minimal resistance. **Difficulty in advancing the guidewire or the patient complaining of pain requires removal of the guidewire and introducer needle as a unit. Never withdraw the guidewire through the introducer needle.** The tip of the introducer needle can shear off the guidewire resulting in a piece of the guidewire in the peritoneal cavity and necessitating an operative procedure. Reinsert the introducer needle and restart the procedure.

Stabilize the guidewire and withdraw the introducer needle over the guidewire (**Figure 66-4C**). Make a small incision in the skin and subcutaneous tissue alongside the guidewire with a #11 scalpel blade to facilitate passage of the lavage catheter (**Figure 66-4D**). This incision should be no more than 5 mm in length. It is important not to incise the skin until the operator is sure that the guidewire is within the peritoneal cavity. Making the skin incision prior to inserting the guidewire may result in unnecessary skin incisions if the introducer needle is placed at another location.

Place the lavage catheter over the guidewire (**Figure 66-4E**). Advance the lavage catheter into the peritoneal cavity (**Figure 66-4F**). It may be helpful to twist the catheter as it passes through the fascia to aid in inserting it into the peritoneal cavity. Advance the catheter until its hub is against the abdominal wall in the adult patient. Securely hold the hub of the lavage catheter. Remove the guidewire (**Figure 66-4G**). Attach a 5 to 10 mL syringe to the hub of the lavage catheter. Apply negative pressure to the syringe. Note if any blood is aspirated. The aspiration of blood is not considered to be a positive tap and the procedure should continue.

The presence of gross blood upon entering the peritoneal cavity should be considered an indication for laparotomy. Likewise, blood obtained through the introducer needle is considered a positive peritoneal tap and represents blood throughout the peritoneum. Confusion exists, however, when blood is withdrawn through the lavage catheter (peritoneal aspirate). Because the catheter has been directed into the most dependent portion of the peritoneal cavity, the pelvis, a small amount of blood withdrawn through the catheter may represent the only blood present within the abdomen. This does not indicate that the patient is intrinsically unstable. The patient does not require a laparotomy if the subsequent lavage is negative.[14] Therefore, while the aspiration of blood through the introducer needle (positive tap) does require a trip to the Operating Room, aspiration of blood through the catheter (positive aspirate) means nothing and is not a reason to terminate the procedure.

Continue the procedure. Pass the proximal end of the IV tubing to a nonsterile assistant to insert into a bag of IV fluid (i.e., 0.9% NaCl or Ringer lactate) and prime the tubing. Warmed IV fluid is preferable to room temperature fluid, if available. Attach the distal end of the IV tubing to the lavage catheter (**Figure 66-5A**). Open the clamp on the IV tubing and allow the lavage fluid to flow freely into the peritoneal cavity (**Figure 66-5A**). The lavage catheter may not be within the peritoneal cavity if the lavage fluid does not flow quickly but seems to drip in slowly. Reassess the catheter position. If necessary, remove and reinsert the lavage catheter. Infuse 1 L in the adult patient and 10 to 20 mL/kg (maximum 1 L) in the pediatric patient.[8,13] Stabilize the catheter with one hand during the infusion of the lavage fluid.

After the lavage fluid has been instilled, place the IV bag on the floor to allow the fluid to flow out from the peritoneal cavity (**Figure 66-5B**). There should be a steady rate of flow. Diminution of flow usually results from the omentum blocking the side holes of the lavage catheter. Firm palpation of the patient's abdomen may increase the flow rate if it seems to drop off. The lavage catheter may need to be withdrawn slightly and reinserted. These maneuvers may help to dislodge the omentum. If manipulation of the catheter does not improve flow, a second liter of fluid may be infused (additional 10 mL/kg in children). If this becomes necessary, the threshold for a positive DPL must be halved (i.e., down from 100,000 to

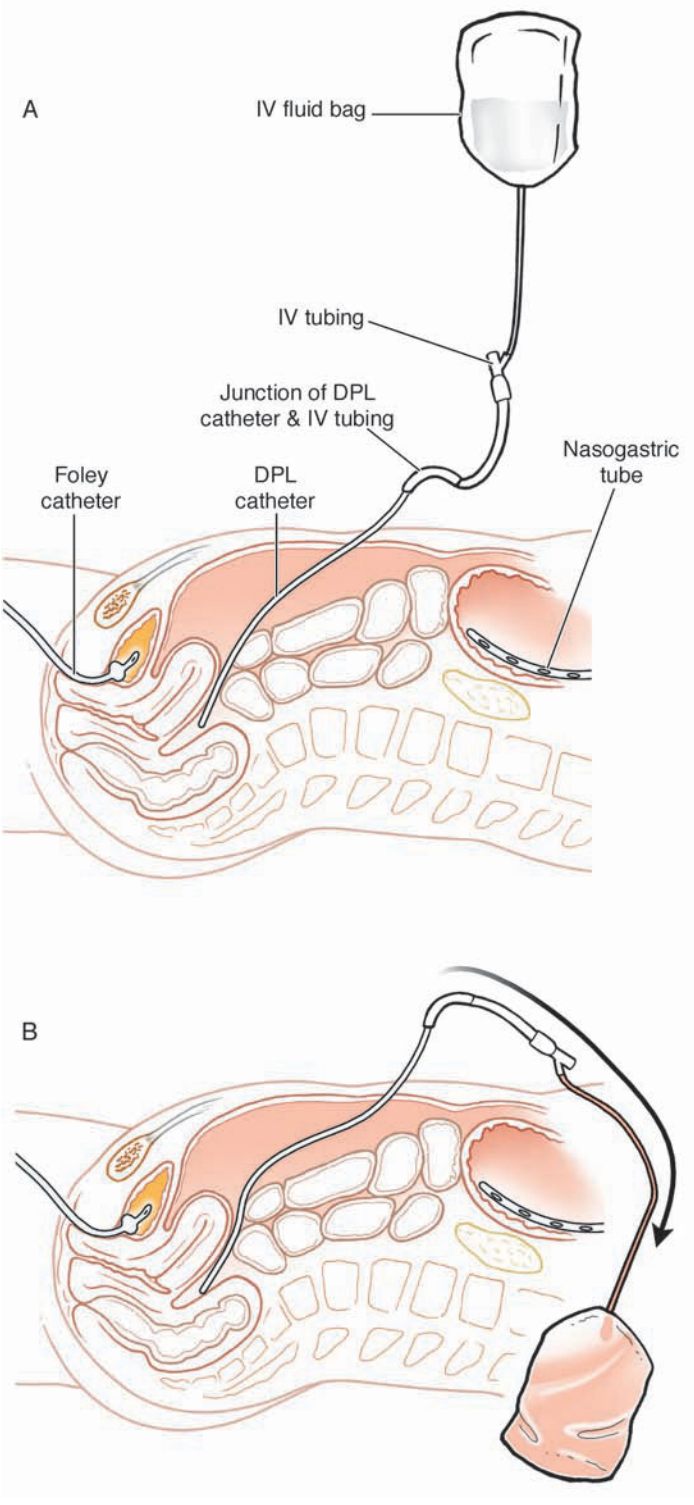

FIGURE 66-5. The instillation and removal of lavage fluid. **A.** The bag of IV fluid is attached to the lavage catheter using IV tubing. The bag of fluid is then suspended and allowed to infuse into the peritoneal cavity. **B.** The IV bag is placed on the floor to allow the lavage fluid to exit the peritoneal cavity and flow back into the bag.

50,000 RBC/mm^3 in blunt trauma); as twice the fluid is infused and results in a halving of the RBC count.

At least 200 to 250 mL of lavage fluid should be returned from the peritoneal cavity to result in a reliable cell count.[24–26] This fluid is referred to as the effluent. Place a new lavage catheter if less than 200 to 250 mL of effluent is obtained after the manipulations described above.[8] Remove the existing lavage catheter while maintaining the sterility of the distal end of the IV tubing. Place a second lavage catheter 1 cm inferior to the site of the first lavage catheter. Reconnect the IV tubing and place the IV bag to gravity drainage to obtain the effluent.

Remove the lavage catheter after obtaining as much effluent as possible from the peritoneal cavity. Place a small gauze dressing over the skin puncture site and remove the drapes. Transfer a small aliquot of the lavage effluent to a purple top blood collection tube. Transport the tube to the laboratory for a cell count. The remainder of the lavage effluent may be discarded or reserved for subsequent testing.

OPEN TECHNIQUE

Prepare the patient as described previously. Infiltrate the skin, subcutaneous tissue, and fascia with a local anesthetic solution in the area where the incision is to be made. Begin the incision 2 cm below the umbilicus and extend it 5 to 6 cm inferiorly in patients who have an upper abdominal scar (**Figure 66-2B**). Begin the incision 2 cm above the umbilicus and extend it 5 to 6 cm superiorly in patients with a pelvic fracture or lower abdominal scar (**Figure 66-2C**). Make the incision in the midline above the uterine fundus in patients who are pregnant.

Incise the skin and subcutaneous tissue longitudinally for a distance of 5 to 6 cm in the midline (**Figure 66-6A**). The incision may need to be longer in an obese patient. Clamp and ligate any small vessels that are bleeding with absorbable suture prior to incising the fascia. This will minimize the incidence of false-positive lavage results. Retract the skin and subcutaneous tissues with a Weitlaner retractor or skin rakes to aid in viewing the fascia (**Figure 66-6B**). The fascial midline may be identified by the interdigitation of its fibers (**Figure 66-6B**). Carefully incise the fascia longitudinally along the length of the previous skin incision (**Figure 66-6C**). Identify the peritoneum. Any preperitoneal fat that is present can be gently moved aside by an assistant using either a forceps or gauze. Grasp and elevate the peritoneum using two Allis clamps (**Figure 66-6D**). **Use extreme care to ensure that no bowel is included in the clamps.**

Make a small (<5 mm) incision in the peritoneum. Insert the lavage catheter through the incision and directed caudally into the pelvis (**Figure 66-6E**).[7] The remainder of the procedure is as described above in the percutaneous (closed) technique. It may be necessary to gently retract the peritoneum upward with the Allis clamps to prevent leakage of the lavage fluid around the catheter.

Remove the lavage catheter and Allis clamps after obtaining as much effluent as possible from the peritoneal cavity. It is not necessary to suture the peritoneum. Close the fascia with # 0 Maxon, Prolene, Vicryl, or Dexon suture in a running fashion. Inspect the edges of the incision for any bleeding blood vessels. Obtain hemostasis of the subcutaneous tissue by ligating small vessels with absorbable suture. Close the skin with interrupted 4-0 nylon sutures or skin staples. Place a gauze dressing over the incision site. Remove the drapes.

SEMI-OPEN TECHNIQUE

This technique is used primarily for patients in whom there is no contraindication to the performance of a closed lavage and their abdominal wall is thicker (>2.5 in.) than the length of the introducer needle. The procedure often begins as a closed technique and is converted to a semi-open technique once it is realized that the introducer needle is not long enough to enter the peritoneal cavity. It is a modification of both the closed and open techniques.[16]

Prepare the patient and begin the procedure as if performing the open technique. Make the midline incision and retract the tissues (**Figures 66-6A & B**). Identify the interdigitations of the fascia in the midline. Place the introducer needle on a 5 mL syringe. Insert the introducer needle through the midline and at a 45° angle directed toward the pelvis (**Figure 66-4A**). Apply negative pressure to the syringe while advancing the needle. A pop will be felt as the introducer needle penetrates the peritoneum. The remainder of the procedure is as described above under the percutaneous or closed technique.

Remove the lavage catheter after obtaining as much lavage fluid as possible from the peritoneal cavity. Inspect the edges of the incision for any bleeding blood vessels. Obtain hemostasis of the subcutaneous tissue by ligating small vessels with absorbable suture. Close the skin using interrupted 4-0 nylon sutures or skin staples. Place a gauze dressing over the skin incision site. Remove the drapes.

LAPAROSCOPIC DPL

The technique of laparoscopic DPL (L-DPL) should be considered in hemodynamically stable patients with penetrating lower thoracic or abdominal stab wounds.[6] It is especially applicable for Trauma Surgeons with only basic experience in laparoscopic techniques. The procedure is used to obtain conclusive evidence of significant intraabdominal injury, confirm peritoneal penetration, control intraabdominal bleeding, and repair lacerations to the diaphragm and abdominal wall. The combination of laparoscopy and DPL adds to the sensitivity and specificity of DPL and avoids under or over sensitivity, which has limited the use of DPL in the hemodynamically stable trauma patients with suspicious or proven peritoneal penetration.

ANALYSIS OF PERITONEAL LAVAGE FLUID

There are several laboratory evaluations that can be performed on the lavage effluent to determine whether the patient requires a laparotomy.[39] Gross evidence of injury exists when there is a positive peritoneal tap (i.e., gross blood obtained either through the introducer needle or noted upon opening the peritoneum during the open DPL), bile stained peritoneal fluid is noted, or enteric contents are seen in the effluent.[9,27] The most commonly used laboratory determination is that of the erythrocyte or RBC count. Other determinations include the leukocyte count and the presence of amylase in the lavage effluent.

Peritoneal lavage was first described as utilizing visual inspection of fluid for the presence of blood.[1,3,9] This has been subsequently shown to be very inaccurate, even when performed by experienced physicians.[28] A much better method of quantification of the presence of blood utilizes the counting of erythrocytes, done either manually or with an automated cell counter.

A positive DPL in an adult classically requires one of the following results: 10 mL of gross blood on initial aspiration, greater than 500/mm^3 RBCs, greater than 100,000/mm^3 WBCs, or the presence of enteric contents or food matter. The RBC count threshold can be adjusted from 100,000 RBC/mm^3 in patients who have sustained blunt trauma or an anterior abdominal stab wound, to a lower 10,000 RBC/mm^3 in patients who may have suffered penetration of the abdominal cavity. Both counts appear to be very sensitive, specific, and accurate at diagnosing either injury or penetration.[29]

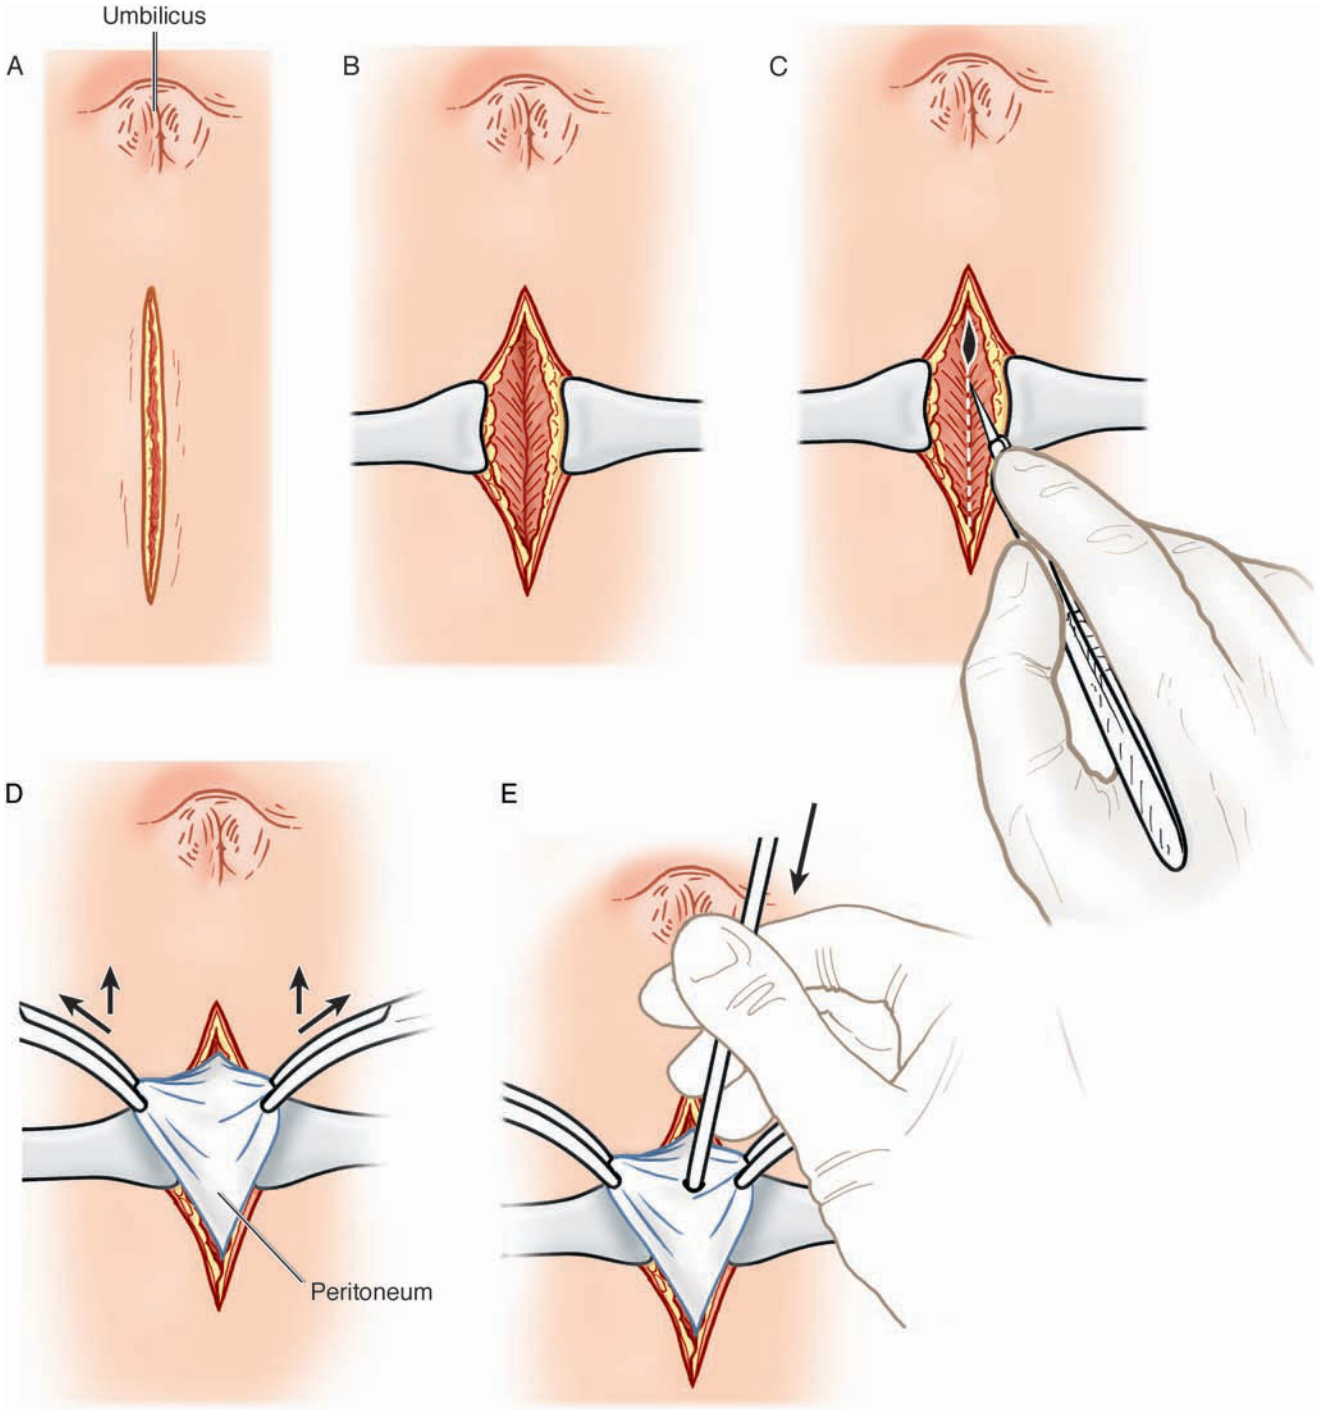

FIGURE 66-6. The open DPL. **A.** An incision is made in the skin and subcutaneous tissues. **B.** The skin and subcutaneous tissues are retracted. Note the interdigitation of the fibers of the fascia in the midline. **C.** An incision is made in the fascia. **D.** The peritoneum is grasped and elevated with Allis clamps. **E.** The lavage catheter is inserted through a small incision (<5 mm) in the peritoneum.

In blunt abdominal trauma, 100,000 RBCs/mm^3 is the most commonly used threshold for a laparotomy.[7,11,27] This corresponds roughly to the presence of 20 mL of blood in the peritoneal cavity. Using the count of 100,000 RBCs/mm^3 to determine the presence of a hemoperitoneum provides a sensitivity of 97%, a specificity of 99.6%, and an accuracy of 99%.[11] The false positives that occur are usually the result of bleeding from the lavage site. False-negative DPLs usually result in RBC counts in the mid-10,000s, which some authors refer to as indeterminate.[7] The injuries that are missed by a count of 100,000 RBCs/mm^3 are injuries to hollow viscera and the diaphragm, organs that may not bleed enough to result in a positive lavage.

Penetrating trauma, on the other hand, has no universally agreed upon threshold for a laparotomy. Documentation of penetration of the peritoneal cavity is felt to be an indication for laparotomy in all gunshot wounds and most stab wounds to the abdomen. Penetration of the peritoneum by a gunshot wound results in a significant intraperitoneal injury in 98% of cases.[30] Therefore, DPL to prove abdominal penetration is useful in cases of potentially tangential gunshot wounds.[15,32] Likewise, penetration into the peritoneal cavity from a

thoracoabdominal wound results, by definition, in a diaphragmatic injury that should be repaired.[17,33] Penetration through the retroperitoneum, from the back or flank, will cause a significant injury in 73% of cases.[15,25] Therefore, DPL is useful in these wounds as well. Penetration of the peritoneal cavity may not bleed enough to result in a 100,000 RBCs/mm^3 count. Most authors believe that a lower RBC count should be used. Unfortunately, there is little consensus as to what that count should be.

The RBC count varies from 1000 to 50,000 RBCs/mm^3 as a threshold for laparotomy in penetrating trauma.[11,15,24,33–35] The higher the count that is used, the more likely there will be a missed injury with an increased false-negative rate.[11,14,17] The lower the count that is used, the more likely that a negative laparotomy will result with an increased false-positive rate.[11,14,17] A threshold of 10,000 RBCs/mm^3 provides the most acceptable balance between false-negative and false-positive results.[17,31,32] This threshold results in a sensitivity of 88% to 99%, a specificity of 97% to 98%, and an accuracy of 95% to 98%.[14,17,32]

A special case of penetrating abdominal trauma exists when there is a stab wound to the anterior abdomen. We know that only two-thirds of these wounds will penetrate the peritoneum, and of those that penetrate, less than 50% will cause an injury that requires repair.[15] Therefore, using a lower threshold for DPL to determine penetration will result in a greater than 50% negative laparotomy rate. For this reason, wounds to the anterior abdomen are lavaged with the standard RBC count of 100,000 RBCs/mm^3 to determine injury, and not penetration, as the threshold for an operation.[36]

Many laboratories will routinely report the WBC count on the lavage effluent. The presence of over 500 WBCs/mm^3 is often quoted as a standard indication for laparotomy.[27] Unfortunately, the presence of an elevated lavage WBC count by itself has poor predictive value in the trauma patient.[25] Most commonly, there is an associated elevation in the RBC count that will trigger a laparotomy. A recently described "cell count ratio" may help to diagnose the presence of a hollow viscus injury by comparing the WBC/RBC ratio in the lavage effluent to the WBC/RBC ratio in the blood.[37] If the lavage ratio is greater than that of blood, there is a high likelihood of hollow viscus injury. This ratio is not universally accepted.

While the quantification of RBCs, and occasionally WBCs in the DPL effluent is the most common test, other laboratory tests may be utilized in indeterminate cases. The most commonly used is the determination of amylase.[2,7,9] Amylase may be elevated in the presence of an injury to the gastrointestinal tract. Unfortunately, the amylase level is neither sensitive nor specific.[10]

AFTERCARE

The patient should be observed in the hospital for up to 24 hours after a negative DPL. The Foley catheter and nasogastric tube may be removed if they are no longer needed for other indications. Reexamine the patient periodically during this observation period for the development of peritonitis that may result from a false-negative lavage or a complication of the lavage procedure itself. The performance of the lavage should not alter the patient's examination; although there may be localized wound tenderness if the lavage was performed using the open or semi-open technique.[1] The patient should receive analgesics as needed after an open or semi-open DPL. Keep the patient NPO during the initial portion of their observation. They can be fed near the end of the 24 hours to insure that they tolerate oral intake prior to discharge.

Discharge instructions to the patients should instruct them to return for the development of a fever, increasing abdominal pain, nausea, vomiting, worsening wound pain, or wound drainage. After undergoing an open or semi-open DPL, the patient should be seen in 7 to 10 days for removal of the skin sutures or staples. No evidence exists supporting the use of prophylactic antibiotics.

COMPLICATIONS

The complication rate for a DPL is relatively low. It varies between 0.6% and 2.3%.[13,38] There is no difference in complication rates between the three techniques.[20–24] The complications may be classified as wound-related or puncture-related.

Wound-related complications occur primarily with open or semi-open lavage techniques. Inadequate hemostasis during performance of the DPL may result in bleeding and a hematoma formation at the wound site.[7,13,38] As with any surgical procedure, there is a risk of wound infection at the lavage site.[7] This infection is usually due to skin flora and may be treated simply by opening the wound and performing twice daily wet-to-dry dressing changes.

Puncture-related complications may occur after any DPL technique. Virtually any organ within the abdominal cavity may be punctured by the introducer needle, the guidewire, or the lavage catheter. Puncture of the bladder and stomach may be avoided by placing a Foley catheter and nasogastric tube, respectively, prior to performing the DPL.[14,17] A punctured bladder is usually noted by obtaining urine during syringe aspiration or by lavage fluid exiting through the Foley catheter. Removing the lavage catheter and continuing Foley catheter drainage for 24 to 48 hours will treat this complication.[9] Puncture of the small bowel, colon, and their mesenteries may also occur.[7,13,14,31,38] Likewise, puncture of blood vessels ranging from mesenteric vessels to iliac vessels has been described.[1] These latter complications will usually result in a positive DPL based on bleeding or return of enteric contents and are repaired at laparotomy.

Some advocate using the abdominal wound to insert the lavage catheter and not making a fresh entry site.[40] This cannot be routinely recommended. This can result in false-positive results from blood in the wound tract, the potential for infection, the wound may be too far away that the catheter cannot reach into the pelvic recesses, and the lavage catheter could track through injured organs.

Occasionally, the lavage fluid may be instilled into the abdominal wall or the retroperitoneum.[1,14] This may result in a false-positive lavage, a false-negative lavage, or more commonly an inadequate lavage fluid return. This complication requires no specific treatment other than recognition. The body will reabsorb the fluid over time.

SUMMARY

The DPL is a well-described procedure for determining the need for a laparotomy after trauma. It has undergone several modifications since its initial description over 45 years ago. The procedure may be performed using a closed, semi-open, or open technique depending upon the patient's history and associated injuries. All three techniques are safe, accurate, and easily performed. Several criteria may indicate a positive result, and knowledge of these criteria is important in the evaluation of the DPL effluent.

Because this is an invasive procedure, it is important that it should be performed after informed consent (if feasible) and using strict aseptic technique. There is a small risk of complications as well as missed injuries necessitating the close observation of the patient with a negative DPL.

The DPL remains one of the most useful tests in the patient with abdominal trauma.[41] Despite advances in imaging technology, the DPL remains the test of choice in the patient with penetrating abdominal trauma and in select patients with blunt abdominal trauma.

67 Anal Fissure Management

Marilyn M. Hallock and Eric F. Reichman

INTRODUCTION

An anal fissure, or fissure-in-ano, is one of the most common anal disorders seen by physicians. It is a linear tear or crack that extends into the anoderm from the mucocutaneous junction to the dentate line (**Figure 67-1**). An anal fissure usually results from the passage of hard stool that traumatizes and tears the anoderm. Frequent bowel movements with diarrhea can cause similar "cracks" that eventually result in fissures. Anal fissures are often seen in infants, but primarily are a condition of young and middle-aged adults.[1–3] It is the most common cause of acute onset painful rectal bleeding in adults and in the first year of life.

A fissure may be acute or chronic, occur at any age, and affect both genders equally. It is the most common cause of rectal bleeding in infants. Fissures are typically a few millimeters long and occur primarily (90%) in the posterior midline. The remaining 10% are found in the anterior area.[4–6] There is a slight gender difference with 1% to 7% of anal fissures found anteriorly in men and up to 12% anteriorly in women.[7] Atypical locations (e.g., lateral) suggest the presence of an underlying disease such as Crohn's disease, anal cancer, previous anal surgery, leukemia, syphilis, tuberculosis, and other infections.

ANATOMY AND PATHOPHYSIOLOGY

The anal canal begins at the level of the anorectal ring and extends distally for 4 cm to the anal verge. The internal anal sphincter and external anal sphincter muscles surround the anal canal. The internal anal sphincter muscle is a continuation of the involuntary layer of circular smooth muscle of the rectum that begins at the anorectal ring. It is contracted at rest so that the lower margin can be palpated 1 to 2 cm below the dentate line in the intersphincteric groove. The internal anal sphincter muscle supplies up to 60% of the resting tone of the anus.[8] The external anal sphincter muscle is an elliptical cylinder of voluntary striated muscle tethered to the coccyx and surrounding the anal canal. Columnar epithelium lines the upper anal canal while the lower anal canal is lined by squamous epithelium. The transitional zone lies between the two different types of mucosa. The anoderm is a thin layer of stratified squamous epithelium around the anus, distal to the dentate or pectinate line, that lacks sweat glands and hair follicles. This area is richly endowed with cutaneous sensory nerve endings.

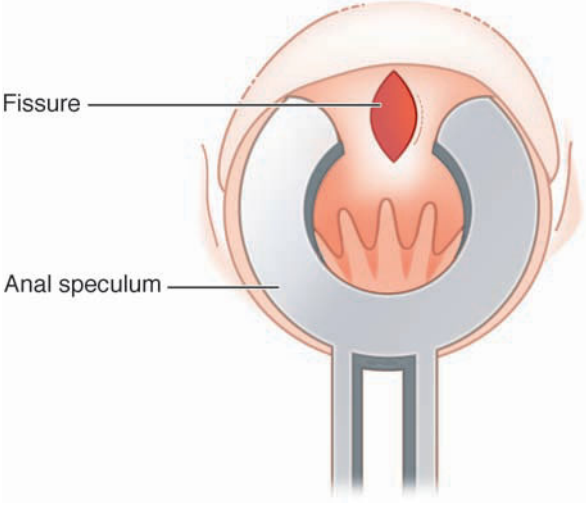

FIGURE 67-1. The anal fissure.

It is hypothesized that anal fissures usually occur in the posterior midline secondary to a decreased vascular supply causing ischemia or a decreased number of external sphincter muscle fibers predisposing the posterior area to a weakness.[9] Constipation or a hard bowel movement causes a tear in the anoderm that causes pain. The tear often results in a vicious cycle of injury by exposing the underlying internal sphincter muscle. This results in spasms of the muscle, which causes severe pain, and results in further separation of the fissure edges and possible further tearing during subsequent stool passage. A delay in wound healing may result, and can ultimately lead to a chronic anal fissure.

Ischemia may contribute to the cycle of injury. The posterior midline, being the primary location for anal fissures, has less than half the blood flow compared to other quadrants in the anal canal.[10,11] Individuals with chronic anal fissures have higher anal pressures than controls or patients with other colorectal disorders due to increased internal anal sphincter tone, which results in blood flow reduction as well.[12,13] These factors lead to the rationale for the use of topical nitroglycerin in treating anal fissures.

A tight anal sphincter is another hypothesis for the etiology of a fissure. Anal manometry in patients with fissures reveals an elevation of the resting anal canal pressures and infrequent spontaneous relaxation of the internal anal sphincter muscle.[13] These high pressures can impede blood flow. The anodermal blood supply passes through the internal anal sphincter muscle and increased resting pressure may result in an ischemic ulcer or fissure.

An acute anal fissure has the appearance of a clean longitudinal tear in the anoderm with minimal inflammation (**Figure 67-1**). A chronic anal fissure is deeper, and exposed internal anal sphincter muscle fibers may be seen at its base. A skin tag or sentinel pile is usually seen externally and a hypertrophied anal papilla may be found at its upper aspect. Patients with a chronic anal fissure may also complain of anal discharge, pruritus, or "a lump." Many people complaining to their physicians of bright red blood per rectum and anal pain think they are suffering from "hemorrhoids." A good history and physical examination can confirm the diagnosis of an anal fissure. These patients will typically describe a sharp, burning, or shearing pain with defecation that lasts for a few moments up to an hour afterward. Some people will complain of a chronic ache that is exacerbated with a bowel movement. The prolonged pain is usually attributed to internal anal sphincter muscle spasm. Bright red blood is usually seen on the stool or toilet paper. Occasionally, a few drops of blood will fall into the toilet bowl.

Patients can usually describe the initial event that triggered the fissure as either an episode of constipation with a hard bowel movement or diarrhea. Most patients with a painful anal fissure will not tolerate a digital rectal examination or anoscopy. A close inspection of the anus can be performed after reassuring the patient and gently pulling the buttocks apart. An anal fissure with a sentinel pile, an abscess, or a thrombosed external hemorrhoid may also be seen. The application of anesthetic jelly may be required to examine the patient with an acute, painful anal fissure. Palpating the anal fissure with a gloved finger or cotton swab will reproduce the patient's pain.

INDICATIONS

Anal fissures are extremely painful and uncomfortable for the patient. They can cause poor job attendance or performance. All anal fissures should be treated when they are identified. Initial therapy is conservative, followed by topical medications and injection

therapy. Surgical treatment is warranted for patients for whom nonoperative therapy fails or who experience severe anal pain.

CONTRAINDICATIONS

A patient with perianal Crohn's disease or ulcerative colitis is a relative contraindication to performing a lateral internal sphincterotomy. Medical management is advocated to initially treat these fissures associated with inflammatory bowel disease followed by the judicious use of an internal sphincterotomy.[14] A patient who has had multiple fistulotomies in the past or a sphincteroplasty should have their anal sphincter evaluated by anal ultrasound or manometry. The patient may have marginal sphincter function and an internal sphincterotomy can render them completely incontinent. A sphincterotomy should be performed only by a Colorectal Surgeon in these difficult patients.

EQUIPMENT

Anal Anesthesia

- Povidone iodine or chlorhexidine solution
- 10 mL syringe
- 27 gauge needle, 2 in. long
- Local anesthetic solution with epinephrine
- 4 × 4 gauze squares
- Sodium bicarbonate solution

Lateral Internal Sphincterotomy

- Anal speculum
- #15 scalpel blade on a handle
- Metzenbaum scissors
- Forceps
- 4-0 chromic gut sutures

Miscellaneous (depending on technique)

- Topical nitroglycerine (0.2% to 2%)
- Topical nifedipine
- Botulinum toxin
- #11 scalpel blade

Dressing

- 4 × 4 gauze squares
- Gelfoam
- 2 in adhesive tape

PATIENT PREPARATION

Explain to the patient and/or their representative the risks, benefits, complications, and the options for treatment. The following discussion applies to the injection or surgical treatment of an anal fissure. Explain the postoperative care if a surgical technique is to be performed. Obtain an informed consent for the procedure. Undress the patient from the waist down. Place the patient prone or in the prone jackknife position (**Figure 67-2**). Tape the buttocks apart and to the procedure table to gain better exposure of the anus (**Figure 67-3**). Clean any dirt and debris from around the anus. Apply povidone iodine or chlorhexidine solution and allow it to dry. Place drapes to delineate a sterile field.

Perform an anal block. Mix 10 mL of local anesthetic solution with epinephrine in a syringe with 1 mL of sodium bicarbonate. This will decrease the burning sensation upon injection of the anesthetic solution. Inject the anesthetic solution into the subcutaneous tissue circumferentially around the anus, under the fissure, and laterally to anesthetize the pudendal nerves. The use of procedural sedation (Chapter 129) is recommended, but not required.

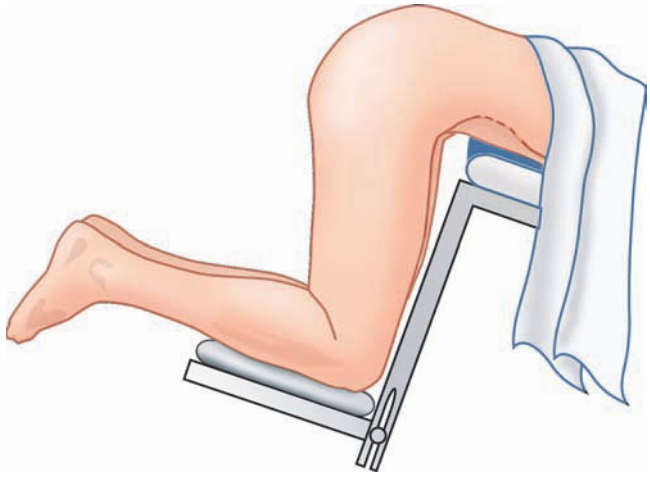

FIGURE 67-2. The prone jackknife position. Note that the lower abdomen is not touching the edge of the table.

TECHNIQUES

Begin the examination with a slow, gentle separation of the buttocks. This usually provides adequate visualization of the clean slit-like, acute anal fissure. The chronic fissure will appear similar to a deep ulcer with skin tags and enlarged anal papillae. Chronic fissures can be confused for external hemorrhoids when accompanied by a sentinel pile, which is a swollen external tag of skin at the base of the fissure. Test for adequate anesthesia. Inspect the lateral areas for an avascular area, usually on the right side between the right posterior and right anterior hemorrhoid complexes. Palpate the intersphincteric groove in the avascular area. It is a palpable depression between the caudal ends of the internal and external anal sphincter muscles.

Anoscopy can be performed for enhanced visualization when necessary. Most patients have too much pain and involuntary

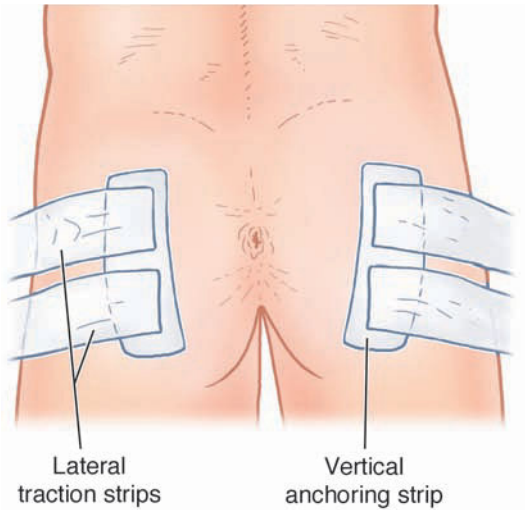

FIGURE 67-3. Taping the buttocks open in the prone patient allows for unobstructed access. The lateral traction strips are taped to the examination table or gurney.

sphincter spasm, which precludes a digital or anoscopic exam. Some require an exam under anesthesia. A proctoscopic exam may assist for ruling out secondary causes.

Atypical appearances of anal fissures, which might be eccentrically located, should prompt alternative diagnoses, such as inflammatory bowel disease, ulcerative colitis, and Crohn's disease. Sexually transmitted infections, such as chlamydia, gonorrhea, herpes, syphilis, and HIV, as well as tuberculosis, anal neoplasms, and sickle cell disease can present with anal fissures. If rectal bleeding is a prominent finding, endoscopy plus sigmoidoscopy or colonoscopy should be performed.

Management of an anal fissure begins conservatively. If unsuccessful, the next steps include topical preparations and injection therapy. A surgical sphincterotomy is the procedure of choice in refractory cases and has a 95% success rate.

FOUR-FINGER ANAL STRETCH

In the past, a four-finger anal stretch technique was performed. This involved putting the index and long fingers of both hands into the patient's anal canal and pulling the anal canal forcibly open. This would often cause an uncontrolled tear in the internal anal sphincter muscle. Although patients had relief of their symptoms, 40% developed a recurrence of the fissure and a significant proportion had some level of incontinence. **This technique is no longer recommended and should never be performed**. It is included only for the sake of completeness.

CONSERVATIVE MANAGEMENT

Most remedies for an anal fissure aim to alleviate internal sphincter hypertonia and anal pain. A trial of conservative treatment is employed for acute fissures and chronic fissures with mild to moderate symptoms. This consists of bulk fiber supplements, a high-fiber diet, increased oral intake of water, sitz baths, and topical anesthetics. The large, soft, bulky stools that result gently dilate the anal sphincter. The topical anesthetics and sitz baths in warm water after bowel movements will cleanse the area, alleviate the anal pain, and relieve internal anal sphincter muscle spasm.[15] Topical anesthetics such as lidocaine gel may be soothing, but are not more effective than fiber and sitz baths alone.[16] Oral pain medications and muscle relaxants such as diazepam may benefit. Suppositories are not recommended because they ascend to the rectal ampulla and do not effectively treat the problem within the anal canal. If an initial trial of conservative therapy for 4 weeks fails, the patient can undergo pharmacological therapy, injection therapy, or operative treatment.

TOPICAL TREATMENT

Nitric oxide has been identified as a chemical messenger mediating relaxation of the internal anal sphincter muscle. Patients treated with 0.2% glyceryl trinitrate ointment to their lower anal canal (near the fissure) twice daily exhibited relief of their anal pain, reduced maximal anal resting pressure, and increased anodermal blood flow as measured by laser Doppler flowmetry.[17] Topical nitroglycerin increases blood flow to the site, which is thought to result in less internal anal sphincter pressure, less pain, and a resultant improvement in healing rates in acute and chronic anal fissures.[18,19] After 8 weeks, 68% of patients treated with glyceryl trinitrate had healed their fissures. Some studies have shown no significant difference in healing rates when compared to placebo.[20] However, up to 75% of patients will have an adverse reaction, mainly a headache unresponsive to mild pain relievers or develop a tolerance to the nitrate.[21] Up to 33% of patients will have a recurrence of an anal fissure after the initial anal fissure has healed with nitroglycerin treatment.[22] Oral nifedipine, topical nifedipine 0.2% gel, oral diltiazem, topical diltiazem, and bethanechol have also been studied for the treatment of anal fissures.[23–29,36,37] They were all found to be comparable to topical nitroglycerin and with fewer side effects.[23–29,36,37]

Side effects such as a headache, primarily, may occur 10 minutes after application of topical nitroglycerin and typically lasts less than 30 minutes. Orthostatic hypotension has also been described in patients. Patients taking medications for erectile dysfunction (i.e., Cialis, Levitra, or Viagra) should not receive nitroglycerin-containing medications within 24 hours of their use due to the potential for life-threatening hypotension. After 24 hours, a lower concentration of nitroglycerin (e.g., 0.2% glyceryl trinitrate) is recommended compared to standard 2% ointments.

Topical nifedipine gel in a concentration of 0.2% used every 12 hours for 3 weeks has been successfully used to decrease anal sphincter pressures and help heal fissures.[30] No systemic side effects or significant anorectal bleeding was observed in 141 patients treated with topical nifedipine.[30]

BOTULINUM TOXIN

Botulinum toxin is another pharmacological approach to the treatment of a chronic anal fissure. Botulinum toxin inhibits the release of acetylcholine from nerve endings and has been shown to be a beneficial treatment for chronic anal fissures.[31] Injection close to each side of the fissure improves healing rates.[31] Inject 20 units of botulinum toxin A (Botox, Allergan, Irvine, CA) or 0.4 mL (50 U/mL) into the internal anal sphincter muscle on either side of the fissure using a 27 gauge needle. This can alleviate anal pain, decrease anal sphincter pressure, and promote healing.[32] Unfortunately, this can result in some form of temporary incontinence.[31,32]

LATERAL INTERNAL SPHINCTEROTOMY

The mainstay of operative therapy is a lateral internal sphincterotomy. This technique is curative in 95% of patients. Unfortunately, approximately 15% of patients will be left with some form of minor incontinence. The technique divides the internal anal sphincter muscle between the dentate line and the anal verge. A meta-analysis of 2727 patients undergoing operative techniques for anal fissures revealed no significant difference between open versus closed lateral internal sphincterotomy for persistence of fissure or incontinence.[33] However, significant differences were found when anal stretch was compared to all forms of sphincterotomy.

CLOSED LATERAL INTERNAL SPHINCTEROTOMY

The closed lateral internal sphincterotomy technique is preferred by some physicians (**Figure 67-4**). Its advantage is that a smaller wound is created. Unfortunately, this is a blind procedure and can result in injury to the patient and the physician.

Prepare the patient as described previously. Place a well-lubricated anal speculum into the anal canal. Open the speculum to provide a slight stretch to the anal sphincter muscles. Expose and view the left or right posterolateral quadrant of the anal canal. Place a gloved finger into the anal canal and palpate the internal aspect of the internal anal sphincter muscle. **Perform the remainder of this procedure while carefully palpating the course of the scalpel blade with the gloved finger in the anus.**

Insert a #11 scalpel blade horizontally through the skin and into the intersphincteric groove (**Figure 67-4A**). Advance the scalpel blade into the plane between the internal and external anal sphincter muscles and up to the level of the dentate line (**Figure 67-4A**). Direct the scalpel blade medially by turning it 90° (**Figure 67-4B**). Slowly divide the full thickness of the internal anal sphincter muscle while

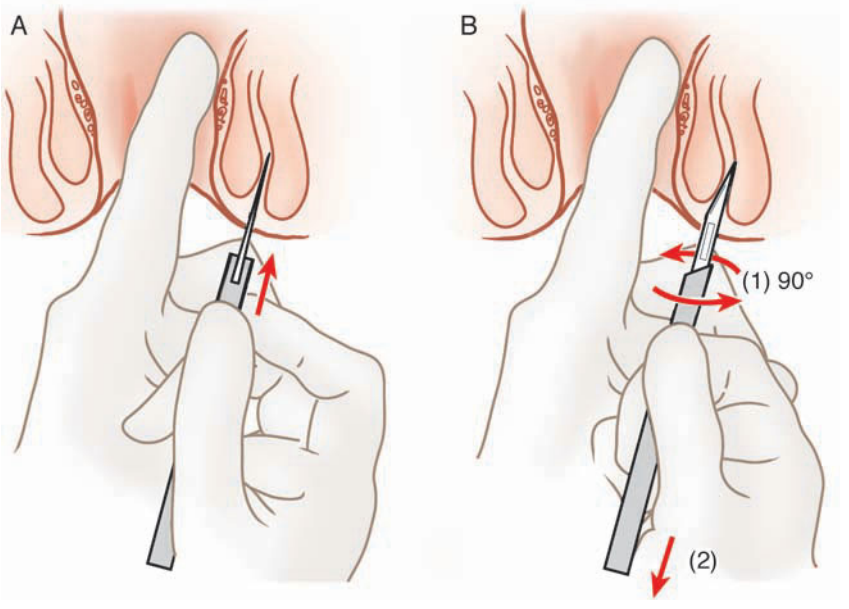

FIGURE 67-4. The closed lateral internal sphincterotomy. **A.** The #11 scalpel blade is inserted horizontally between the internal and external anal sphincter muscles. **B.** The scalpel blade is turned 90° (1) then withdrawn (2) to transect the internal anal sphincter muscle.

withdrawing the scalpel blade. **Do not cut the anoderm.** Withdraw the scalpel from the anal canal. Remove the anal speculum. Close the incision site with 1 or 2 size 4-0 chromic gut interrupted sutures. Pack the anal canal with 4 × 4 gauze squares for 10 to 15 minutes to aid hemostasis and prevent the formation of a hematoma.

OPEN LATERAL INTERNAL SPHINCTEROTOMY

The open technique provides a clear exposure to the anatomy of the region. This is especially important for those less experienced with the procedure. It avoids the potential for injury to the physician when compared to the closed technique.

Prepare the patient as described previously. Place a well-lubricated anal speculum into the anal canal. Open the speculum to provide a slight stretch to the anal sphincters and view the fissure (**Figure 67-5A**). Rotate the speculum 90° to expose and view the left or right posterolateral quadrant of the anal canal (**Figure 67-5B**). Place a gloved finger into the anal canal and palpate the internal aspect of the internal anal sphincter muscle.

Make a 1 cm longitudinal incision through the skin and subcutaneous tissue, between the dentate line and the anal verge (**Figure 67-5B**). This will center the edge of the internal anal sphincter muscle in the middle of the incision. Slide a scissors submucosally along the white internal anal sphincter muscle until the tips are at the level of the fissure, but not beyond the dentate line. Spread the arms of the scissors once to open the jaws of the scissors. Repeat this process on the other (deep) side of the internal sphincter muscle. Grasp and elevate the internal anal sphincter muscle with a forceps. Use a scissors to make a cut in the internal sphincter muscle the same length as the length of the anal fissure (**Figure 67-5C**).[34] **Do not completely transect the internal anal sphincter muscle. Preserve at least one-third of the proximal internal sphincter**

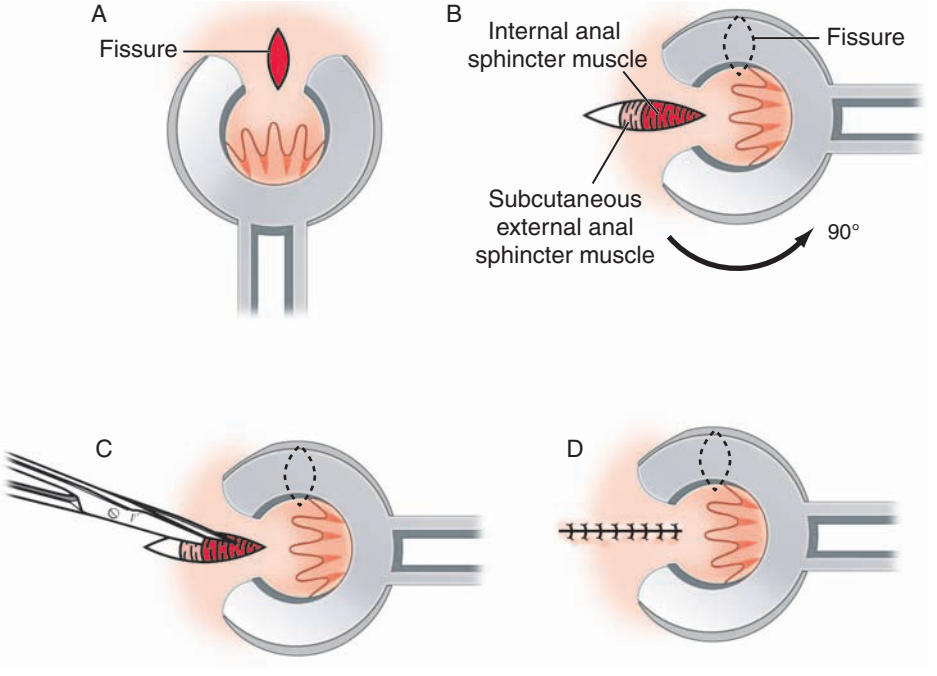

FIGURE 67-5. The open lateral internal sphincterotomy. **A.** The anoscope is inserted so that the anal fissure is visible. **B.** The anoscope has been rotated 90°. An incision has been made through the anoderm and subcutaneous tissue to expose the underlying anal sphincter muscles. **C.** The internal anal sphincter muscle is partially transected with a scissors. **D.** Closure of the incision.

muscle intact.[34] Pack the anal canal with 4 × 4 gauze squares to apply pressure to the area for 10 to 15 minutes to aid in hemostasis and to prevent the formation of a hematoma. Suture the incision closed with size 4-0 interrupted chromic gut (**Figure 67-5D**). Place a small piece of Gelfoam over the wound. Remove the anal speculum. Dress the incision site with 4 × 4 gauze squares.

AFTERCARE

Instruct the patient to remove the dressing in 12 to 24 hours or before a bowel movement. Warm sitz baths four times a day will keep the area clean and alleviate any pain. Prescribe a high-fiber diet with oral stool softener supplements to keep the stools soft and bulky. Oral analgesics such as acetaminophen or nonsteroidal anti-inflammatory medications with supplementary narcotic analgesics will often ease the immediate and postoperative pain. The patient should follow up in 1 to 2 weeks for reevaluation. The patient should immediately return to the Emergency Department if a fever, severe pain, or bleeding from the incision site develops.

COMPLICATIONS

Many complications have been associated with a lateral sphincterotomy. Itching, burning, bleeding, delayed wound healing, and constipation are minor problems. The patient may complain of mucus drainage or fecal soiling during the healing phase. Bulking agents or a high-fiber diet may help decrease the drainage. Recurrent fissures occur in about 8% of patients, 66% of which heal with conservative treatment. Up to 45% of patients may experience some degree of incontinence, but only 3% of patients may have their life affected.[35] A fecal impaction, abscess, or hemorrhage can become significant. Enemas are useful for the constipated patient. An abscess should be incised and drained, preferably in the Operating Room for adequate anesthesia to completely explore the wound and debride any necrotic tissue. A subcutaneous fistula can develop if the anoderm is violated during the sphincterotomy and not recognized. This is easily taken care of by doing a fistulotomy of this superficial skin bridge. The physician may be injured while performing the closed technique. This technique should be reserved for those with experience and a patient that is sedated to decrease the chances of injury.

SUMMARY

Anal pain with bleeding due to an anal fissure is initially treated conservatively with a high-fiber diet, stool softeners, and warm sitz baths. Most patients will respond to these measures. A few will fail conservative therapy and need pharmacological or operative therapy. The goal of all the different regimens is to decrease anal pain, reduce anal sphincter spasm, and heal the fissure.

68 External Hemorrhoid Management

Charles Orsay and Eric F. Reichman

INTRODUCTION

The primary disease process affecting external hemorrhoids is thrombosis. The mainstay of treatment is excision. **It is important to remember that the excision is to alleviate or palliate the pain.** The natural history of an untreated thrombosed external hemorrhoid is to rupture and spontaneously evacuate the clot or to resorb the clot over time. Therefore, treatment should give the maximum amount of pain relief with the least chance of complications. To make this decision it will be important to obtain a good history of the length of the pain, how severe it is, and whether there has been improvement. It is important to perform a physical examination to rule out prolapsed grade IV internal hemorrhoids, perianal abscesses, and other perianal masses.

ANATOMY AND PATHOPHYSIOLOGY

External hemorrhoids fall into three main groups: left lateral, right anterior, and right posterior (**Figure 68-1**). They are covered with anoderm and visible on the outside of the anal canal. They are composed of a venous plexus mixed with connective tissue. They drain into the middle and inferior rectal veins that terminate into the internal iliac and femoral veins, respectively. External hemorrhoids do not prolapse like internal hemorrhoids. They engorge and thrombose. It will not benefit the patient to try to reduce an external hemorrhoid since their normal location is mostly outside the anal canal and reduction will not remove the clot. External hemorrhoids are never covered with mucosa. The overlying skin may appear to look shiny, swollen, gangrenous, or like an orange peel mimicking the look of mucosa.

It is important to differentiate internal versus external hemorrhoids. Internal hemorrhoids originate above the dentate line, lack sensation, and are covered with mucosa. Prolapsed internal hemorrhoids are painless unless they become gangrenous, infected, strangulated, or thrombosed. External hemorrhoids originate below the dentate line, have sensory innervation, and are covered with squamous epithelium that matches the surrounding skin.

The patient usually complains of a history of the sudden onset of pain and swelling. The exact cause of thrombosed external hemorrhoids is unknown. It is probably related more to straining with lifting, jogging, or bicycling than chronic constipation. This explains why this problem occurs more often than internal hemorrhoidal disease in a younger age group.

External hemorrhoids can be diagnosed when a patient complains of a sudden onset of pain and swelling, usually with no

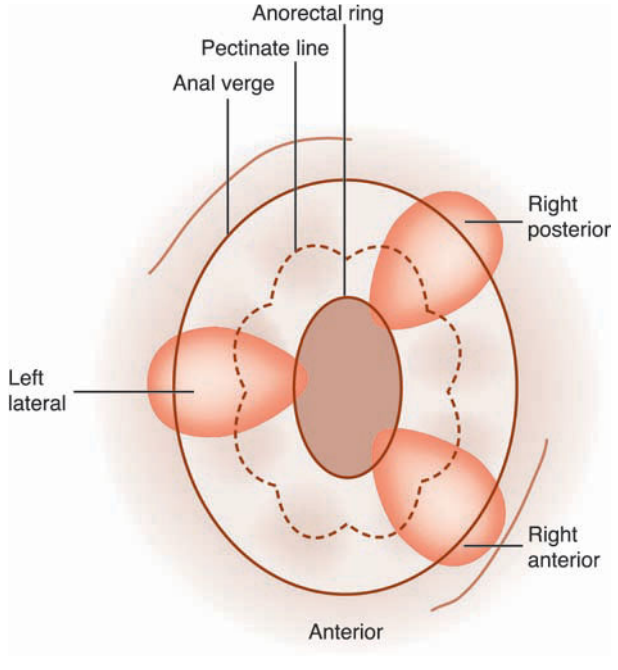

FIGURE 68-1. The position of the three main groups of external hemorrhoids.

bleeding. The physical examination will reveal a tensely swollen area covered with anoderm. The swelling will be visible by gently spreading the buttocks and inspecting the area near the anal canal. They have a bluish coloration, especially in patients with little skin pigmentation, and almost no redness. The swelling is abrupt, like placing a marble under a sheet and tucking in the edges. This differentiates the appearance of a thrombosed external hemorrhoid from the appearance of an abscess that would have erythema and gently sloping sides from edema.

INDICATIONS

The primary indication for the excision of a thrombosed external hemorrhoid is pain. The excision should occur as soon as possible from the onset of pain and usually not after the fourth day.[1] The pain should become tolerable in the normal course of events after the fourth day. The clot is already being absorbed at this time and the chance of having problems with bleeding increases and medical management is indicated. Improving pain suggests that medical management is the more appropriate method of care as thrombosed external hemorrhoids will spontaneously resolve in a few weeks with no complications. Medical management includes fiber supplements, sitz baths, stool softeners, topical corticosteroids (i.e., Proctofoam HC or Anusol HC), and over the counter hemorrhoidal agents (e.g., Preparation H). There is, however, a small subgroup of patients who do not seem to improve with medical management and will require excision, even late in the course of the disease. Surgical excision has a lower frequency of recurrence and a longer time interval to recurrence than conservative treatment.[2] The thrombosis to be excised should involve one or at most two hemorrhoids.

CONTRAINDICATIONS

There are several contraindications to the Emergency Department incision and drainage of a thrombosed external hemorrhoid. Grade IV internal hemorrhoids with thrombosed external hemorrhoids, circumferential hemorrhoids, or very large thrombosed external hemorrhoids should be managed by a Surgeon in the Operating Room using electrocautery or suture ligation to control hemorrhage. Patients taking anticoagulants require meticulous care and possible reversal of the coagulopathy. An allergy to local anesthetic agents will require a trip to the Operating Room to excise the hemorrhoid. Painless masses are never thrombosed external hemorrhoids and require evaluation by a Surgeon. Draining external hemorrhoids should be followed up in 24 hours by a Surgeon. Patients who are unable to cooperate with the procedure may require procedural sedation or general anesthesia. A Surgeon should manage patients who have thrombosed external hemorrhoids and also have inflammatory bowel disease, anorectal fissures, perianal infections, portal hypertension, rectal prolapse, anorectal tumors or who are immunocompromised. Patients with external hemorrhoids that are not thrombosed usually require no treatment for their external hemorrhoids. They may need appropriate referral for their anal pain.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Local anesthetic solution with epinephrine
- 5 mL syringe
- 25 gauge needle
- 18 gauge needle
- #11 scalpel blade on a handle
- 4 × 4 gauze squares
- 2-0 absorbable sutures (Vicryl, Dexon, chromic gut, or plain gut)
- 3-0 absorbable sutures (Vicryl, Dexon, chromic gut, or plain gut)
- Small dissecting scissors
- Small grasping forceps
- 2 in. adhesive tape
- Tincture of benzoin
- Silver nitrate applicator sticks
- Moisture-resistant drapes
- Posthemorrhoidectomy pack or 18 gauge Foley catheter

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedures to the patient and/or their representative. It is also important to explain to the patient what to expect after the procedure. Obtain an informed consent for the procedure.

It is crucial to position the patient so that the anus is clearly visible and the Emergency Physician can work with both hands. Place the patient in the prone or prone jackknife position with their hips flexed (**Figure 68-2**). Tape the buttocks to the procedure table (**Figure 68-3**). Apply tincture of benzoin to the buttocks and allow it to dry. Place strips of 2 inch adhesive tape on the left and right cheeks of the buttocks and perpendicular to the anus. Apply lateral and slightly cranial traction with adhesive tape to get the proper exposure. Attach the distal ends of the tape to the procedure table or stretcher to maintain exposure during the procedure. This positioning works best in the Operating Room when the patient is under anesthesia and unlikely to move. Explain to the patient that they must relax and refrain from squeezing their buttocks shut. If the patient is poorly positioned and there is difficulty with hemorrhage in the middle of the procedure, it is very difficult to stop and reposition the patient to place a suture for control. Apply drapes to protect the patient and clothing from spills. Clean the anus and surrounding area of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry.

The patient usually is in significant pain. The injection of local anesthetic solution can be excruciating. Consider the use of ice packs to the area for 5 to 10 minutes before injection, intravenous analgesics, sedatives, or procedural sedation. This will be greatly appreciated by the patient.

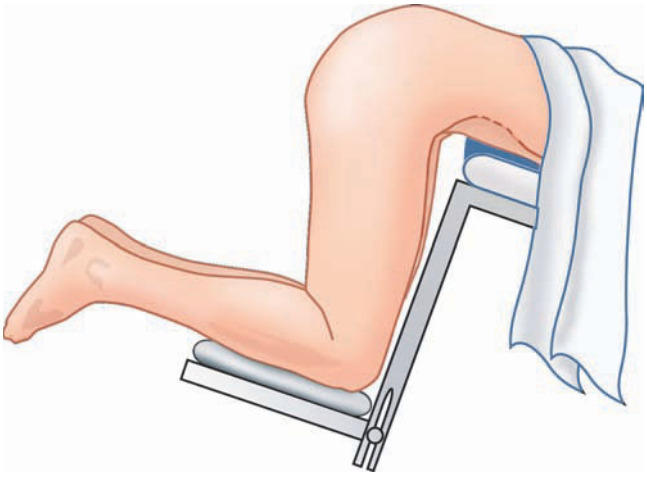

FIGURE 68-2. The prone jackknife position. Note that the lower abdomen is not touching the edge of the table.

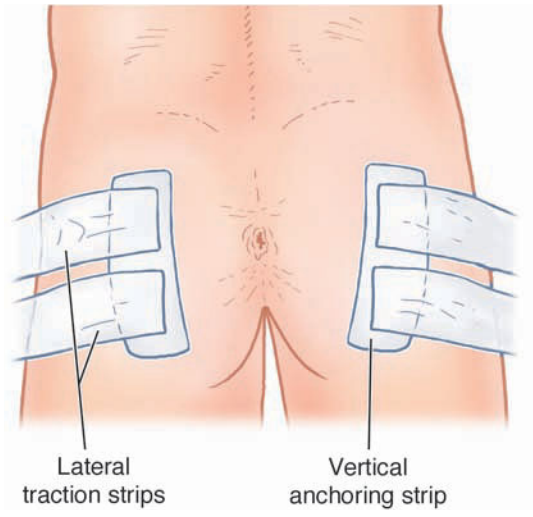

FIGURE 68-3. Taping the buttocks open in the prone patient allows for unobstructed access. The lateral traction strips are taped to the examination table or gurney.

TECHNIQUE

Determine the area of the incision. **The best pain relief will be achieved if the thrombosis is excised rather than incised.** If the hemorrhoid is very large, one-third or greater of the anal circumference, it is best to excise the middle third of the hemorrhoid leaving as much anoderm as possible to prevent the wound healing with a stricture. Excision can be achieved with two radial incisions starting near the center of the anus and enclosing an ellipse of skin that will be removed with the thrombosis (**Figure 68-4A**).

Inject local anesthetic solution containing epinephrine starting laterally and injecting medially to and beyond the thrombosed hemorrhoid (**Figure 68-4B**).[1] The injection should include both lines of the planned incision and, if possible, the area medial to the thrombosis. The local anesthetic agent should also cross the midline anteriorly and posteriorly to include nerve fibers crossing over from the opposite side of the anus. Allow 5 minutes for the local anesthetic to take effect. The degree of local anesthesia can be checked by pinprick or by pinching the thrombosed hemorrhoid with forceps.

Make the incisions with a #11 scalpel blade when satisfactory local anesthesia has been achieved. Dissect the ellipse of skin and the underlying clot from lateral to medial with a scissors (**Figure 68-4C**). **Do not cut the anal sphincter at the base of the wound (Figure 68-4D). It is important to remove the entire clot since the purpose of the excision is only to palliate the patient's pain.** Small clots in or between the sphincter muscles may still cause considerable pain. These can be grasped with a fine forceps and removed.

Examine the wound carefully for hemostasis. Localized areas of bleeding can often be controlled with the application of silver nitrate to cauterize the wound. It is the author's personal belief that there is less discomfort if silver nitrate is used for hemostasis than if one is forced to use suture ligature. However, if there is continued bleeding, a 3-0 absorbable suture can be used in a figure-of-eight formation over the area of bleeding. Plain catgut is preferred because the suture will dissolve very quickly. A suture that remains in place for several weeks in this area can sometimes be very uncomfortable for the patient. Dress the wound with 3 or 4 gauze squares folded in half and one piece of tape across the buttocks to hold the dressing in place.

AFTERCARE

The patient should leave the dressing in place until the next day or the next bowel movement. It is best to remove the dressing in a sitz bath and replace it with dry 4 × 4 gauze placed between the buttocks to collect any moisture. Frequently, tape is not necessary. Encourage the patient to take three or four sitz baths per day and after every bowel movement. The water should be warm, not hot, and the bath

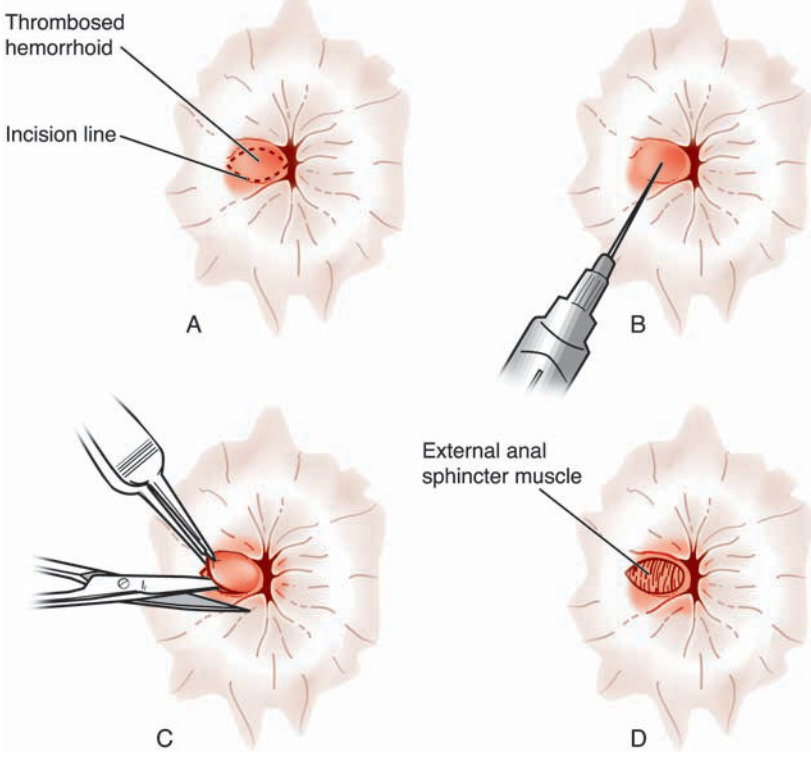

FIGURE 68-4. Excision of the thrombosed external hemorrhoid. **A.** The dotted line represents the incision lines to remove the skin and underlying thrombosis. **B.** Injection of local anesthetic solution. **C.** The skin incision has already been performed. The skin and underlying thrombosis are dissected free with a scissors. **D.** The ellipse of skin and the underlying thrombosis have been removed. The fibers of the underlying external anal sphincter muscle are visible.

should be for 20 minutes each time. The sitz bath serves two functions. It keeps the wound clean and helps relax the internal anal sphincter muscle spasm, which helps relieve the pain. An alternative to wiping after bowel movements and sitz baths is to shower. The shower will gently wash away any material and not hurt like wiping. The sitz baths and dressing changes should continue until the wound is healed.

Fiber supplements and stool softeners should be continued for at least 6 weeks. Prescribe one tablespoon of psyllium products (e.g., Metamucil) with water twice a day to soften and bulk the stool. The goal is to achieve an atraumatic stool that gently dilates the anus as it passes. If the patient is unable to tolerate psyllium, 100 mg of docusate orally once or twice a day can be used to soften the stool but will not provide the bulk.

The patient should feel much less pain after the thrombosed hemorrhoid is excised. The remaining pain can frequently be controlled with the sitz baths. Some form of oral analgesia is required. Acetaminophen or ibuprofen is usually adequate. The use of codeine or opiates has a pronounced constipating effect that could result in painful bowel movements. Do not prescribe narcotic analgesics for more than 24 hours. The patient should return to the Emergency Department if the pain is not improved, if bleeding continues, or if they develop a fever. The wound must be watched for infection, which fortunately is very rare.

COMPLICATIONS

The rate of complications for excision of thrombosed external hemorrhoids is not well reported.[1–6] Reported complication rates for more major anal surgery show that bleeding occurs in 1.5% to 4.0% of patients and infection occurs in 2% of patients.[1–3] Considering the persistent fecal contamination at the anus, this is a very low rate of infection. We can estimate that the complication rate for the excision of a thrombosed external hemorrhoid would be even less.

Any posthemorrhoidectomy bleeding that is minimal can be managed by the application of local pressure. Moderate to severe bleeding will require the insertion of a commercially available posthemorrhoidectomy pack.[7] This is an accordion-like pack that is inserted through the anoscope and into the anal canal. Pulling the two strings of the pack accordions the pack down into the anal canal to tamponade the bleeding. A Foley catheter may be substituted if the packs are not available. These patients require intravenous analgesics, intravenous sedation, and hospitalization.

The treatment for a patient with an infection in the perianal area who has not had surgery is to open the abscess and place the patient on sitz baths. Infection is very unlikely since the wound is already open from the excision procedure and the patient is taking sitz baths. Broad-spectrum antibiotics for aerobic and anaerobic bacteria should be given to any patient with a postprocedural infection and the wound examined under general anesthesia to rule out any underlying pathology.

Long-term theoretical complications include stricture and incontinence. These are exceedingly rare and can be prevented by not removing too much anoderm and not injuring the underlying external anal sphincter muscle.

The use of a linear incision should be avoided. The stretched skin will close and create a pocket in which a hematoma or abscess can form. Removal of clots through a linear incision (rather than an elliptical incision) is often difficult, inadequate, and may lead to a higher incidence of recurrence.

SUMMARY

External hemorrhoids may thrombose and cause the patient considerable pain. The natural history of this disease is for the clot to drain or resorb without significant long-term morbidity. Excision of the thrombosed external hemorrhoid will provide considerable relief if the patient presents acutely. It is important to achieve good hemostasis and not damage the underlying external anal sphincter muscle or remove too much anoderm to avoid problems with continence or stricture formation. Fiber supplements and sitz baths should be prescribed rather than surgical excision if the patient presents later in the course of the disease.

69 Prolapsed Rectum Reduction

Jamil D. Bayram and Eric F. Reichman

INTRODUCTION

Rectal prolapse is an uncommon condition. It was first described in the Bible (2 Chronicles 21). "You yourself will be very ill with a lingering disease of the bowels, until the disease causes your bowels to come out. … After all this, the Lord afflicted Jehoram with an incurable disease of the bowels. In the course of time, at the end of the second year, his bowels came out because of the disease, and he died in great pain." The pathophysiology of a rectal prolapse has been evolving since 1543 when Vesalius described the detailed anatomy of the anorectum. Today, three types of rectal prolapse are recognized and they represent three stages of a continuum.[1]

Rectal prolapse usually affects people at the extremes of age. It is most common in the very young and the elderly. The condition usually manifests itself in children within the first 4 years of life, with the highest incidence occurring in the first year.[2] The gender incidence in children is equal but slightly weighted toward males.[1] The peak incidence in the elderly is approximately between 60 and 70 years of age. It affects primarily elderly women, with a 6:1 ratio of females to males.[3]

ANATOMY AND PATHOPHYSIOLOGY

A rectal prolapse is classified into one of three stages (**Figure 69-1**). An internal prolapse is the prolapse of the upper rectum and sigmoid colon into the rectal ampulla (**Figure 69-1A**). It is also known as a hidden or occult prolapse. This type of prolapse does not emerge through the anus. Mucosal prolapse is more common in children. It results from the loose attachment of the mucosa to the submucosal layers and an associated weakness of the anal sphincter. A mucosal prolapse is diagnosed by the presence of radial folds and the absence of muscular wall.[3]

If the condition progresses, it leads to the protrusion of part or all layers of the rectum through the anal orifice. If only the mucosa is prolapsed, it is classified as an incomplete prolapse (**Figures 69-1B & C**). Synonyms include mucosal prolapse and partial prolapse. A complete rectal prolapse occurs when all bowel layers, including the muscular wall, are involved (**Figures 69-1D & E**). This condition is also known as a procidentia. The complete rectal prolapse is more common in the elderly. It results from generalized weakening of the pelvic floor and anal sphincter muscles. A complete rectal prolapse is characterized by the presence of concentric folds. A double thickness muscular wall will be felt upon palpation.[4]

Numerous risk factors are associated with a rectal prolapse.[4–11] These include malnutrition, chronic constipation, excessive straining, and diarrheal disorders such as amoebiasis, giardiasis, and other parasitic infections. Rectal prolapse in children is often idiopathic. However, there is an association with paraplegia, meningomyelocele,

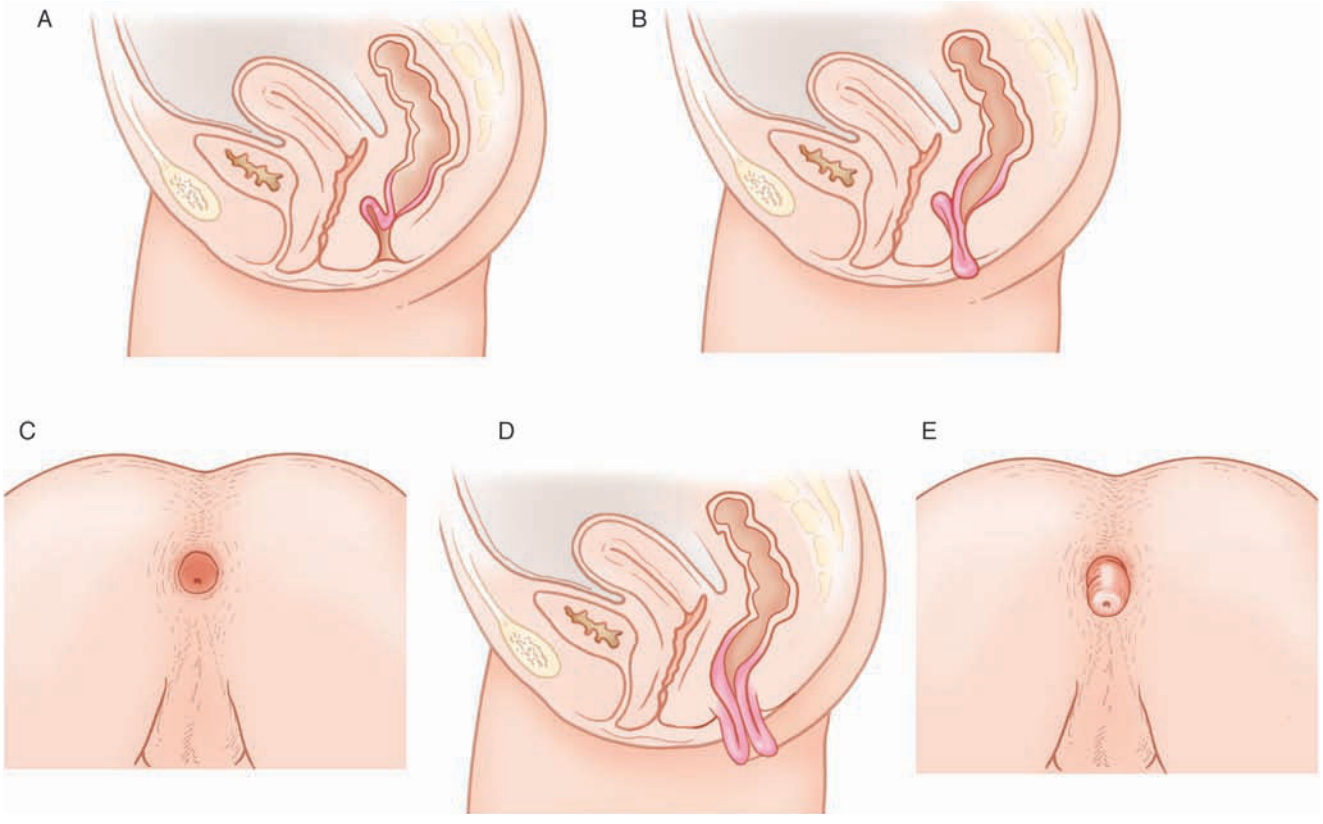

FIGURE 69-1. Types of rectal prolapse. **A.** Midsagittal view of the internal, hidden, or occult prolapse. **B.** Midsagittal view of the incomplete, mucosal, or partial prolapse. **C.** Posterior view of the incomplete, mucosal, or partial prolapse. **D.** Midsagittal view of the complete prolapse or procidentia. **E.** Posterior view of the complete prolapse or procidentia.

and pinworms. Anatomic variations such as a vertical course of the rectum, flat sacrum and coccyx, and lack of levator ani support can also result in a rectal prolapse. Children placed on adult toilet seats for prolonged periods of time may develop a rectal prolapse. One of the most serious risk factors for a rectal prolapse in children is cystic fibrosis.[6] Patients with cystic fibrosis have an 18% incidence of rectal prolapse. Children with no apparent cause for a rectal prolapse should be considered for a sweat chloride test. In the elderly, rectal prolapse is associated with collagen vascular diseases, malignancy, pelvic floor weakness, mental retardation, organic brain syndrome, stroke, chronic psychiatric conditions, and chronic neurologic conditions (e.g., tabes dorsalis, cauda equina, and multiple sclerosis).[5,11] It is important to note that patients with rectal prolapse often present with no apparent causes. The physician should maintain a high index of suspicion for the risk factors mentioned above.

The diagnosis can be difficult in the early stages when the prolapse remains in the upper canal (i.e., internal or hidden prolapse). The patient may complain of anorectal pain, back pain, discomfort during defecation, difficulty initiating a bowel movement, feeling of incomplete evacuation, tenesmus, pelvic fullness or pain, bloody discharge, or mucoid discharge. At this stage, asking the patient to strain may provoke the prolapse.

The diagnosis becomes easier in a partial or complete prolapse because it protrudes through the anus (**Figures 69-1C & E**). These patients may complain of an anal mass when they sit, stand, or walk.[1,5] It is usually the parent who notes the anal mass during defecation in the pediatric patient. The Emergency Physician should consider the mass described by the parents to be a rectal prolapse if the physical examination is negative.[2] Spontaneous reduction will often occur in this age group. It might be noted as an incidental finding on physical examination.

The differential diagnosis of a rectal prolapse includes anal warts, hemorrhoids, intussusception, prolapsed rectal polyp, or a prolapsed rectal tumor. **Mistaking an intussusception for a rectal prolapse may result in significant morbidity and mortality. Differentiating features of an intussusception include the ability to pass the finger between the prolapsed bowel and the anal sphincter (Figure 69-2). This is in contrast to patients with a rectal prolapse in which the protruding mucosa is continuous with the perianal skin and the examiner's finger will not pass that junction (Figure 69-1D).**[1,2,7] Patients with an intussusception usually appear ill whereas those

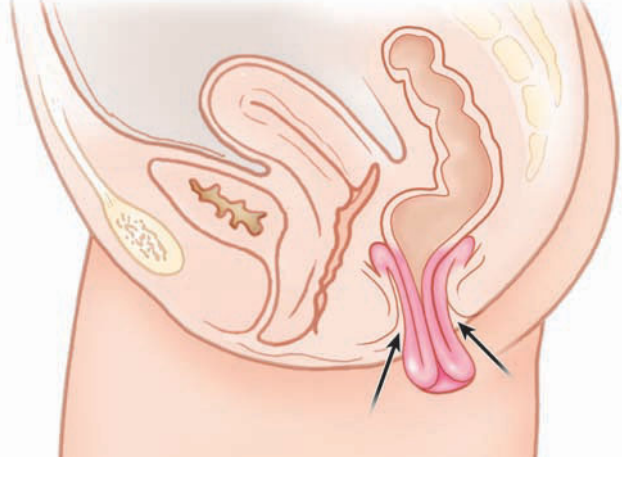

FIGURE 69-2. An intussusception. Note the junction where the finger can be passed (*arrows*).

with a rectal prolapse appear well.[2] Prolapsing hemorrhoids are more often seen in adolescents and adults, are usually purple in color, have deep grooves between the areas of prolapsing tissue, and lack radial or concentric folds. A prolapsed polyp or tumor is plum-colored, does not involve the entire anal circumference, is movable, and is usually palpable as a small growth on a stalk.[2,8]

INDICATIONS

Reduction should be attempted on all patients with a visible rectal prolapse as soon as possible to avoid vascular compromise of the bowel. It is easier to reduce before edema occurs from prolonged prolapse. Early reduction may avoid complications and stretch damage to the pelvic floor ligaments, the pelvic floor muscles, and the anal sphincter muscles.

CONTRAINDICATIONS

There are few absolute contraindications to the reduction of a rectal prolapse. Gangrene, necrosis, or ulceration of the mucosa are signs of vascular compromise or ischemia and require an emergent consultation by a General Surgeon or Colorectal Surgeon. **Do not reduce ischemic tissue as it may precipitate peritonitis or cause a perforation of the rectum. If the Surgeon's arrival is delayed, prompt gentle reduction should be attempted only after discussions with the Surgeon. Do not reduce an intussusception.** Consult a Surgeon for further evaluation and management of an intussusception.

EQUIPMENT

- Gloves
- Water-soluble lubricant
- 4 × 4 gauze squares
- 2 in. wide adhesive tape
- Benzoin spray or swabs
- Sedatives as necessary

PATIENT PREPARATION

Explain the reduction procedure to the patient and/or their representative. Reduction is most likely successful in a relaxed and nonstraining patient. Sedation may sometimes be required in adults. Sedation is more often needed in pediatric patients. Children tend to be more anxious, crying, fighting, or straining; all of which will increase the intraabdominal pressure and make reduction more difficult. The sedation may be administered intramuscularly, intravenously, orally, or subcutaneously.

Position the patient.[8,9] Place the child in the prone knee-chest position on the parent's lap or on the examination table (**Figure 69-3**). Place the adult patient in the prone position on an examination table. Large buttocks or tense buttocks may interfere with the reduction of a prolapsed rectum. In these cases, apply benzoin to the buttocks and allow it to dry. Tape the buttocks open for better access (**Figure 69-4**). Alternatively, in both age groups, the patient can be placed in the lateral decubitus position.

TECHNIQUE

Position the patient. Liberally apply water-soluble lubricant onto the prolapsed rectum. Apply gauze squares onto the prolapsed tissue at the 3 o'clock and 9 o'clock positions (**Figure 69-5**). The bowel wall is quite slippery after lubrication and the gauze will improve the grip on the mucosa. Place both thumbs near the bowel lumen with the hands stabilized on the buttocks (**Figure 69-5A**). Apply steady, gentle

FIGURE 69-3. The prone knee-chest position for children.

thumb pressure to gently roll the prolapsed rectum back through the anus. Alternatively, the index and the middle fingers can be used to reduce the prolapsed rectum (**Figure 69-5B**). **Regardless of the method used, constant and steady pressure must be applied to the prolapse.** The reduction often requires patience as it may take up to 15 minutes to reduce a prolapsed rectum.

The rectum will become edematous, and swelling will be noted, if the rectal mucosa has been prolapsed for a prolonged period of time. Wrap a gauze square around the prolapsed rectum and apply gentle manual compression for 3 to 5 minutes before attempting the reduction. If the first effort is unsuccessful without sedation, a second attempt at reduction after administering sedation is appropriate. If the prolapse rectum will not reduce (i.e., incarcerated), consult a General Surgeon or Colorectal Surgeon for reduction under general anesthesia and possible surgical repair.

ALTERNATIVE TECHNIQUES

A novel method to help reduce a prolapsed rectum uses simple table sugar.[12] The longer the rectum is prolapsed, it becomes more edematous and the more difficult to reduce. Apply a liberal amount of sugar onto the prolapsed rectum and cover it with several layers of gauze. Allow the patient to relax for 15 to 30 minutes. The hyperosmotic sugar draws fluid out from the edematous prolapsed rectum. Gently wipe off the sugar with saline or water moistened gauze. Attempt manual reduction as described above.

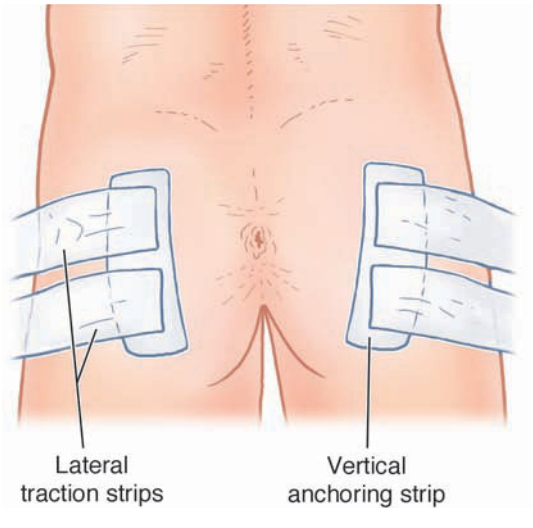

FIGURE 69-4. Taping the buttocks open in the prone patient allows for unobstructed access. The lateral traction strips are taped to the gurney or examination table.

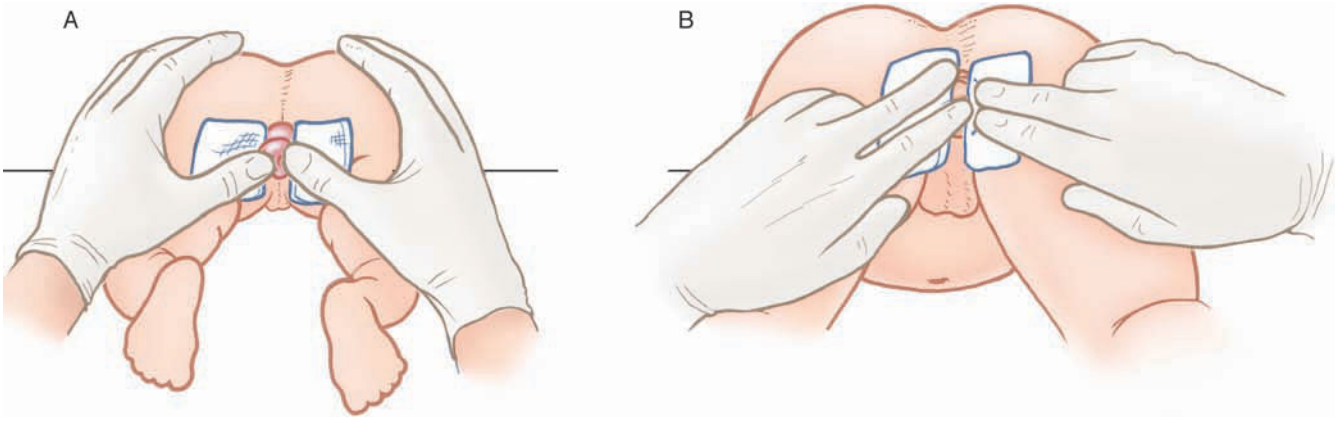

FIGURE 69-5. Rectal prolapse reduction techniques. **A.** Thumb method. **B.** Finger method.

ASSESSMENT

Perform a digital rectal examination to ensure that the reduction is complete.[8] If not, apply pressure with the examination finger to completely reduce the prolapse.

AFTERCARE

The application of a bulky pressure dressing will prevent an acute recurrence of the prolapse. Apply petrolatum gauze over the anus. Apply several gauze squares over the petrolatum gauze and into the gluteal cleft. Tape the buttocks together. **The patient and the family must be informed that reduction might be temporary and the prolapse could recur.** Training cooperative parents to reduce the prolapse is warranted in cases of recurrent rectal prolapse in the pediatric age group. Be sure to send them home with gauze squares, gloves, and lubricant.

The underlying cause of the rectal prolapse should be treated. A prophylactic regimen of laxatives and stool softeners should be started if the patient is constipated. Instruct the patient on proper eating habits including fruits, vegetables, and roughage. In cases of diarrhea, treatment should target the underlying causes. Seating children on a child's potty-chair or on an adult toilet seat with a small hole may prevent future episodes of rectal prolapse. Discourage excessive squatting and straining.[3]

All patients who have undergone successful reduction should be referred to a Colorectal Surgeon for further evaluation. Children should be followed up to rule out serious etiologies such as cystic fibrosis. As the child grows, the supporting tissue around the rectum develops. Therefore, rectal prolapse in this age group is usually self-limited and surgery is rarely required. Adults should be referred for proctosigmoidoscopy to rule out a tumor. Conservative management in the elderly is rarely successful and most patients eventually require surgical repair. Early referral can avoid complications and stretch damage to the pelvic floor ligaments, pelvic floor muscles, and the anal sphincter muscles.

COMPLICATIONS

The complications of the procedure are often minimal. The reduction itself may lead to minimal mucosal bleeding that is self-limited. The patients may experience a slight discomfort in the anus for up to 24 hours after the reduction. This can be managed with oral acetaminophen or nonsteroidal anti-inflammatory drugs.

The inability to reduce a rectal prolapse is an indication for surgical consultation in the Emergency Department. An incarcerated rectal prolapse can lead to vascular compromise. Signs of vascular compromise include mucosal gangrene, necrosis, and ulceration. These patients require admission to the hospital with an emergent surgical consultation, even if the reduction is felt to be successful, due to the risk of reducing ischemic bowel that could perforate. Very rarely, the rupture of an incarcerated rectal prolapse with small bowel herniation through the tear has been reported during attempted reduction.[10] Fecal and urinary incontinence may also occur as a result of a long-standing prolapse. This is due to the entrapment and stretching of the pudendal or perineal nerve resulting in neurovascular dysfunction and not a complication of the reduction procedure.

SUMMARY

Rectal prolapse is an uncommon condition affecting the very young and the elderly. Reduction can usually be performed in the Emergency Department. It is important to differentiate a prolapsed rectum from an intussusception and from external hemorrhoids. The reduction procedure is quick and simple. The application of constant, firm, and gentle pressure to the rectum in a relaxed and nonstraining patient will reduce most rectal prolapses. All patients with a prolapsed rectum should be referred for further evaluation to rule out underlying pathologic causes for the prolapse.

70 Anoscopy

Charles Orsay and Eric F. Reichman

INTRODUCTION

Examination of the anal canal is important to evaluate several common patient complaints relating to the anus including itching, pain, and bleeding. While it is possible to examine parts of this area with flexible instruments or a rigid rectosigmoidoscope, the only method that will give a consistent clear view of the anal canal is anoscopy.[1] To properly perform this examination, it is necessary to thoroughly understand the anatomy, be aware of the possible causes of the symptoms you are evaluating, use the appropriate equipment, and position the patient correctly.

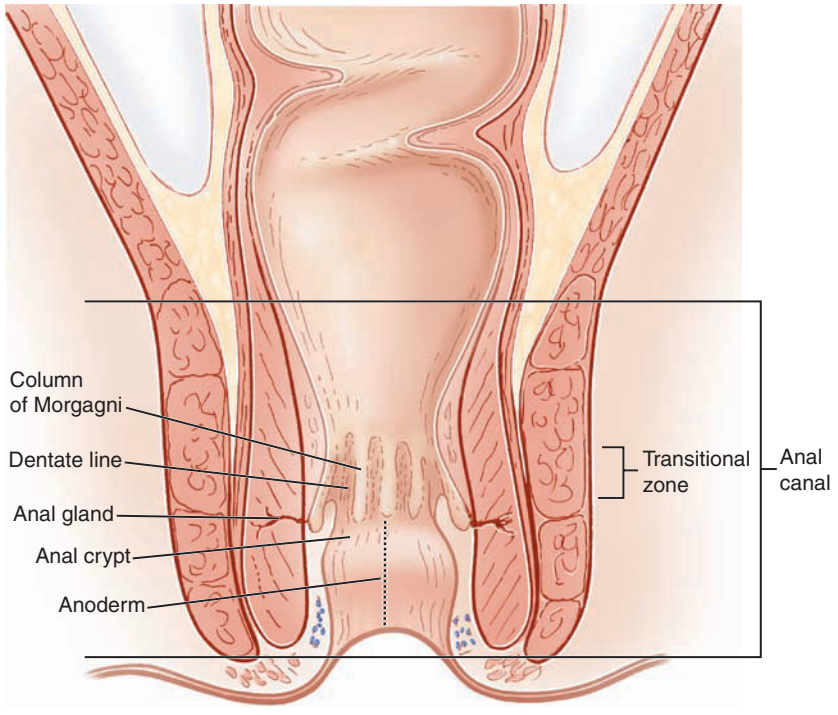

FIGURE 70-1. The topical anatomy of the anal canal.

ANATOMY AND PATHOPHYSIOLOGY

It is necessary to understand the anatomy of the anal canal in order to evaluate the patient's signs and symptoms properly. The anatomy can be divided into topical anatomy and major supporting structures.[2] The topical anatomy is depicted in **Figure 70-1**.

Perineal skin covers the perineum, is fully innervated, and includes both hair follicles and apocrine glands. It can be grossly distinguished from the anoderm surrounding the anal canal by the visible hair. The anoderm is specialized squamous epithelium that lines the majority of the anal canal. It is fully innervated but does not have apocrine glands or hair follicles. This epithelium is very thin, elastic, and if destroyed by surgery or infection may relate to stricture formation during healing.

Looking into the anal canal, the anoderm can be seen to end in an irregular line called the dentate line. This is a demarcation of anoderm to transition zone mucosa. Proximal to the dentate line there is no longer cutaneous sensation. This allows minor therapeutic procedures like banding or suture ligation to be done without an anesthetic agent. It is also the reason that internal hemorrhoids do not routinely cause pain. The transition zone continues proximally for a variable length of 6 to 12 mm before it becomes the rectal mucosa. The junction of the transitional zone with the rectal mucosa is not visible to the naked eye. The rectal mucosa decreases in diameter in the area of the transitional zone. The mucosa appears to be bunched together in columns called the Columns of Morgagni at the level of the dentate line. Crypts are formed between the columns as the transitional zone becomes the dentate line. Under the anoderm in the crypts are multiple anal glands. Blockage of the anal glands by foreign material leads to infection. Blockage or primary infection of the glands causes the majority of abscesses that arise around the anus. The crypts also are areas to look for foreign bodies such as fish or chicken bones.

External hemorrhoids are located in the left-lateral, right-posterior, and right-anterior portions of the distal anal canal and are covered with anoderm. Their normal position is outside the anal canal and they can be examined by gently spreading the buttocks. The internal hemorrhoids also are located at the left-lateral, right-posterior, and right-anterior positions. They are normally located in the distal rectum and are covered with transitional epithelium and rectal mucosa. They can best be examined with an anoscope if they are not prolapsed. It is possible to see them with a retroflexed sigmoidoscope or colonoscope, but the increased air pressure tends to flatten them out giving a false impression as to their size.

The anoscope is used to examine the closed portion of the anal canal. It dilates the anal sphincter and allows one to examine the underlying canal through an opening cut out from the side of the anoscope called a fenestration. It is important to understand the anatomy and functions of the anal sphincter musculature to properly perform this examination (**Figure 70-2**). Immediately below the anoderm is the internal anal sphincter muscle. It is circumferential and consists of a thickening and rounding of the continuation of circular smooth muscle from the rectum. This muscle is not under conscious control. The first response of the internal anal sphincter muscle to a rectal examination or anoscopy is contraction. It is necessary to pause and use slow gentle dilatation to prevent patient discomfort and complete the examination. The axis of the anal canal will normally follow an imaginary line drawn from the anus to the umbilicus. Surrounding the internal anal sphincter muscle is the external anal sphincter muscle. This is comprised of three external sphincters of striated muscle that are more loop-like than circumferential. Deep to these muscles and at the top of the anal canal is the puborectalis muscle. This forms a sling, pulling the anus anterior. It is connected to both the anal sphincters and the levator ani group of muscles. The puborectalis muscle can be felt as funnel-shaped during the digital rectal examination.

INDICATIONS

Anoscopy is indicated for the evaluation of most anal symptoms.[1–6] There are numerous common complaints and conditions where an anoscope, in conjunction with visualization and a digital rectal examination, would be used for evaluation or therapy.[3–5] Anoscopy can be used diagnostically to evaluate rectal bleeding, anal pain, pain with defecation, perirectal infections, fistulas, foreign bodies,

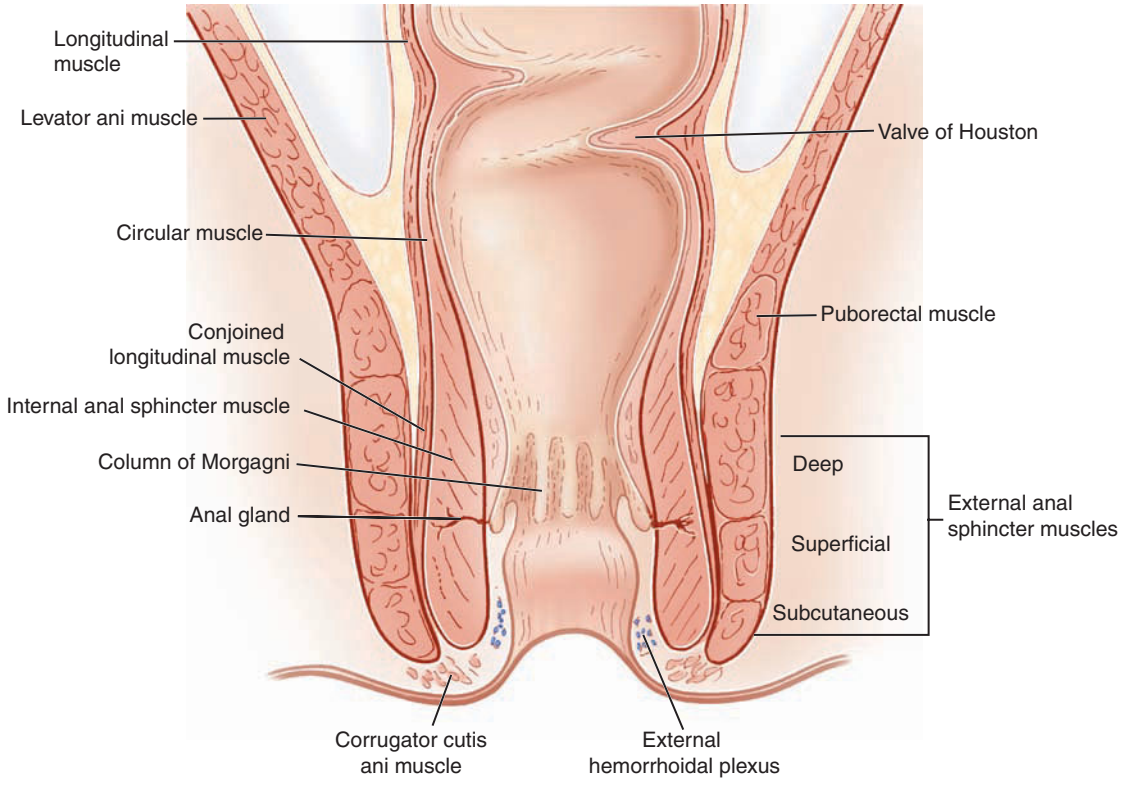

FIGURE 70-2. The major supporting structures of the anal canal.

internal hemorrhoids, anal masses, and abnormal digital rectal examinations. Anoscopy can be used therapeutically to open the anus and allow the application of medications, procedures to be performed, or for observation in the management of anal fissures, intraanal condylomata, and hemorrhoids.

CONTRAINDICATIONS

Most contraindications to anoscopy are relative. The amount of discomfort a patient will undergo relates to their tolerance. Minor discomfort associated with topical skin excoriations can be treated with 2% lidocaine jelly used as a lubricant and the examination can then continue. Moderate pain can be managed with the application of procedural sedation. Severe pain associated with anal fissures or anal abscesses is best managed in the Operating Room under general anesthesia.

Strictures can occur from postsurgical changes, inflammatory bowel disease, chronic diarrhea, and other disease processes. Anoscopy should not be performed if the patient has anal strictures, a partially imperforate anus, or a completely imperforate anus. The physician should determine if the anoscope will pass through the anus during the visual examination and the digital rectal examination. **Never insert the anoscope if resistance is encountered. The anoscope should not be used to dilate the anus.**

Anoscopy is contraindicated if any recent surgical procedure has been performed on the anus. The possible exception is for that of the physician who performed the surgical procedure.

EQUIPMENT

- Water-soluble lubricant
- Lidocaine jelly, can be used as lubricant for patients with pain
- Anoscope or Vernon-David rectal speculum
- Drapes
- Examination table, preferably a proctoscopy table
- Nonsterile examination gloves
- 4 × 4 gauze squares
- Large cotton-tipped applicators
- 4-0 chromic gut suture
- Suction, optional
- Bright directional light source
- Tincture of benzoin
- 2 in. adhesive tape

There are many different types of anoscopes available. The type of instrument chosen is largely the preference of the examining physician. The Vernon-David type anoscope is often preferred as it has a wide fenestration and a diameter that is not too large for most patients while allowing the best view. The Ives anoscope may be used if a larger diameter instrument is required. Some of the metal reusable and plastic disposable anoscopes allow for the attachment of a fiberoptic light source. Unfortunately, many of these anoscopes do not allow the same view as a Vernon-David anoscope. **Some physicians use a glass test tube as a substitute for an anoscope. This is to be discouraged as the test tube can break and cause serious complications.**

The anoscope is a two-piece device (**Figure 70-3**). It ranges from 7 to 25 cm in length. It can be manufactured from clear plastic, opaque plastic, or metal. The anoscope may have a handle that allows the operator to control its movements. The proximal end is funnel-like and tapers into the cylindrical shaft that is approximately 2.5 cm in diameter. The distal end of the anoscope is tapered on one side and known as the fenestration. The fenestration allows the mucosa to be viewed within the anoscope. It is also where procedures are

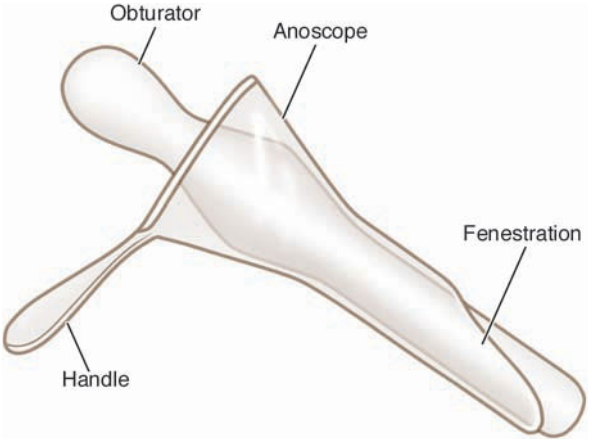

FIGURE 70-3. An example of an anoscope.

performed through the anoscope. Some anoscopes have a site proximally to attach a light source. The obturator is smooth tipped, fits within the anoscope, and occludes the anoscope. Its rounded, distal end protrudes from the anoscope. The obturator is used each time the anoscope is inserted to prevent trauma to the anal mucosa. It is removed after the anoscope is inserted to allow viewing through the anoscope.

PATIENT PREPARATION

The area being examined is within the anal canal and requires no special preparation to view correctly. The patient should be given an opportunity to voluntarily evacuate their bowels prior to the examination. It is necessary to have the patient remove their clothes from the waist down and provide protective barriers to protect the patient, the patient's clothing, and the surrounding area from spills. It is usually wise to avoid enema preparations, as liquid stool is much more difficult to contain than solid stool.

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. Explain to the patient what to expect. Discuss the order of examination, the importance of relaxing, the reason for multiple insertions and withdrawals of the anoscope, and what you are looking for or expect to find.

Anoscopy can be performed with the patient in one of many positions. The position that allows the best observation in most patients is the knee-chest or prone position (**Figure 70-4**). This allows the buttocks to be to either side and places the anus at the proper angle.

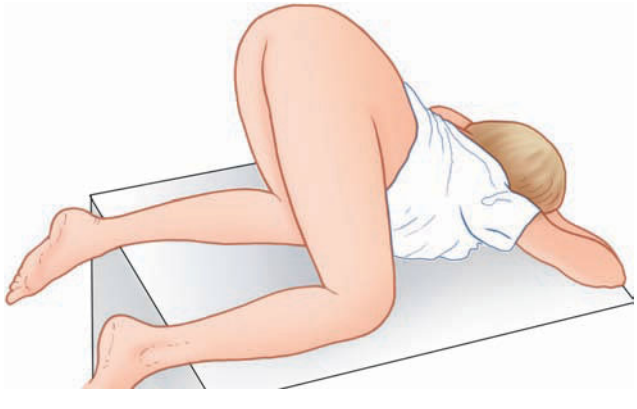

FIGURE 70-4. The knee-chest position.

Examination of the anus in this position is easiest on a proctoscopy table, but can also be performed on an examination table. The lateral decubitus position with the knees drawn up and the buttocks protruding partly off the table is acceptable for limited diagnostic examinations. Large buttocks may prevent the examination. Apply tincture of benzoin to the buttocks and allow it to dry. Apply 2 in. adhesive tape to the buttocks and tape them to the examination table to spread the buttocks apart (**Figure 68-3**). Place a Mayo stand or bedside examination table next to the patient's buttocks.

Carefully inspect the entire perineum and anal verge. Many types of pathology such as fissures, fistulas, hemorrhoids, condylomata, and dermatologic conditions can be seen at this time. **A digital rectal examination with a well-lubricated gloved finger prior to anoscopy is mandatory.** The digital rectal examination has many advantages. It allows one to find pathology that is better palpated than viewed. It gives the examiner the size and angle of the anal canal. It will allow the examiner to identify if the patient has tenderness that would preclude anoscopy. Any strictures will be identified, allowing the examiner to prevent the anoscope from advancing through these strictures and lacerating the tissues. It may identify pathology, so that the examiner can focus the anoscopy in a specific area. It prelubricates the anal canal, making insertion of the anoscope easier. Lidocaine jelly can be used as a lubricant and as an anesthetic if the patient has pain from excoriation. The use of intravenous analgesics, intravenous sedatives, procedural sedation, or general anesthesia may be occasionally required if the patient has significant pain.

TECHNIQUE

The technique of anoscopy is rather simple.[6] Look closely at the anoscope and be sure it is intact and correctly assembled. Liberally lubricate the obturator and anoscope. Ensure that the obturator is easily removed and replaced from within the anoscope. Grasp the anoscope with the dominant hand, with the obturator secured in place by the thumb of that hand (**Figure 70-5A**).

Use the nondominant hand to spread the anus (**Figure 70-5A**). Place the obturator at the center of the anus. Slowly insert the anoscope, giving time for the internal anal sphincter muscle to relax. Direct the tip of the obturator toward the patient's umbilicus (**Figure 70-5A**). Insert the anoscope to its fullest depth to start the examination with the area of fenestration pointed toward the area you wish to view first (**Figures 70-5B & C**). Slowly remove the obturator and place it on a Mayo stand or a bedside table where it can easily be retrieved. Adjust the directional light for the best illumination.

The usual starting place for the examination is the posterior midline (**Figures 70-5B & C**). Slowly withdraw the anoscope under direct observation to evaluate the entire depth of the anal canal exposed by the fenestration. Remove any fecal material with a cotton-tipped applicator. Note the appearance of the dentate line, the mucosa, and the anoderm. Note the presence and location of any blood, hemorrhoids, masses, mucus, purulence, or other abnormalities. If the anoscope does not fully dilate the columns of mucosa, a cotton-tipped applicator can be used to gently move the mucosa to view between the columns. Continue to withdraw the anoscope as the mucosa is viewed.

Replace the obturator when the anoscope is fully removed from the patient. Rotate the anoscope 30° to 40° and reinsert it into the anal canal. It often takes four or five repeated insertions to evaluate the entire circumference of the anal canal. Some physicians prefer to replace the obturator and rotate the anoscope while it is still within the anal canal. This method is discouraged as it may pinch the tissue of the anus between the obturator and the viewing tube and does not allow the examiner to see the entire depth of the anal canal.

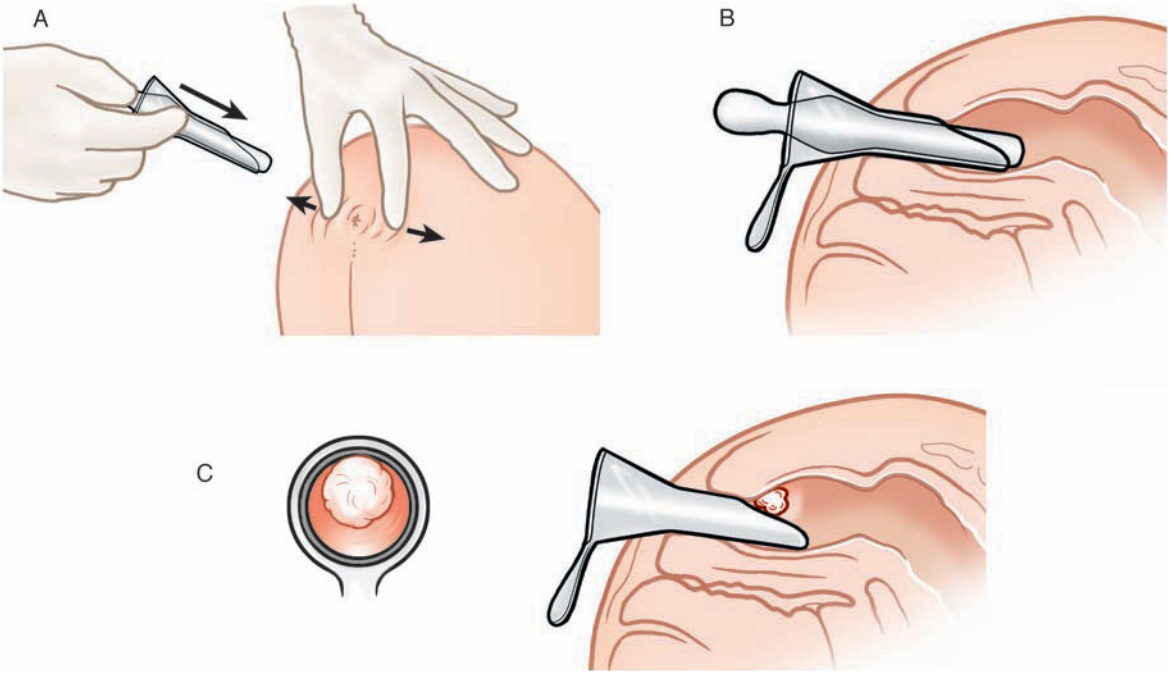

FIGURE 70-5. Placement of the anoscope. **A.** The nondominant hand is used to spread the anus. The anoscope is inserted at an angle and aimed toward the umbilicus. Note that the dominant thumb is used to secure the obturator within the anoscope. The anoscope is completely inserted with the fenestration pointed toward the posterior midline (**B**) or the area of interest (**C**).

It is helpful to ask the patient to bear down when examining the left-lateral, right-posterior, and right-anterior sections of the anal canal when evaluating the internal hemorrhoids. It is often possible to reproduce the prolapsing of internal hemorrhoids to evaluate the grade of the hemorrhoids. Bearing down is particularly important if bleeding is the symptom. It is possible to identify the area of bleeding.

ANOSCOPY IN CHILDREN

Anoscopy may be performed in children for the same indications as an adult. An anoscope of 8 to 10 cm in length and 1 cm in diameter is appropriate for a neonate and young infant. An anoscope of over 12 cm in length and 1.5 cm in diameter is appropriate for an older infant and child. An adult anoscope is appropriate for an older child and adolescent. Position the young child supine with their buttocks at the edge of the examination table. Have an assistant grasp, abduct, and flex the child's thighs so they touch the abdomen without compressing the abdominal wall. The remainder of the procedure is as described above.

COMPLICATIONS

Examination of the anal canal with an anoscope should have minimal or no complications. It is possible to cause abrasions or lacerate the very thin anoderm. This is normally avoidable with adequate lubrication, the use of the obturator when inserting the anoscope, and gentle technique. Minimal bleeding from mucosal irritation is common and self-limited. Dislodgement of a clot may result in hemorrhoidal bleeding that can be controlled with direct pressure, packing the anal canal with gauze squares, or a 4-0 chromic gut figure-of-eight suture. The most common complication is pain. This is avoidable by allowing enough time for the anus to relax while gently inserting the anoscope. The presence of an anal fissure may preclude the examination. The use of a topical anesthetic will usually allow the examination to proceed.

SUMMARY

Anoscopy is a commonly performed procedure in the Emergency Department. The anal canal is a cylindrical structure surrounded by sensitive anoderm and contracting anal sphincter muscles. The best way to examine this area is with a side-viewing fenestrated anoscope. Anoscopy allows direct viewing of the anal canal to best evaluate anal and perianal complaints. Anoscopy will give the most information with minimal discomfort when properly performed. Always perform a digital rectal examination prior to anoscopy.

71 Rigid Rectosigmoidoscopy

Charles Orsay and Eric F. Reichman

INTRODUCTION

Rigid rectosigmoidoscopy has largely been replaced by the flexible sigmoidoscope for routine elective screening and diagnostic workups. The rigid rectosigmoidoscope is superior to the flexible sigmoidoscope in measuring distances accurately, examining an unprepared patient, and when trying to work within the bowel lumen, for example when removing foreign bodies. The larger lumen of the rigid rectosigmoidoscope allows for a larger biopsy of lesions where pathology is in question. The cost associated with this examination is less than that for flexible sigmoidoscopy. The rigid rectosigmoidoscope can be purchased in a disposable model that performs well. It is important for a physician who evaluates and treats problems related to the colon, rectum, and anus to be familiar with rigid rectosigmoidoscopy.

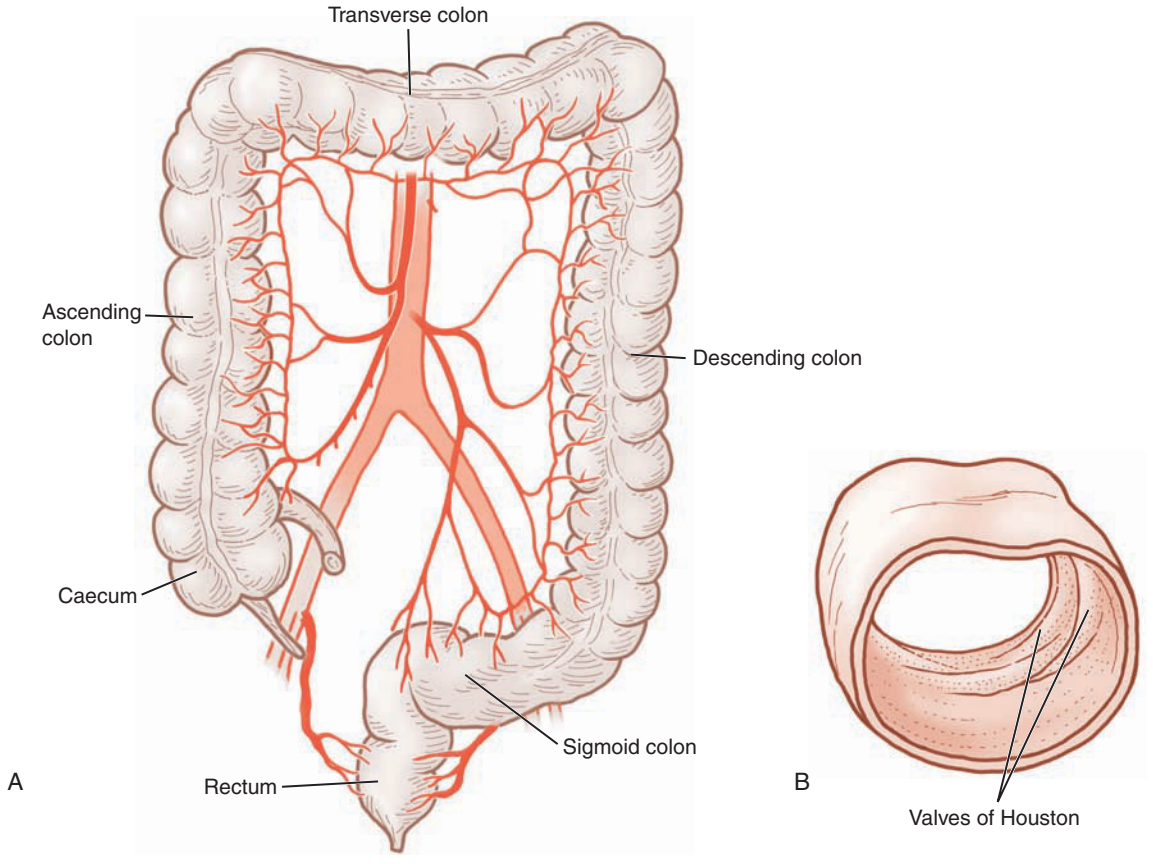

FIGURE 71-1. Anatomy of the colon. **A.** The gross anatomy. **B.** Cross-section through the colon demonstrating the valves of Houston.

ANATOMY AND PATHOPHYSIOLOGY

The significant anatomy of the anal canal that is necessary to understand and to perform rigid rectosigmoidoscopy is covered in Chapter 70 describing the anatomy for anoscopy (**Figures 70-1 & 70-2**). The gross anatomy of the colon is reviewed in **Figure 71-1A**. It is important to be aware of the large folds that impinge on the lumen of the colon called the valves of Houston (**Figure 71-1B**). These folds must be gently flattened to advance the rigid rectosigmoidoscope and clearly see the proximal side of the valve when looking for pathology. It is also necessary to understand the three-dimensional path followed by the distal colon, rectum, and anus. The direction to follow will be toward the patient's umbilicus for 3 to 5 cm initially. The anus then turns posteriorly as it becomes the rectum and follows the curve of the sacrum. The rectosigmoid junction is reached at 10 to 15 cm, at which point the lumen sharply angulates anteriorly and to the left. Because the scope is rigid and straight, it is necessary to angle the tip of the rigid rectosigmoidoscope toward the lumen of the bowel and then gently flatten the haustra or move the patient's colon so that the lumen is in a straight line.

INDICATIONS

Many of the indications for rigid rectosigmoidoscopy are the same as those for performing flexible sigmoidoscopy. The rigid scope is more useful when the bowel is not properly prepared, if a bigger biopsy is needed, or if a larger instrument needs to be passed to the last 25 cm. The following is a list of such indications.

The rigid rectosigmoidoscope may be used to evaluate the rectum and sigmoid colon in the office or the Emergency Department. Rectal bleeding can be evaluated in the unprepared patient. It is particularly helpful to determine if stool is mixed with blood when evaluating hematochezia and determining if colonoscopy is indicated. Foreign bodies in the rectum or sigmoid colon can be removed. The rigid rectosigmoidoscope will allow a much larger biopsy and grasping forceps to assist in removing foreign bodies. Traumatic injuries can be assessed. Since the rectum is seldom prepared in the evaluation of a traumatic injury and flexible instruments are unable to clear solid or thick stool, the rigid rectosigmoidoscope is superior in this instance. A sigmoid volvulus can be decompressed using the rigid rectosigmoidoscope to pass a tube to splint the volvulus. It is much easier to suction out a large volume of obstructed material in the colon and leave a large tube with the rigid rectosigmoidoscope. It can be used for surveillance of colon or rectal cancer after a subtotal colectomy. It can be used to accurately measure the distance to rectal lesions from the anus prior to surgery.

CONTRAINDICATIONS

There are no absolute contraindications to rigid rectosigmoidoscopy.[1] Relative contraindications include severe anal pain that may require general anesthesia, recent surgical anastomosis in the distal 25 cm of the colon and rectum, severe stenosis of the anus or rectum, and peritonitis. This procedure should not be performed by anyone unfamiliar with the equipment and technique as significant complications can occur.

EQUIPMENT

- Phosphate soda enemas
- Rigid rectosigmoidoscope with obturator, air insufflator, eyepiece, and light source

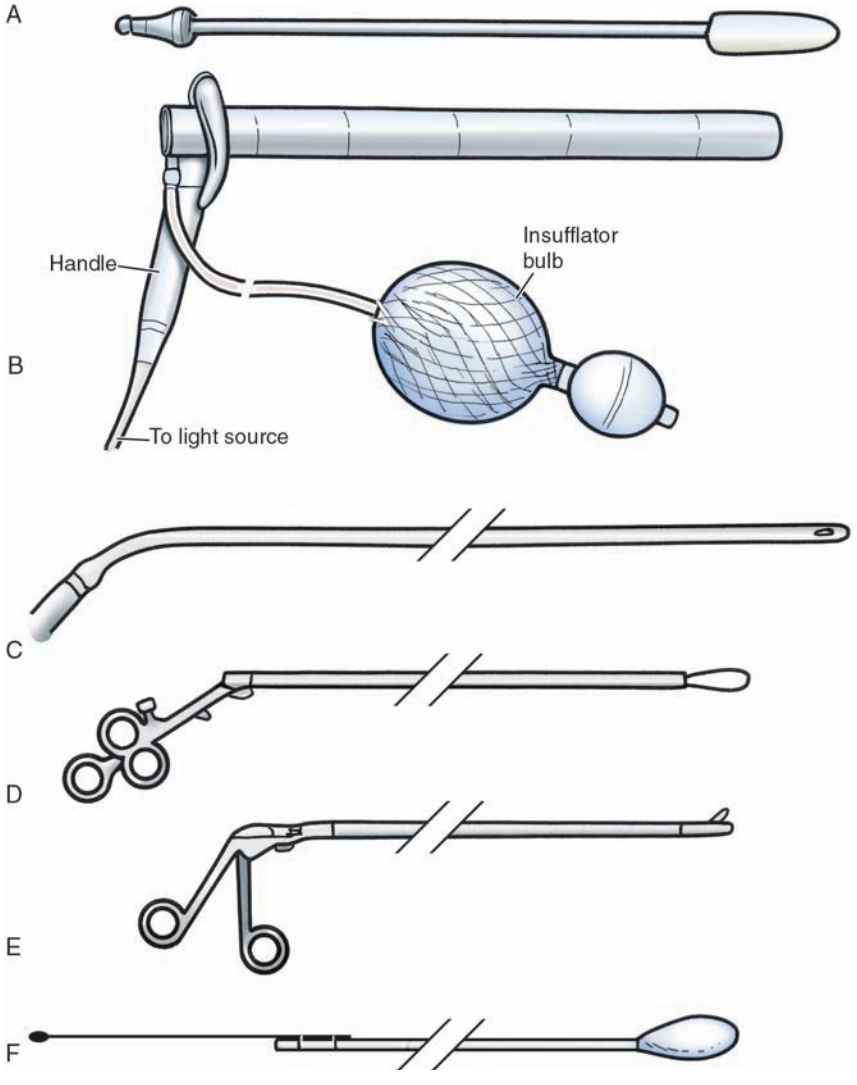

FIGURE 71-2. The instruments required to perform rigid rectosigmoidoscopy. **A.** Obturator. **B.** Rigid rectosigmoidoscope. **C.** Suction catheter. **D.** Polypectomy snare. **E.** Biopsy forceps. **F.** Cotton-tipped applicator with silver nitrate matchstick taped to the opposite side.

- Suction catheter
- Suction machine or wall suction
- Biopsy forceps
- Long cotton-tipped applicator with a silver nitrate applicator on the opposite end
- Proctoscopy table or examination table
- Protective drape with exam fenestration
- 4 × 4 gauze squares
- Water-soluble lubricant
- Exam gloves
- Impermeable gown
- Instrument stand
- Anoscope, should be available to examine the anal canal if indicated

The rigid rectosigmoidoscope and other required instruments are available in preassembled sterile trays. The tray usually contains the rigid scope, an obturator, a suction catheter, polypectomy snare, and biopsy forceps (**Figure 71-2**). These trays are available from the Operating Room, hospital central supply, or the surgical clinics. The trays may contain disposable single-use instruments or multiuse instruments depending upon the institution. The remainder of the equipment must be gathered from around the Emergency Department.

The rigid rectosigmoidoscope is a simple instrument (**Figures 71-2A & B**). The shaft is approximately 30 to 40 cm in length and has 1 cm increments marked on the outside. Attached to the proximal end are an eyepiece, a handle, and an inflation port. The eyepiece swings to open and close over the proximal shaft of the scope. The handle is used to direct and move the scope. Inside the handle is a fiberoptic light source that transmits into the shaft. The insufflator bulb and tubing attach to the inflation port. These are used to insufflate air through the scope and into the colon. The obturator fits within the shaft of the scope. The distal end of the obturator is smooth, occludes the shaft of the scope, and projects 1 to 2 cm distal to the scope.

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. It is also important to explain to the patient what to expect. Discuss the order of examination, the importance of relaxing, the reason for multiple insertions and withdrawals of the rigid rectosigmoidoscope, and what you expect to find. It is important to explain the reason for insufflating air and how this may produce discomfort. Explain that the procedure should not require procedural sedation and that the patient

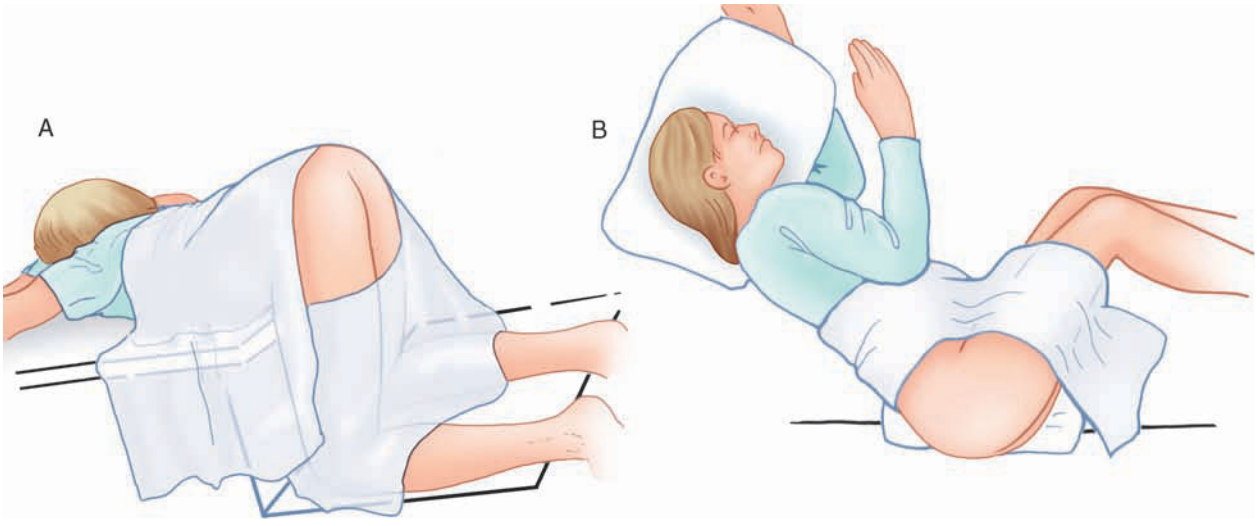

FIGURE 71-3. Patient positioning. **A.** The prone jackknife position on a proctoscopy table. **B.** The left lateral decubitus position on an examination table with the buttocks extended over the edge of the table. Note that the drape is placed so that the buttocks are completely exposed.

should inform the physician of any discomfort. Assure the patient that the complaint of pain will at least temporarily stop the examination. Perforations are unlikely with a relaxed, cooperative patient. Obtain a signed informed consent for this procedure.

While it is possible to perform a rigid rectosigmoidoscopy with this instrument on an unprepared rectum, more information about the mucosa will be obtained if the bowel has been prepared. Two 4 ounce phosphate soda enemas given at 2 and 1 hours before the examination will give an adequate preparation in most patients. The use of high-volume PEG preparations, saline, or mannitol should be reserved for colonoscopy. There is no need to clean the entire colon. The preparations used for colonoscopy are expensive, involve too much preparation, and cause patient discomfort for the extent of this examination. The judicious use of intravenous sedation may be required in some patients who are anxious.

It is important to check the equipment prior to its insertion into the patient. Open the tray and place the instruments and supplies on the Mayo stand. The eyepiece on the proximal end of the scope should open easily, close easily, and seal against the rigid rectosigmoidoscope. Open the eyepiece and insert the obturator completely within the rigid sigmoidoscope. The handle, including the light source, must be firmly attached. Turn on the light source. The light must be seen coming from the end of the scope. The bulb of the insufflator must pump air into the rigid rectosigmoidoscope and should reinflate after the bulb is released. Liberally lubricate the distal 5 cm of the rigid rectosigmoidoscope and the obturator. Reinsert the obturator into the rigid rectosigmoidoscope.

Disrobe the patient from the waist down. Place the patient in the prone jackknife position on a proctoscopy table if one is available (**Figure 71-3A**). If the patient is unable to get in this position, or only a routine examination table or stretcher is available, place the patient in the left lateral decubitus or Sims position (**Figure 71-3B**). The Emergency Physician should be prepared with an impermeable gown and one glove on the left hand and two on the right hand (if right handed). If possible, it is helpful to have someone assist with the remainder of this procedure. Place the fenestrated drape over the patient so that the buttocks are completely exposed (**Figure 71-3**). Place a Mayo stand or bedside procedure table within reach of the patient's buttocks.

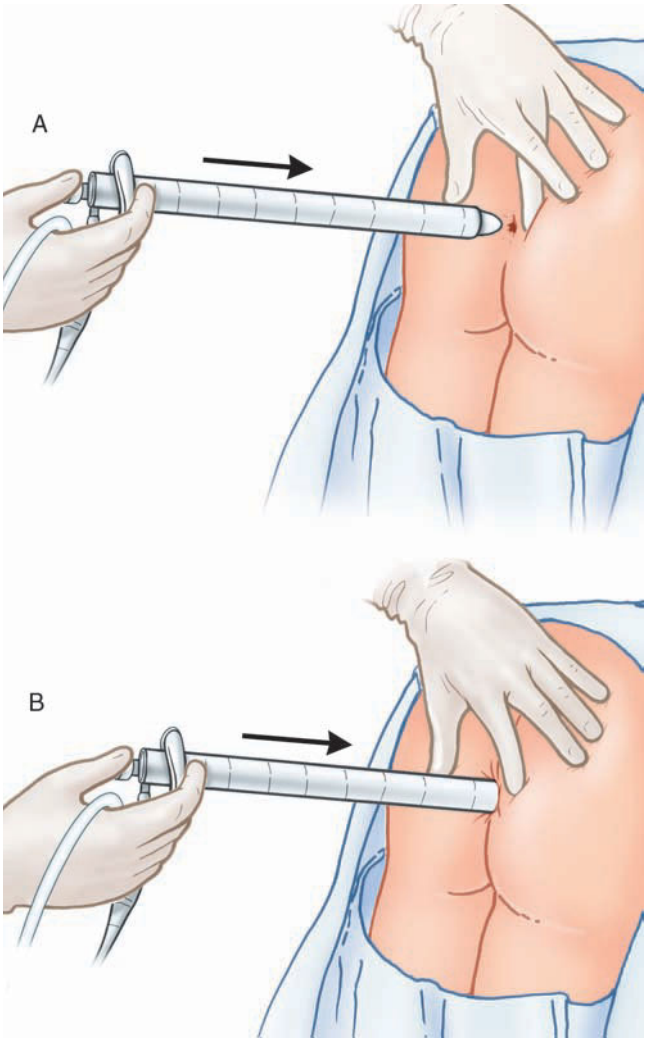

FIGURE 71-4. Insertion of the rigid rectosigmoidoscope. **A.** The left (nondominant) hand is placed on the buttocks and used to spread the buttocks. **B.** The right (dominant) hand is used to insert and advance the scope while the thumb keeps the obturator properly seated.

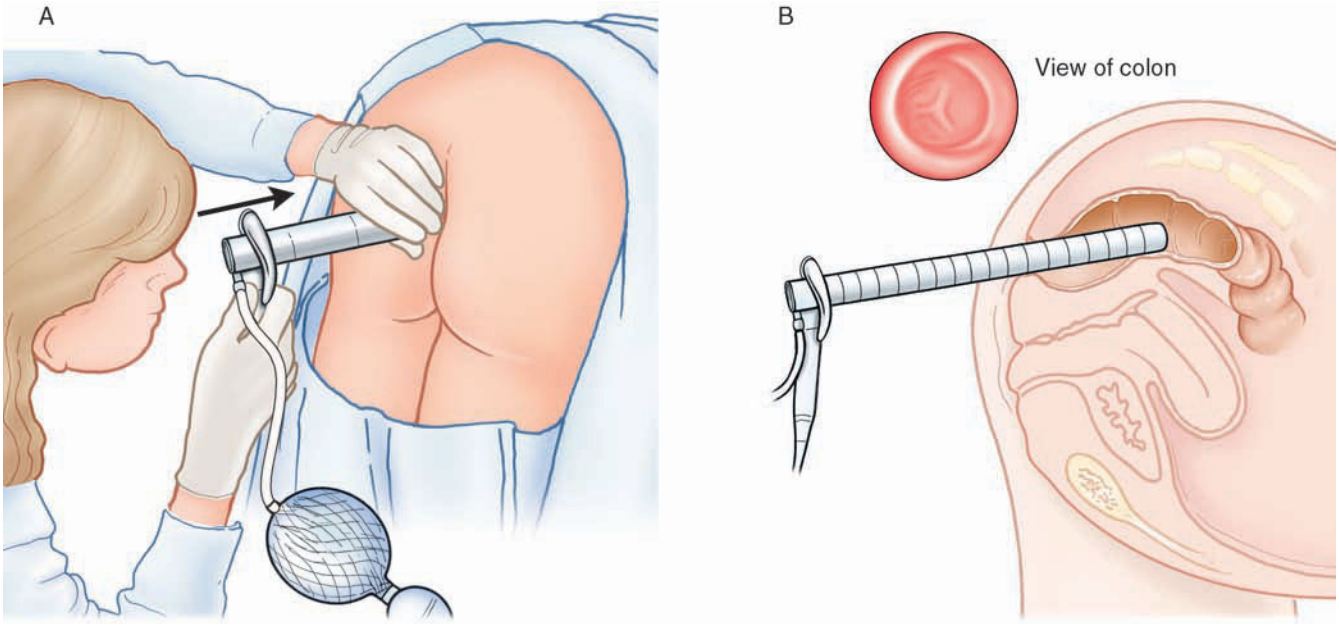

FIGURE 71-5. Advancement of the rigid rectosigmoidoscope. **A.** The nondominant hand stabilizes the scope while the dominant hand advances it under direct visualization. **B.** The rectum begins as the anal canal turns posteriorly toward the sacrum.

As in anoscopy, it is important to carefully inspect the entire perineum and anal verge prior to the examination. Many types of pathology such as fissures, fistulas, hemorrhoids, condylomata, and dermatologic conditions may be seen at this time.

Digital rectal examination prior to the procedure with a well-lubricated, gloved finger is mandatory. It gives the following advantages. It allows the examiner to find pathology that is better palpated than viewed. It gives the examiner the size and angle of the anal canal. It will allow the examiner to identify if the patient has tenderness that would preclude the examination. It may identify pathology so that the examiner can focus in a specific area. It prelubricates the anal canal, making insertion of the rigid rectosigmoidoscope easier. If the patient has pain from excoriation, 2% lidocaine jelly can be used as a lubricant and will provide some local anesthesia. This examination is usually performed with the right hand. Remove the extra glove from the dominant hand before picking up the rigid sigmoidoscope. This prevents the contaminated glove from holding the scope near the Physician's face.

TECHNIQUE

Stand to the left side of or directly behind the patient. Place the left, or nondominant, hand on the patient's buttocks (**Figure 71-4A**). Grasp the handle of the rigid rectosigmoidoscope with the right, or dominant, hand. Place the right thumb on the obturator to keep it properly seated (**Figure 71-4B**). Spread the buttocks with the left hand (**Figure 71-4**). Gently and slowly insert the rigid rectosigmoidoscope into the anus and aimed toward the patient's umbilicus. Advance it to the 5 cm mark.

Support the rigid rectosigmoidoscope at the anus with the left hand (**Figure 71-5A**). This is necessary so that if the patient moves, the instrument will move with the patient. Remove the obturator and place it on the Mayo stand. Close the eyepiece and insufflate air into the rectum.

One must control the insertion and direction of the rigid rectosigmoidoscope with the right hand while stabilizing it with the left hand (Figure 71-5A). Continue to slowly advance the rigid rectosigmoidoscope under direct viewing while simultaneously insufflating air to distend the walls of the colon (**Figure 71-5A**). The anal canal is approximately 4 to 5 cm in length (**Figure 71-6**). The rectum will be seen to turn somewhat posteriorly and follow the hollow of the sacrum (**Figure 71-5B**). Moving the right hand and the rigid rectosigmoidoscope anteriorly will direct the tip posteriorly (**Figure 71-6B**). Use the left hand as a fulcrum to help maneuver

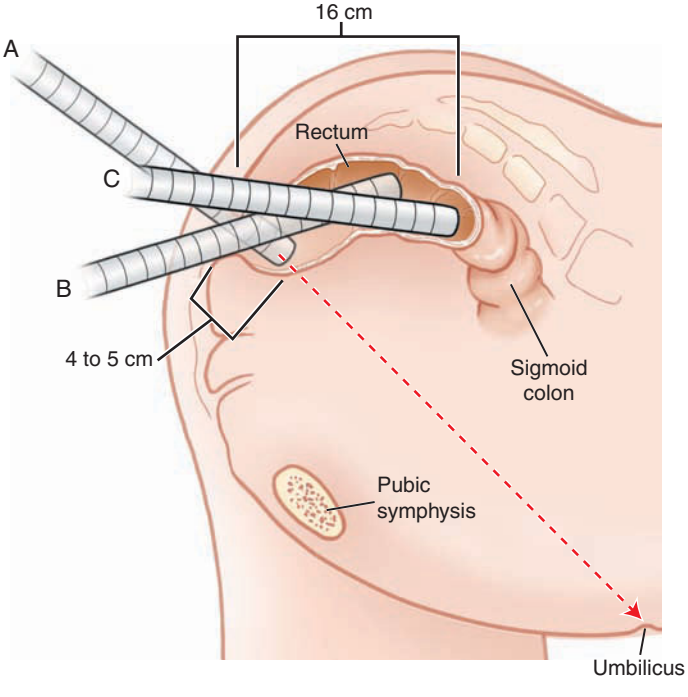

FIGURE 71-6. Insertion and advancement of the rigid rectosigmoidoscope. **A.** The scope is inserted and aimed toward the umbilicus. **B.** Moving the handle anteriorly will direct the tip of the scope posteriorly. **C.** The rectosigmoid junction is located approximately 16 cm from the anus, where the rectal lumen turns anteriorly and to the right.

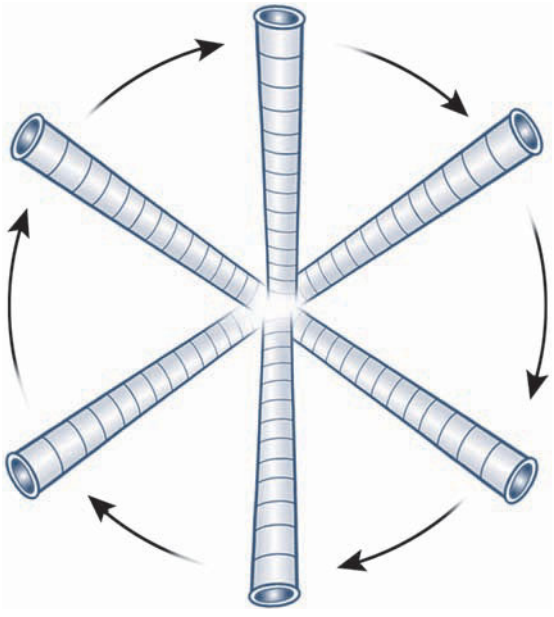

FIGURE 71-7. The rigid rectosigmoidoscope is rotated in a circular motion while simultaneously withdrawing the scope and visualizing the mucosa.

the distal tip of the rigid rectosigmoidoscope to follow the lumen of the rectum (**Figure 71-6**). The sigmoid colon can also be identified by the presence of transverse folds that are lacking in the rectum. The rectosigmoid junction is approximately 16 cm from the anus and can be seen when the lumen turns anteriorly and to the right (**Figure 71-6C**). It is necessary to use the rigid rectosigmoidoscope to gently straighten the colon while completely inserting the instrument to a depth of 25 cm. **It is important to view the bowel lumen at all times. Never advance the instrument blindly as this may cause a perforation.**

Maintain communication with the patient, inform them of what is happening, and elicit the status of their comfort. Open the eyepiece if it becomes clouded with moisture and wipe it with dry gauze so the view is kept clear. Do not keep your face near the eyepiece when opening the eyepiece. The insufflated air may forcefully expel stool and secretions. The bowel must be reinflated when the eyepiece is reclosed.

After the rigid rectosigmoidoscope is advanced to 25 cm, or as far as the patient will allow, slowly remove it with a circular motion (**Figure 71-7**). View the mucosa while removing the rigid rectosigmoidoscope in a circular motion. This flattens out the haustra and valves of Houston so that the entire mucosal surface can be viewed. Attempt to keep at least 50% of the colonic lumen in view at all times. Open the eyepiece just prior to completely removing the rigid rectosigmoidoscope to release as much of the insufflated air as possible. This will make the patient more comfortable.

The viewing window, which seals in the air, must be opened if it is necessary to biopsy or to grasp something. This will result in the collapse of the rectum and loss of view. It is important to place the tip of the rigid rectosigmoidoscope over the area in question so it will stay in the examiner's view. The obturator should be reinserted if it is necessary to reinsert or readvance the rigid rectosigmoidoscope.

ASSESSMENT

Completely and carefully inspect the colonic mucosa. Note the presence, location (i.e., anterior, posterior, left, and right), and the depth of any bleeding, diverticulum, fistulas, hemorrhoids, lesions, masses, mucosal irregularities, and/or polyps. Document any findings in the medical record.

AFTERCARE

The patient may be discharged home after the procedure if there are no complications and there is no other reason to admit them to the hospital. They may experience mild discomfort, flatus, and spotting of blood in the stool for several hours. Instruct the patient to immediately return to the Emergency Department if they develop a fever, abdominal pain, nausea, vomiting, bright red blood per rectum, or if they have any concerns. Follow-up should be arranged with a Family Practitioner, Internist, Gastroenterologist, or Surgeon depending upon the findings of the examination.

COMPLICATIONS

The primary complication of rigid rectosigmoidoscopy is perforation of the rectum or sigmoid colon. Air insufflation may cause an existing perforation, such as may be associated with diverticulitis, to burst, and is the reason one should not perform this examination if the patient has existing peritonitis. Perforation can occur with forceful insertion of the instrument without viewing the colonic lumen or if the patient moves suddenly and the scope is not supported with the left hand. Perforation may also occur with instrumentation in related procedures, such as a biopsy. Perforation should be almost nonexistent if one supports the scope well, views the colonic lumen while advancing the scope, and listens to the patient about complaints of pain.

Minor complications may occur. Trauma to the mucosa from the rigid rectosigmoidoscope or instrumentation in related procedures, such as a biopsy, can result in minor bleeding that is usually self-limited. Brisk bleeding can be controlled by the judicious use of a silver nitrate matchstick. Bacteremia may occur in up to 10% of patients. Antibiotic prophylaxis for endocarditis should be administered, if indicated, prior to the procedure. Mild abdominal discomfort and flatus can last a few hours.

SUMMARY

Rigid rectosigmoidoscopy is inexpensive, easy to perform, and useful in bowels with poor preparation or where a wider access is needed. These characteristics make the instrument useful in many indications. With proper training and understanding of the anatomy, this examination is well tolerated by the patient and will be useful to diagnose and treat many colonic and rectal problems.

72 Rectal Foreign Body Extraction

Charles Orsay and Eric F. Reichman

INTRODUCTION

Foreign bodies within the rectum are the result of an ingestion from above or are placed into the anus from below.[1] Fortunately, the majority of items ingested from above that pass the pylorus and ileocecal valve also pass the anal sphincter. The most frequent types of items found in the anus from above are undigested fish or chicken bones. Foreign bodies that are placed into the rectum from the anus are placed iatrogenically (e.g., enema tips and thermometers), inserted by the patient in an attempt to remove impacted stool, inserted by

the patient or their partner as a form of anorectal auto-eroticism, forcibly placed in the anus during a rape, or placed in the rectum to smuggle objects across a border illegally.

The items placed into the rectum from the anus seem to be limitless and represent all the shapes and sizes imaginable.[2] This makes their removal more difficult. **It is important to attempt to identify the characteristics of the foreign body in order to devise the safest way of removal.** As an example, consider the typical electric lightbulb. The glue that attaches the metal base to the glass loosens with moisture and time. Pulling off the metal base exposes a thin, sharp glass edge. The glass globe is very thin and breaks very easily. If the glass breaks, it may take a long time to remove the fragments and cause considerable damage to the surrounding rectal mucosa or the examining finger. **The idea is to remove the foreign body without causing further damage to the rectum or the anal sphincter muscle.** The more knowledge the Emergency Physician has about the foreign body and how it was inserted, the more likely it is that it will be removed safely.

ANATOMY AND PATHOPHYSIOLOGY

The significant anatomy of the anal canal is discussed in Chapter 70, describing the anatomy for anoscopy. Important anatomic considerations in removing rectal foreign bodies include the axis of the lumen of the anus. The anus is pointed toward the patient's umbilicus, while the curve of the sacrum forms a posterior arc. If the length of the foreign body is longer than the curve of the sacrum, such as a long vibrator or dildo, the sacral promontory causes the distal end of the foreign body to be directed toward the tip of the sacrum or coccyx. When the object is being removed by bringing the distal end anteriorly, the middle portion may push anteriorly (i.e., into the prostate, uterus, or bladder) and cause considerable discomfort.

The important physiologic considerations include the anal sphincter muscles, edema, and the creation of a vacuum. The anal sphincter is a complex group of muscles. The external anal sphincter muscle is made up of voluntary muscle fibers. The internal anal sphincter muscle is made of smooth muscle fibers. The reflex response to dilatation of the rectum is contraction of the external anal sphincter muscle. The normal tone of the anal sphincter comes from the internal anal sphincter, which can go into spasm with manipulation.

Therefore, it is very important to try to remove foreign bodies with slow and steady traction. Maintain constant pressure and wait for the sphincter muscle to fatigue. The technique is not too dissimilar to the methods used to relocate a shoulder. The slow and constant traction will also help with the edema that forms around rectal foreign bodies that have remained in the rectum for a prolonged period of time.

Finally, it is important to consider the formation of a vacuum, which may result from pulling a large, smooth foreign body such as a bottle or lightbulb. It is sometimes necessary to place one or more soft catheters above the foreign body so that air may get around the object as it is removed. This will prevent the formation of a vacuum and allow the foreign body to be removed. Large Foley catheters with the balloon inflated can be used for air insertion to prevent the vacuum and traction to bring the object further down into the rectum.

INDICATIONS

The indication to remove a foreign body from the rectum is the identification of a foreign body in the rectum. The majority of patients with this problem have already tried to pass the item with a bowel movement. They may also have already tried oral laxatives. It is impossible to estimate the number of rectal foreign bodies that are removed at home. It is estimated that very few objects inserted through the anus will pass spontaneously. Waiting is detrimental for the vast majority of items. Sharp foreign bodies may already have begun to perforate the rectum. Large foreign bodies will continue to cause irritation and edema, making removal more difficult with the passage of time.

CONTRAINDICATIONS

There are a few absolute contraindications to removing a rectal foreign body in the Emergency Department. However, the removal of a rectal foreign body that has not perforated is not an emergency. **Time taken to plan the removal and obtain adequate anesthesia and relaxation of the anal sphincter muscles is well spent, especially if the object is difficult to retrieve.** The patient's general condition must be taken into account. Patients with peritonitis require operative removal and exploration. The time taken to remove the object is wasted and identification of the perforation is easier in the Operating Room with the item in place. Patients with lower abdominal pain and fever may have a perforation below the peritoneum that can be confirmed with a water-soluble contrast enema. Foreign bodies that are large, irregularly shaped, or have sharp edges should be extracted in the Operating Room. In patients who have been assaulted, a complete assessment of all the patient's injuries is mandatory. It usually is better to leave the object in place to help identify all the possible associated injuries that may have occurred. The foreign body should be removed in the Operating Room if it is not palpable, not visible upon dilating the anus, or removal of the object may cause injury to the patient. Packets containing illicit drugs should be extracted with a rigid rectosigmoidoscope or in the Operating Room. Rupture of the packets can result in significant morbidity and mortality.

EQUIPMENT

- Local anesthetic solution with epinephrine (1% lidocaine or 0.5% bupivacaine)
- 25 gauge needle, 2 in. long
- 10 mL syringe
- Povidone iodine or chlorhexidine solution
- Anoscope
- Ring forceps
- Tenaculum
- Park retractor
- Hill-Ferguson retractor
- Large spoons
- Foley catheters
- Endotracheal tubes
- Endoscopic snare
- Rigid rectosigmoidoscope
- Vacuum extractor (optional)

PATIENT PREPARATION

The patient must undergo a complete history and physical examination. It is important to ascertain the overall health of the patient in case it is necessary to go to the Operating Room to extract the foreign body. **Attempt to identify patients with rectal perforations as they need to go to the Operating Room quickly.** Biplane plain radiographs with an upright are useful to determine the number, shape, and location of the foreign bodies as well as the

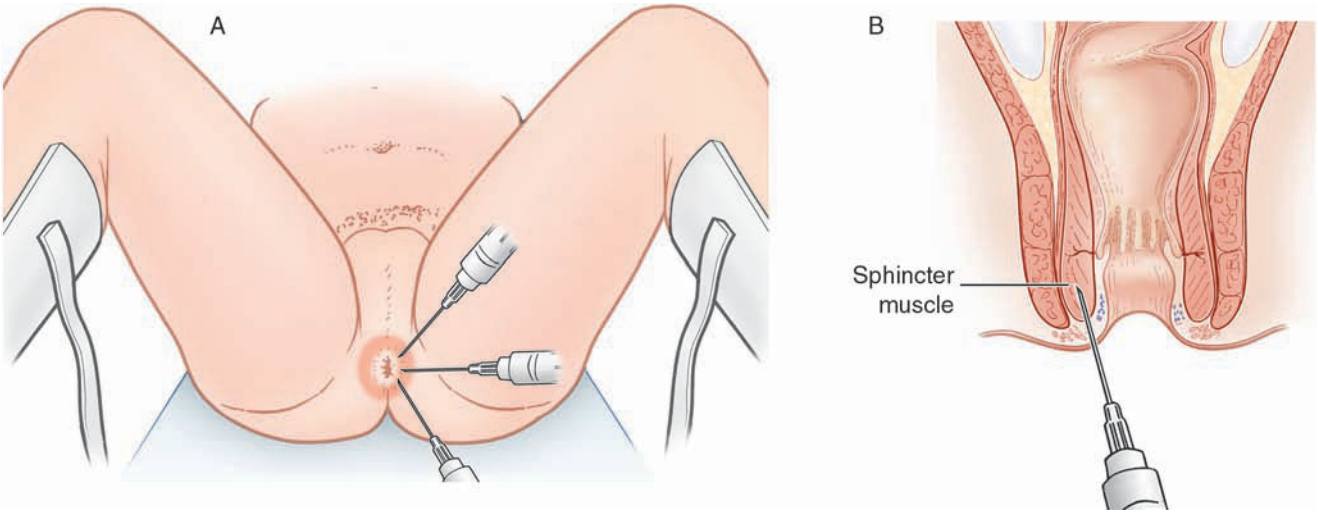

FIGURE 72-1. Anesthesia of the anal region. **A.** Local anesthetic solution is infiltrated subcutaneously and circumferentially around the anus. **B.** Injection of local anesthetic solution into the anal sphincter muscles.

presence of free air under the diaphragm. It is necessary to look at both the anteroposterior view as well as the lateral view to completely appreciate the object in three dimensions.[1] It is important to inform the patient in advance that while 90% of the objects can be removed from below, some may require general anesthesia or even an operation and a temporary colostomy. Explain the local anesthesia and the extraction procedures to the patient and/or their representative. Obtain an informed consent for the extraction of the foreign body.

Ascertain the type and number of objects in the rectum. It is possible to remove one foreign body and miss others that the Emergency Physician was not aware were present. Unfortunately, it is common to find that the patient is unsure of this part of the history; this is why plain radiographs can be so helpful. It is also important to identify the technique of insertion. Patients with objects that were inserted forcefully should undergo a trauma-oriented workup, and sexual abuse must be considered. Determine the length of time since insertion. Edema formation will be significant if the object has been present more than 24 hours. This will make it more likely that an anesthetic will be needed or that it will be necessary to use catheters to break the vacuum that forms during extraction.

The parts of the physical examination that are most helpful are the abdominal and rectal examinations. The abdominal examination should focus on the presence or absence of tenderness, peritonitis, and the palpation of a mass. Many objects are long enough to be palpated in the left lower quadrant. It may be useful to apply pressure on the lower portion of the abdomen to help remove the object. The rectal examination should include a careful external examination looking for evidence of trauma. The digital portion of the examination should roughly quantify the sphincter tone and squeeze pressure.

The remainder of the examination should consist of careful palpation of the foreign body to determine its location, texture, and mobility and to identify possible areas to grasp. Examples would include the open end of a bottle or the narrow end of a lightbulb. Determining if the object is hard, soft rubber, or plastic will help determine which tool would be best suited to grasp the object. **One exception to performing the digital rectal examination would be determining, on radiographs or by history, whether the object is sharp (such as a knife blade) or consists of broken glass. It is recommended to postpone the digital rectal examination, especially in prisoners and psychiatric patients, until a radiograph rules out a sharp foreign body.** If the examiner is not able to palpate the foreign body, a rigid rectosigmoidoscope should be used to identify and remove the object. The technique of rigid rectosigmoidoscopy is described in Chapter 71.

ANESTHESIA

The second general consideration is to have a relaxed anal sphincter. The use of intravenous or procedural sedation will relax the patient and relieve any discomfort associated with the procedure. It may be necessary to inject the anus with local anesthetic solution if the patient experiences pain or if slow steady traction will not overcome the tone of the anal sphincter.[3,4] Anesthesia of the sphincter muscles will provide for patient comfort and allow dilation of the sphincter muscles. Place the patient in the lithotomy position (**Figure 72-1A**). Wipe away any dirt, debris, and fecal material from the perianal skin and surrounding area. Apply povidone iodine or chlorhexidine solution and allow it to dry. Inject local anesthetic solution subcutaneously and circumferentially around the anus (**Figure 72-1A**). Inject 1 to 1.5 mL of local anesthetic solution into the anal sphincter muscles at the 12, 3, 6, and 9 o'clock positions (**Figure 72-1B**).

An alternative is a pudendal nerve block. Determine if the ischial spines are palpable through the rectum. Insert the needle through the skin and toward the ischial spine. Use the finger inside the rectum to palpate and guide the needle to the ischial spine. Inject 3 to 5 mL of local anesthetic solution just medial to the ischial spine. Repeat this procedure on the other side. The main disadvantage of the pudendal nerve block is that it is a blind procedure and has the potential for a needle stick. If these are not successful, it will be necessary to take the patient to the Operating Room for regional or general anesthesia.

The patient may remain in the lithotomy position for the extraction of the foreign body (**Figure 72-2A**). Other positions include the modified Lloyd Davies position (**Figure 72-2B**) and the Sims position (**Figure 72-2C**). The choice of positions is physician dependent and limited by patient comfort.

TECHNIQUES

It is important to understand that since the types of foreign bodies found in the rectum are so variable, it is impossible to give exact instructions on how to remove them. There are some general

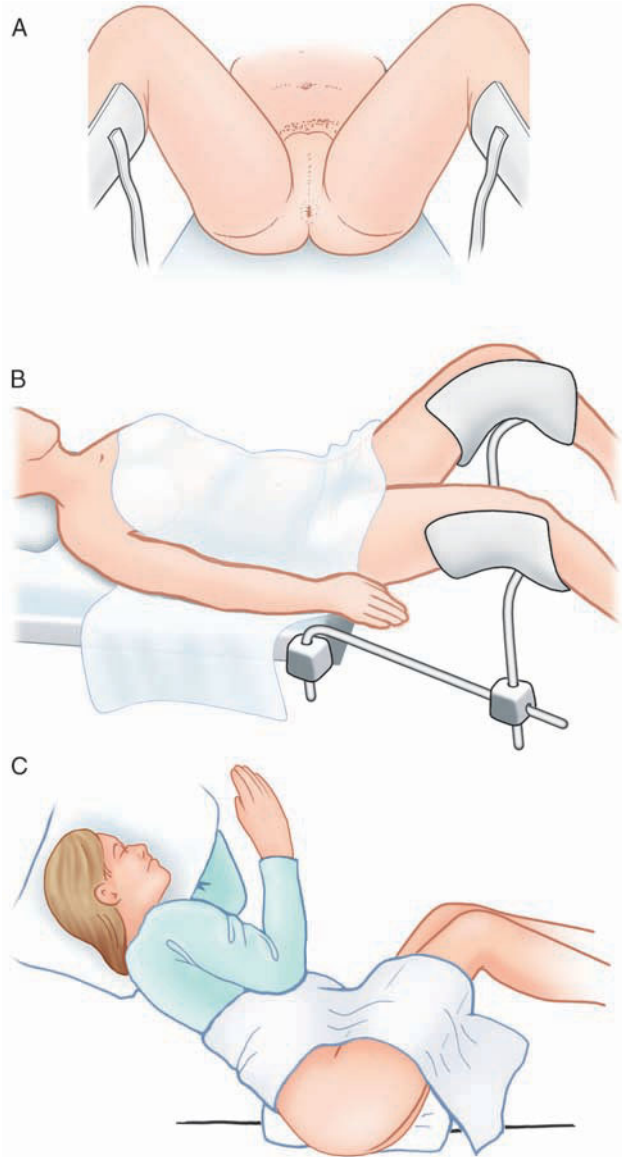

FIGURE 72-2. Patient positioning for removal of rectal foreign bodies. **A.** Lithotomy position. **B.** Modified Lloyd Davies position. **C.** Sims or lateral decubitus position.

considerations to remember. The first is to visualize the foreign body. Gentle suprapubic pressure will often push the foreign body into the distal rectum. The distal end of the foreign body may get caught along the curve of the sacrum. Place a finger in the rectum to redirect the orientation of the foreign body. The second consideration is to grasp the object. Sometimes an object is low-lying and may be grasped with gloved fingers. The object can then be removed by gentle continuous traction. Low-lying objects may be soft enough to be grasped with an instrument. **It is necessary to do this under direct vision so that the rectum will not be damaged in the attempt to grasp the foreign body.** Hard, low-lying objects made of metal or plastic may be grasped with a tenaculum.

Insert two well-lubricated fingers into the anesthetized anus and gently dilate the anal sphincter muscles. The anus can be maintained in the open position by the insertion of a Park retractor (**Figure 72-3A**) or a Hill-Ferguson retractor (**Figure 72-3B**). An anoscope or vaginal speculum may be used if these retractors are not readily available in the Emergency Department. View the distal end of the foreign body. **Never insert instruments unless the foreign body is visualized. Blind insertion of instruments may push the foreign body more proximally or perforate the rectum. Never grasp a foreign body blindly. This can cause injury to the rectum upon removal of the instrument if the rectal mucosa is entrapped between the instrument and the foreign body.**

DIGITAL EXTRACTION TECHNIQUE

Foreign bodies within reach may be grasped with the fingers and extracted. This often proves very difficult as the foreign body will be coated with lubricant, mucus, and/or stool. Instruct the patient to bear down as if having a bowel movement. The intraabdominal pressure generated in this way may expel the foreign body. The foreign body may become entrapped against the sacrum. Insert a finger into the rectum to dislodge the foreign body from against the sacrum as the patient continues to bear down. Attempt one of the techniques described below if digital extraction is ineffective.

FOLEY CATHETER TECHNIQUE

A Foley catheter has been successfully used to aid in the extraction of rectal foreign bodies.[5–7] This is especially helpful if the foreign body is made of glass, an inverted bottle or can, large, or present for more than 12 to 24 hours. Pulling these types of foreign bodies can result in the formation of a vacuum proximally and inhibit their extraction.

Liberally lubricate a Foley catheter. Insert the Foley catheter between the foreign body and the rectal mucosa. Advance the catheter until the balloon is proximal to the foreign body (**Figure 72-4A**). Fluoroscopy, if available, can be used to confirm the location of the balloon and guide the removal of the foreign body.[13] Inflate the balloon with 30 mL of saline or water. Inject air with a syringe through the Foley catheter to break the vacuum proximal to the foreign body. Remove the syringe so that air can move freely through the Foley catheter and prevent a vacuum from becoming reestablished. Apply constant, gentle, and steady traction to the Foley catheter. This will prevent the foreign body from migrating proximally. It may also move the foreign body distally so that it can be grasped and extracted with fingers or an instrument. The use of two to four circumferentially placed Foley catheters may apply evenly distributed traction to extract the foreign body more easily.

ENDOTRACHEAL TUBE TECHNIQUE

An endotracheal tube has been used in place of a Foley catheter by some physicians (**Figure 72-4B**). The advantage of using an endotracheal tube is that it is relatively stiff and can apply more traction than a Foley catheter to help remove the foreign body. Unfortunately, there are also disadvantages. The endotracheal tube is larger and less flexible than a Foley catheter. This may result in difficulty advancing it past the foreign body. The larger and stiffer endotracheal tube can more easily lacerate the rectal mucosa and perforate the rectum. For these reasons, the use of an endotracheal tube cannot be recommended.

SPOON TECHNIQUE

The removal of smooth, round, fragile, or glass foreign bodies can be problematic. This can include lightbulbs, balls, fruits, and vegetables. These foreign bodies can be extracted with a pair of large spoons. Liberally lubricate the posterior surface of a pair of spoons. Insert a Foley catheter to eliminate the vacuum proximal to the foreign body. Insert the spoons until they are cupping the foreign body (**Figure 72-4C**). Grasp and gently squeeze the handles of the spoons so that they hold the foreign body. Withdraw the spoons and the foreign body.

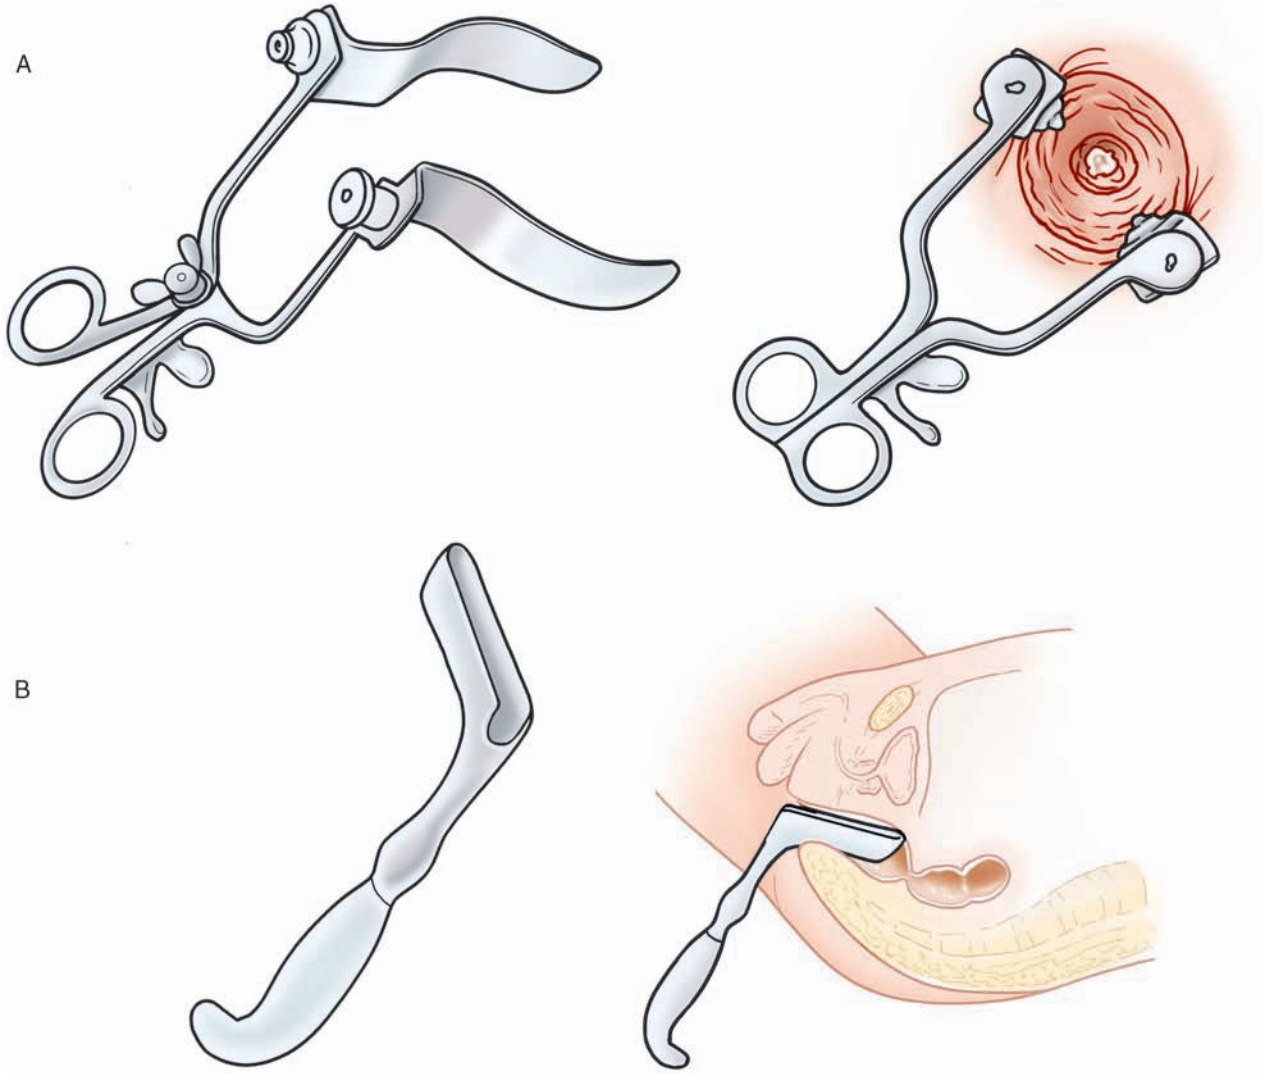

FIGURE 72-3. Retractors placed in the anus allow for better exposure and easier extraction of the foreign body. **A.** The Park retractor. **B.** The Hill-Ferguson retractor.

A more readily available alternative to large spoons are obstetric forceps. These have also been successfully used to extract a rectal foreign body. **The use of obstetric forceps cannot be recommended due to their large size, unfamiliarity to most Emergency Physicians, and the potential to perforate the rectum.**

RING FORCEPS OR TENACULUM TECHNIQUE

Rectal foreign bodies that are not fragile may be grasped with a ring forceps or tenaculum and then extracted. Insert a Foley catheter to eliminate the vacuum proximal to the foreign body. Firmly grasp the foreign body with a ring forceps or a tenaculum (**Figure 72-4D**). A tenaculum has teeth on its distal tips. These may be advantageous as the teeth can grip and firmly hold the foreign body, making the extraction easier. **This must be performed under direct visualization to ensure that the rectal mucosa is not entrapped between the instrument and the foreign body.** Apply gentle, firm traction to extract the foreign body.

VACUUM EXTRACTION TECHNIQUE

A vacuum dart or obstetrical vacuum extractor may be used to extract a rectal foreign body.[6,8] Emergency Physicians are usually not trained in the proper use of a vacuum extraction device. It may be beneficial to have an Obstetrician, Gynecologist, Family Practitioner with obstetric experience, or a Nurse Midwife to assist with this technique.

Insert a Foley catheter to eliminate the vacuum proximal to the foreign body. Place the vacuum cup of the device onto the foreign body. **Ensure that none of the rectal mucosa is entrapped between the rim of the suction cup and the foreign body.** Apply the suction to seal the cup against the foreign body. **Recheck to ensure that none of the rectal mucosa has become entrapped.** Apply steady traction to extract the foreign body.

MISCELLANEOUS TECHNIQUES

Numerous other techniques have been devised to remove a rectal foreign body.[9–12] These include the use of proctoscopes and snares, de Pezzer catheters, cyanoacrylate glue, clamps covered with rubber tubing, a tonsil snare, Sengstaken–Blakemore tubes, and plaster of Paris. Cyanoacrylate glue can be used to attach a handle to the foreign body. The foreign body can be extracted by withdrawing the handle after the glue has dried. A Sengstaken–Blakemore tube can be inserted into a foreign body with a small opening (e.g., glass bottle, soda can, etc.). Inflate the balloons and apply traction to extract the foreign body. Plaster of Paris can be used to fill a hollow object and allowed to harden around a tongue blade (**Figure 72-4E**). This is

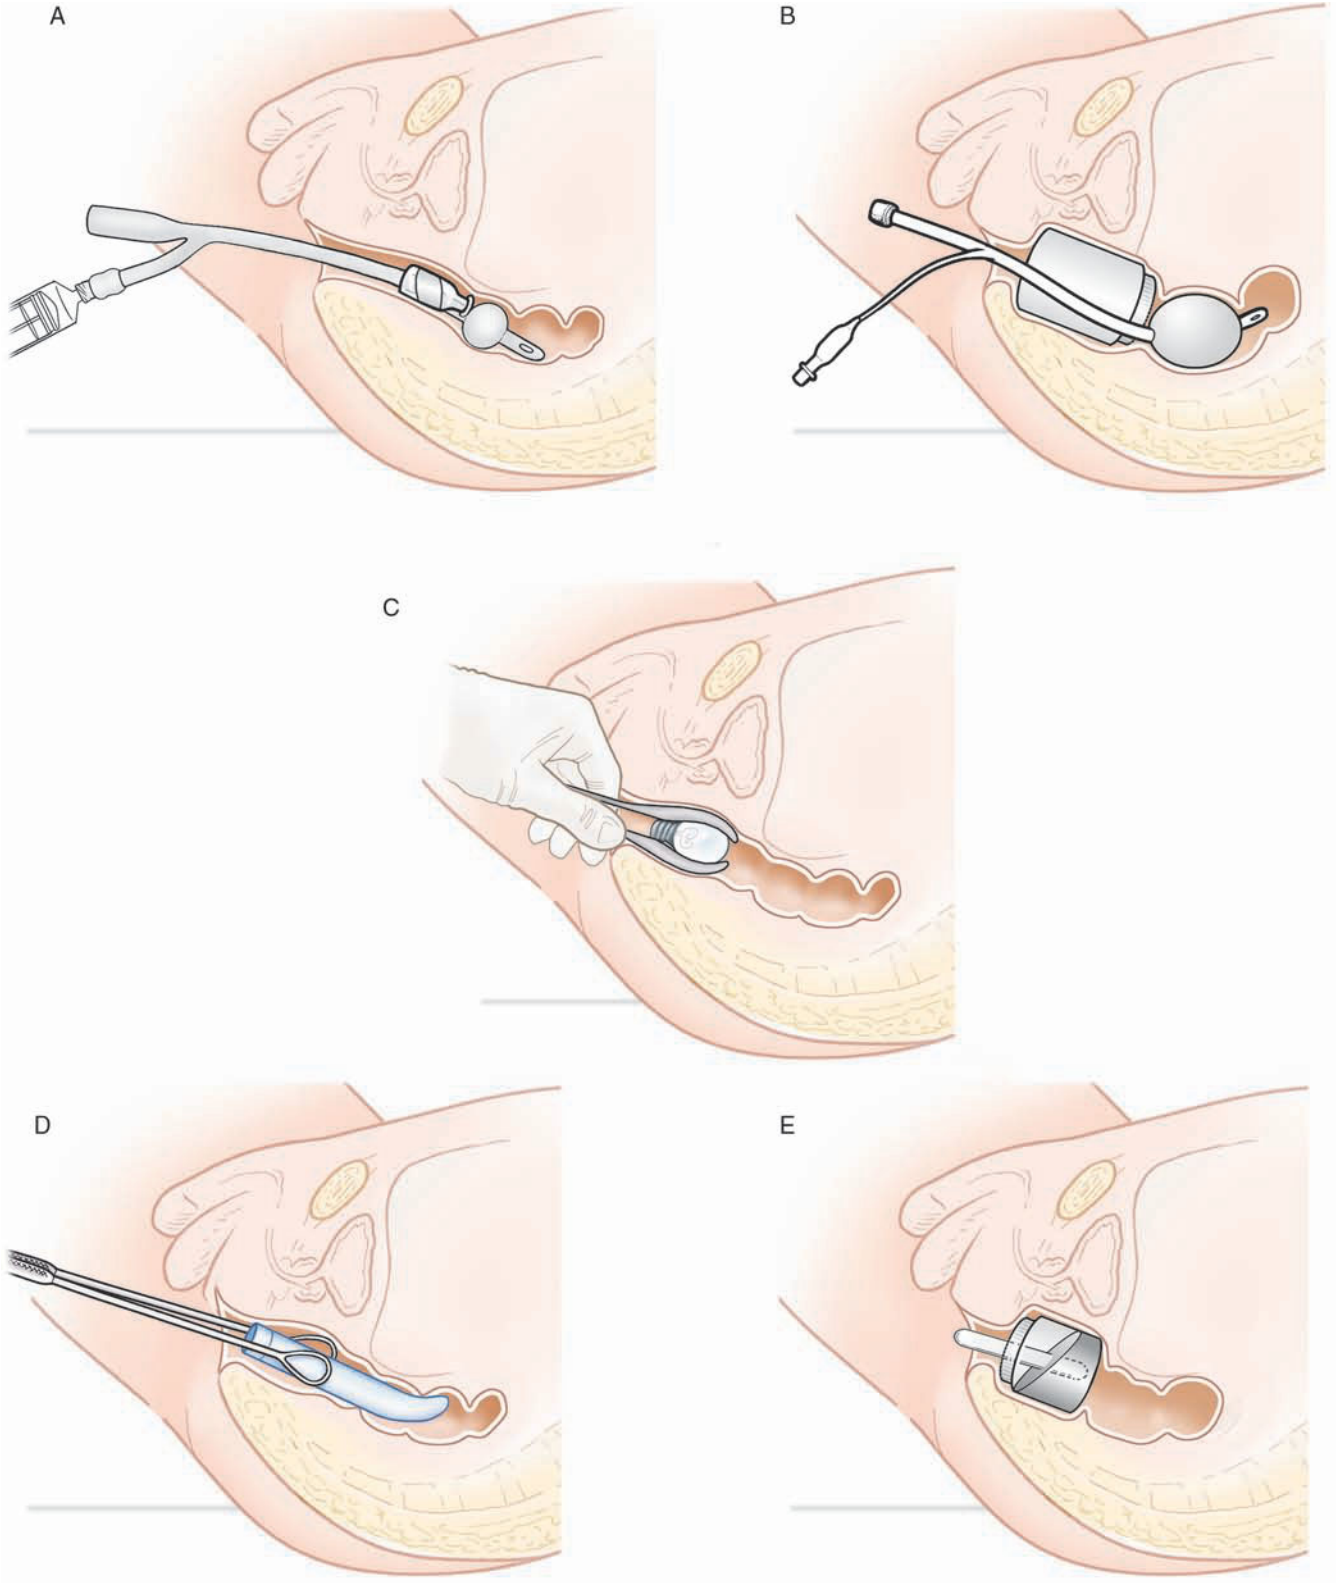

FIGURE 72-4. A sampling of methods to remove rectal foreign bodies. **A.** Foley catheter technique. **B.** Endotracheal tube technique. **C.** Spoons to remove a fragile object. **D.** Ring forceps technique. **E.** Plaster and a tongue depressor are placed in a jar. After the plaster cures, the tongue depressor can be used as a handle to remove the jar.

analogous to making a popsicle on a stick. The major disadvantage of using plaster of Paris is that it generates heat as it hardens. This heat may damage the rectal mucosa or shatter a glass bottle. The technique used and the choice of devices are limited only by one's imagination.

ASSESSMENT

Examine the rectum with a rigid rectosigmoidoscope to assess the mucosa for tears or perforations after the foreign body is extracted. Some physicians believe that this examination is not necessary if the

patient is asymptomatic, the foreign body is smooth, it was extracted atraumatically, and no complications arose from the extraction procedure. These patients may be discharged with follow-up as an outpatient for rectosigmoidoscopy. If obvious damage to the mucosa exists, the patients should remain in the hospital for observation. The patient should remain NPO and be prepared for possible surgery. Other indications for admissions include abdominal pain, significant bleeding, or the suspicion of a rectal perforation. Broad-spectrum intravenous antibiotics should be administered if a rectal perforation is suspected.

Perform a digital rectal examination to document the presence and quality of anal sphincter tone after the procedure. This should be delayed until the effects of any general, local, or regional anesthesia have dissipated. Rectal tone that is decreased or diminished from the initial (i.e., preprocedural) digital rectal examination requires the consultation of a General or Colorectal Surgeon.

AFTERCARE

Patients may be discharged home after the extraction procedure if they are asymptomatic, have normal rectal tone, and have no complications demonstrated on rigid rectosigmoidoscopy. They should be instructed to return to the Emergency Department immediately if they develop abdominal pain, pelvic pain, bright red blood per rectum, or a fever.

COMPLICATIONS

The major complications include rectal bleeding, rectal perforation, and damage to the anal sphincter. **Since the patient may very well have presented with these complications, it is important to document them or their absence on the initial (i.e., preprocedural) examination.** Rectal bleeding is common after a difficult extraction. It is important to rule out a perforation. This can be performed with the rigid rectosigmoidoscope after the extraction. Most perforations occur at the rectosigmoid junction, approximately 15 to 16 cm from the anus. Perforation above the peritoneal reflection will result in peritonitis and free air noted under the diaphragm on upright plain radiographs. Perforation below the peritoneal reflection may take several days to manifest pelvic pain, signs of a pelvic abscess, or sepsis. If there is no evidence of perforation or significant mucosal damage, the patient may still be discharged. However, large amounts of bleeding or significant mucosal damage require observation at the least. A Gastrografin enema without the use of the balloon may be used to identify a perforation if there is significant concern that it exists. Patients with perforation of an unprepared rectum require surgical intervention and broad-spectrum intravenous antibiotics. Any evidence of acute sphincter damage requires a surgical evaluation for possible debridement. The majority of these lesions are observed, allowed to heal secondarily, and then repaired surgically.

SUMMARY

The majority of rectal foreign bodies can undergo transanal extraction. Removal of rectal foreign bodies should include an appropriate history and physical; biplane abdominal radiographs; relaxation of the anal sphincter; firm attachment to the foreign body and slow, firm traction extraction; and postextraction rectosigmoidoscopy. Inpatient observation is indicated if the rectal mucosa is traumatized. The patient should be taken to the Operating Room if the foreign body cannot be removed in the Emergency Department, for pain control, if a perforation is suspected, or if removal may result in secondary injury.

SECTION 6

Orthopedic and Musculoskeletal Procedures

73 Bursitis and Tendonitis Therapy

Dedra Tolson

INTRODUCTION

Bursitis and tendonitis are frequent complaints evaluated in the Emergency Department. Bursitis represents an acute or chronic inflammation of the bursa. Similarly, tendonitis involves inflammation surrounding the bony insertion sites of the tendons. Typically, these complaints are treated conservatively with reduction of inflammation as the goal. Treatment often includes rest, elevation, application of cold and heat, and the introduction of anti-inflammatory agents. However, joint and soft tissue injections are helpful for both the diagnosis and therapy of a variety of musculoskeletal complaints. Diagnostic goals include a means for fluid aspiration and to provide symptom relief of the affected body part. Therapeutic goals include delivery of local anesthetics for acute pain relief, delivery of corticosteroid for suppression of inflammation, and increased mobility.[1] Injection therapy along with the above generalized treatment guidelines are a critical component of a multifaceted treatment regimen that should be considered by the Emergency Physician.

Definitive care can often be easily initiated by the administration of a steroid injection during the patient's earliest presentation. It has been shown that the clinical response to injectable corticosteroids is quite positive.[2–5] The techniques of aspiration and injection are easily mastered. These techniques are generally safe and effective when appropriate guidelines are followed.[1] While injection therapy can be effective, it must be remembered that this treatment should not replace cessation or modification of the offending activity if identified.

ANATOMY AND PATHOPHYSIOLOGY

Bursae are round, fluid filled, pad-like sacs or cavities. There are roughly over 160 bursae in the body. They are usually located at sites of friction such as joints, or in areas where tendons pass over bony prominences. Bursae are lined with a synovial membrane and contain synovial fluid. Their primary purpose is to reduce friction when movement occurs and to provide a mechanical advantage for tendon function. Bursitis often results from trauma, chronic overuse, inflammatory arthritis such as rheumatoid arthritis, crystal deposition, and infection.

Tendons are fibrous connective tissue bands attaching muscles to bones. A synovial sheath containing synovial fluid surrounds most tendons. Tendons mainly transmit forces from muscle to the skeleton. Pathologic findings are typified by inflammation, mucoid degeneration, and fibrinoid degeneration.[6]

Bursitis and tendonitis are often grouped together because the history, symptomatology, physical examination findings, and the treatment for these two inflammatory processes often coincide. **Corticosteroid injections serve to decrease inflammation, provide pain control, and promote healing. The goal of injection into tendon sheaths and bursae is to attain concentrated steroid levels to maximize the local anti-inflammatory effect while minimizing systemic effects.**

INDICATIONS

Injections of corticosteroids should be performed for an inflammatory bursitis or synovitis when systemic therapy is contraindicated and as an adjunct to physical therapy or systemic therapy. Many inflammatory conditions, including articular and nonarticular processes, are improved with local corticosteroid injection therapy.[1,7,8] The articular processes that are helped by injection therapy include gout, pseudogout, spondyloarthropathies, rheumatoid arthritis, neuritis, osteoarthritis, and crystalloid arthropathies. The nonarticular processes that are helped by injection therapy include bursitis, periarthritis, adhesive capsulitis, tenosynovitis, epicondylitis, trigger points, ganglion cysts, entrapment syndromes, tendonitis, plantar fasciitis, and neuritis.

CONTRAINDICATIONS

Both absolute and relative contraindications should be assessed when corticosteroid injection therapy is contemplated. The absolute contraindications include overlying cellulitis, septic arthritis, adjacent acute fracture, bacteremia, unstable joints, joints containing a prosthesis, and a history of an allergy or anaphylaxis to local anesthetics. Relative contraindications include inaccessibility of the joint, joints requiring radiographic guidance to ensure proper needle placement, meniscal or labral tears as a cause of symptoms, joints with loose bodies as a cause of symptoms, coagulopathy, anticoagulant therapy, or greater than three injections annually into a weight-bearing joint. Systemic conditions such as renal failure, cardiac failure, hypertension, diabetes, and other conditions that may be affected by the injection of corticosteroids should also be considered prior to proceeding with any injection therapy.

EQUIPMENT

- Povidine iodine or chlorhexidine solutions
- Sterile gloves
- Sterile drapes and towels
- 18 gauge needles, 1.5 to 2 in. long
- 22 gauge needles, 1.5 to 2 in. long
- 23 gauge needles, 1.5 to 2 in. long
- 25 gauge needles, 1.5 to 2 in. long
- Syringes (1, 5, and 10 mL)
- Injectable steroidal preparation (**Table 73-1**)
- Licocaine (1% and 2%) without epinephrine
- Bupivacaine (0.25% and 0.50%) without epinephrine
- Mepivacaine (1%) without epinephrine
- Adhesive bandages (to be placed postinjection)

TABLE 73-1 Corticosteroid Preparations Available for Injection

Generic name	Trade name	Strength (mg/mL)	Relative potency	Dose range (mg)	Biological half-life (h)
Hydrocortisone acetate	Cortef Solu-Cortef	25	1	12.5–100	8–12
Triamcinolone acetonide	Kenalog-10	10	2.5	4.0–40	18–36
	Kenalog-40	40	10.0		
Triamcinolone hexacetonide	Aristospan	20	8	4.0–25	18–36
Dexamethasone acetate	Decadron, Hexadrol, Dexone	4, 8	20–30	0.8–4.0	36–54
Betamethasone sodium phosphate	Celestone	6	20–30	1.5–6.0	36–54
Methylprednisolone acetate	Medrol, Depo-Medrol, Solu-Medrol	20, 40, 80	5, 10, 20	4.0–30	18–36

PATIENT PREPARATION

Explain the procedure, its risks, and its benefits to the patient and/or their representative. Obtain a written informed consent to perform the procedure. Position the patient so that they are comfortable and the injection site is easily accessible. Identify the injection site using the appropriate anatomic landmarks. It may be necessary to outline structures with a skin pencil when landmarks are difficult to palpate. Clean any dirt and debris from the skin. Apply povidone iodine or chlorhexidine solutions over the injection site and surrounding skin. Allow it to dry. Generally, sterile drapes and gloves are recommended for the novice but are not absolutely necessary depending upon operator experience.[9,12] A no-touch technique is indicated if a sterile field is not created.

TECHNIQUES

Medication dosing in bursae and soft tissue injections is influenced by the bursa size, the presence or absence of synovial fluid, the presence or absence of edema, the severity of synovitis, and the steroid preparation selected. **Table 73-1** summarizes the characteristics of commonly available corticosteroid preparations. The duration of action is chiefly dependent on the solubility of the preparation. For example, a dose of 20 to 30 mg of methylprednisolone acetate or equivalent is appropriate for large spaces such as the subacromial, olecranon, and the trochanteric bursae. This can be increased to a 30 to 40 mg dose if a large amount of synovial fluid is present. A dose of 10 to 20 mg is appropriate for intermediate size bursae present in the wrists, knees, and heels. A dose of 5 to 15 mg is appropriate for tendon sheaths. Triamcinolone hexacetonide and acetonide are the least soluble preparations available. The local effects of these steroid preparations may take several days for effects to be noticed initially, but these effects will ultimately last weeks or months. More soluble preparations such as hydrocortisone acetate have effects that last a few days. Many physicians prefer triamcinolone due to its prolonged duration of action. **Corticosteroids are often mixed with a local anesthetic solution prior to injection. The local anesthetic solution provides immediate pain relief for the patient. It also confirms for the physician that the injection was placed at the appropriate anatomic site.** If less volume is needed for the injection, consider using higher concentrations of local anesthetics such as 2% lidocaine instead of 1%.

Injection techniques for pediatric patients are not different than those for adults. However, smaller injected volumes maybe required depending on the age and size of the child. Soft tissue corticosteroid injections should be performed by a Rheumatologist or an Orthopedic Surgeon as these injections can affect bone growth, cartilage growth, and damage growth plates.

The sites for joint injections are typically based on anatomic landmarks. When superficial bursitis, tendonitis, and large effusions are involved, ultrasound may be helpful if available and depending upon physician experience. When deep bursae are involved or the target structure is difficult to reach, ultrasound can be helpful.[6,10,11] The deep injections requiring ultrasonographic guidance may require a specialist. The procedure can be time consuming and difficult to perform for the Emergency Physician who does not possess the skills and experience with ultrasound-guided procedures.[6,10,11]

SUBACROMIAL BURSITIS

The subacromial bursa lies between the rotator cuff muscles inferiorly (i.e., supraspinatus, infraspinatus, teres minor, and subscapularis muscles) and the overlying acromion, teres major muscle, and deltoid muscle. It cushions the coracoacromial ligament from the supraspinatus muscle. The subacromial space contains the long head of the biceps, the rotator cuff tendons, and the subacromial bursa. The syndromes of calcific tendonitis, supraspinatus tendonitis, and subacromial bursitis are so similar that the signs of each are difficult to distinguish. Anatomic proximity may cause associated irritative inflammation of adjacent structures, so that these conditions often overlap and coexist. Pain from these syndromes is elicited by shoulder abduction.

Patients often present holding the affected arm in a protective fashion against the chest wall. The classic sign of subacromial bursitis is tenderness over the greater trochanter that disappears with arm adduction. The "subacromial painful arc" is painful active abduction of the shoulder with maximal pain occurring between 70° and 100° of abduction. This differs from acromioclavicular joint inflammation, which results in a painful arc from 120° to 180° of shoulder abduction.

Three techniques are described to inject the subacromial bursa: the lateral approach, the anterior approach, and the posterior approach. The lateral approach is the most commonly used technique. Some prefer the anterior (or subcoracoid) approach provided that the practitioner has good familiarity with the anatomic landmarks. However, the anterior approach is more difficult for the less experienced to perform.

Place the patient seated upright or supine on a gurney. Palpate the indentation under the acromion process of the scapula for the lateral approach. This indentation is located between the acromion process and the greater tuberosity of the humerus. Fill a syringe with 1 mL of local anesthetic solution and 1 mL of a selected corticosteroid such as dexamethasone. Apply a 22 to 25 gauge needle to the syringe. Insert the needle into the indentation and direct it superomedially. Advance the needle until the tip touches the inferior surface of the acromion (**Figure 73-1**). Inject the steroid–anesthetic mixture. Withdraw the needle and apply a bandage.

Alternative approaches include the anterior and posterior approaches. Position the patient as above for the anterior approach. Identify the coracoid process of the scapula. Insert the needle 1.5 cm lateral to the coracoid process. Direct the needle horizontally and posteriorly. Advance the needle approximately 2.5 cm to gain direct access to the subacromial space. Inject the steroid–anesthetic mixture. Withdraw the needle and apply a bandage.

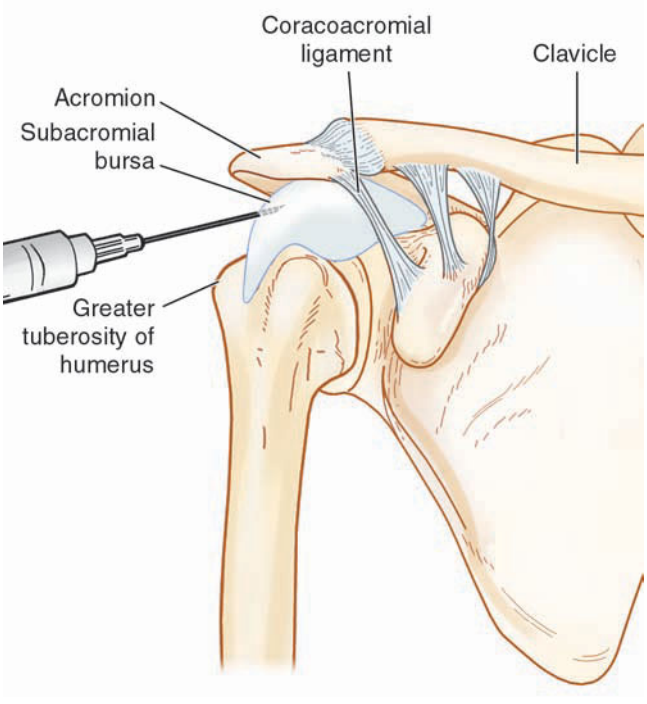

FIGURE 73-1. Lateral approach for subacromial bursitis.

The posterior approach may also be used. The distance from the coracoacromial ligamentous arch in this approach is great and may limit efficacy. Place the patient sitting upright with the effected forearm resting in their lap. Palpate the most lateral point of the acromion process posteriorly. Insert the needle at this landmark. Aim the needle toward the center of the humeral head and at an upward angle of 10° (**Figure 73-2**). Advance the needle 3 to 5 cm until the bursa is entered. Inject the steroid–anesthetic mixture. Withdraw the needle and apply a bandage.

SHOULDER IMPINGEMENT SYNDROME

A shoulder impingement syndrome results from rotator cuff, particularly the supraspinatus muscle, compression between the humerus and the coracoacromial arch. This is part of a pathophysiologic continuum with an endpoint of complete rotator cuff rupture in some cases. A history of overhead activities such as painting a ceiling is

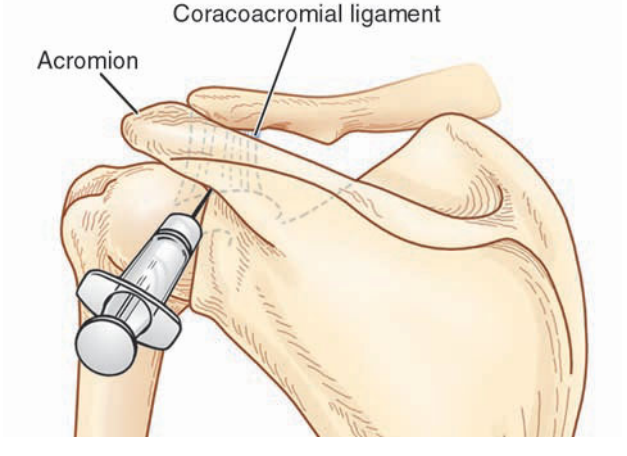

FIGURE 73-2. Posterior approach for subacromial bursitis.

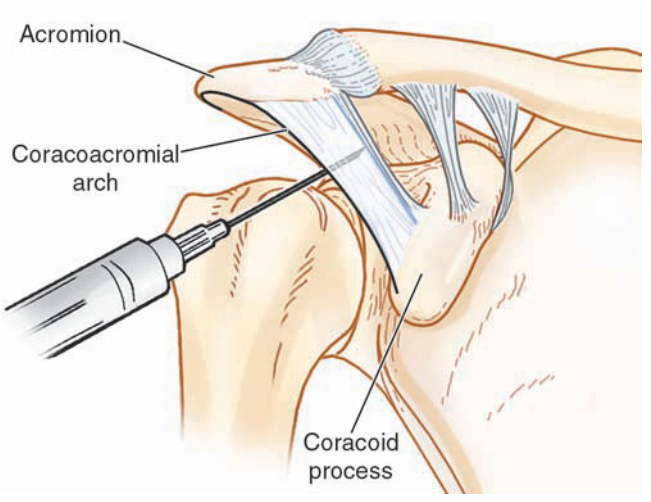

FIGURE 73-3. Injection for painful arch (impingement) syndrome.

common. The clinical hallmark is a painful arch of abduction from 60° to 120°. Pain typically begins at 60° to 70° of abduction and is maximal from 100° to 120°. Tenderness at the tendon insertion site over the greater tuberosity of the humerus may be present.

The impingement injection test may separate the pain of impingement from other causes of shoulder pain. First, the examiner prevents scapular rotation by holding the patients scapula against their rib cage. Extend the patient's affected arm in forced forward elevation. Pain with this movement may signify a number of inflammatory shoulder conditions. Repeat this maneuver after injecting 10 mL of local anesthetic solution beneath the anterior acromion process. The absence of pain after local anesthetic injection defines an impingement syndrome.

Place the patient sitting upright or supine on a gurney. Identify the coracoacromial ligament, which is found by palpating the coracoid process and the tip of acromion process. The coracoacromial ligament connects these two bony points (**Figure 73-3**). This ligament is a thick, dense, fibrous band. Fill a syringe with 80 mg of triamcinolone and 2 mL of bupivacaine or mepivacaine. Apply a 22 to 25 gauge needle to the syringe.[12] Insert the needle under the coracoacromial arch and inject the steroid–anesthetic mixture (**Figure 73-3**). **The plunger should depress easily and without resistance. Forceful injection indicates that the tip of the needle is within the rotator cuff tendons.** Advance the needle another 0.5 cm and reattempt the injection, seeking minimal resistance. Withdraw the needle and apply a bandage.

BICIPITAL TENDONITIS

The long head of the biceps tendon passes through the bicipital groove of the humerus (**Figure 73-4**). In this condition, the inflamed tendon is tender to palpation along the anterior humerus. Yergason's test is a clinical indicator of bicipital tendonitis. Flex the patient's elbow 90°. Grasp the patient's affected arm as if shaking hands. A positive test is the elicitation of pain in the biceps muscle while the examiner provides resisted supination to the patient's hand. Lipman's test is another clinical indicator of bicipital tendonitis. Tenderness of the bicipital tendon as it is rolled or plucked within the bicipital groove is considered a positive test. In general, pain causes restricted motion. Shoulder elevation will aggravate the patient's symptoms.

Place the patient seated with the affected arm externally rotated 20°. The bicipital groove and tendon are now pointing directly anterior. Fill a syringe with 10 to 15 mg of triamcinolone and 2 mL

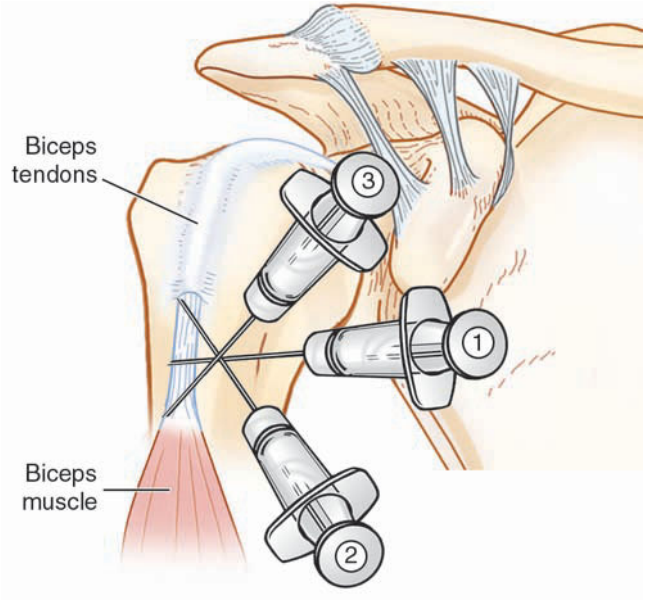

FIGURE 73-4. Injection for bicipital tendonitis.

of local anesthetic solution. Apply a 22 to 25 gauge needle to the syringe. Palpate the bicipital tendon and identify the point of maximal tenderness. Insert and direct the needle into the tendon sheath and aim toward the border of the bicipital groove at the site of maximal tenderness (**Figure 73-4**). Inject one-third of the dose into the peritendinous space (**Figure 73-4(1)**). **Confirmation of the needle placement within the tendon sheath is made by free flow of the steroid–anesthetic mixture with minimal resistance. Difficulty depressing the plunger indicates that the tip of the needle is within the tendon.** If resistance to injection occurs, withdraw the needle slightly and aim more parallel to the tendon to allow penetration of the sheath and not the tendon substance. Withdraw the needle to just under the skin and redirect it 2.5 cm superiorly, touching the border of the bicipital groove, and inject another one-third of the dose (**Figure 73-4(2)**). The final one-third of the dose is deposited by again withdrawing the needle to the subcutaneous area and redirecting the tip 2.5 cm inferiorly to the first injection site and touching the border of the bicipital groove (**Figure 73-4(3)**). Withdraw the needle and apply a bandage.

LATERAL EPICONDYLITIS (TENNIS ELBOW)

Lateral epicondylitis, or tennis elbow, is pain at the origin of the wrist and finger extensor muscles. Pain is elicited on palpation of the lateral epicondyle of the humerus. It is also elicited during resisted wrist extension. A history of playing racquet sports or doing manual labor is common.

Locate the injection site by palpating the base of the lateral epicondyle with the elbow flexed 90°. Fill a syringe with 1 mL of local anesthetic solution, 1 mL of methylprednisolone, and 0.5 mL of dexamethasone. Apply a 22 to 25 gauge needle to the syringe. Alternatively, mix the local anesthetic solution with 40 mg of triamcinolone. A total volume of 2 mL is required. Insert the needle in the indentation between the lateral epicondyle and the radial head, beginning at the radial head (**Figure 73-5A**). Slowly advance the needle toward the lateral epicondyle. **The radial nerve runs in this area, and care must be taken not to penetrate and inject the nerve.** Paresthesias and pain will be felt if the needle enters the nerve.

Inject 0.5 mL of the steroid–anesthetic mixture into the teno-periosteum at the base of the lateral epicondyle. Withdraw the needle until the tip is at the level of the radial head while simultaneously infiltrating with 0.25 mL of the steroid–anesthetic mixture. Infiltrate 0.5 mL of the steroid–anesthetic mixture when the tip of the needle reaches the level of the radial head. Redirect the needle over the proximal extensor muscle bellies (**Figure 73-5B**). Inject the remaining steroid–anesthetic mixture in a fan-like pattern over the extensor muscle bellies (**Figure 73-5B**). Withdraw the needle and apply a bandage.

MEDIAL EPICONDYLITIS (GOLFER'S ELBOW)

Patients affected with medial epicondylitis, or golfer's elbow, are most commonly Little League pitchers, golfers, and bowlers. Pain is felt in the medial aspect of the elbow upon flexion and supination of the wrist. Tenderness is elicited on palpation just distal to the medial epicondyle. It is important to exclude an avulsion fracture of the medial epicondyle or a compression fracture of the subchondral

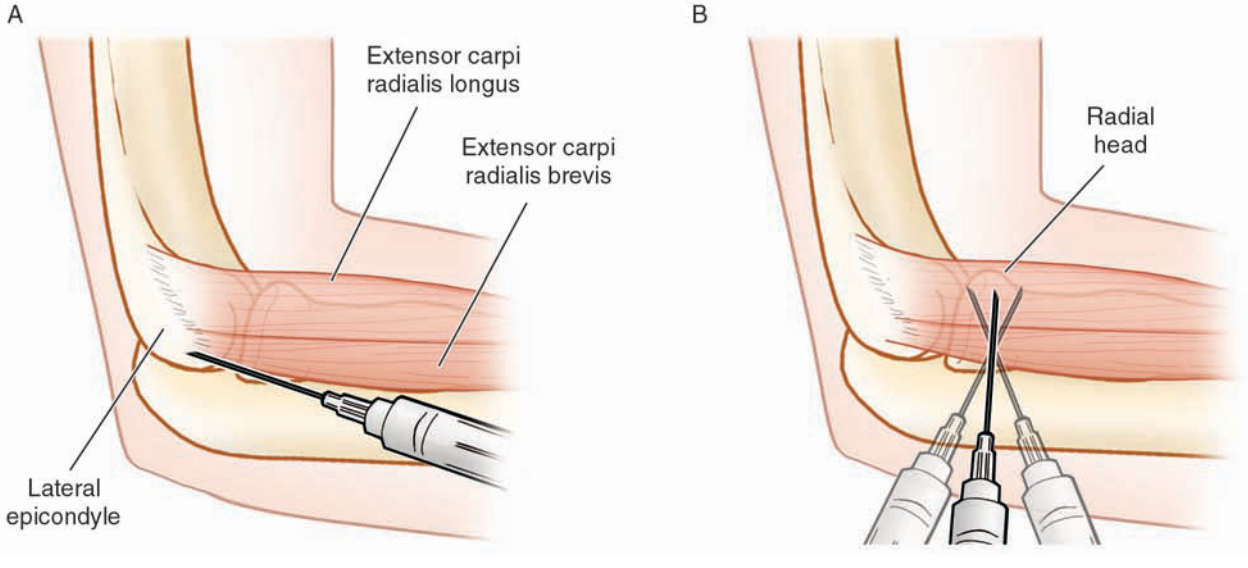

FIGURE 73-5. Injection for lateral epicondylitis. **A.** The needle is inserted at the level of the radial head and advanced to the base of the lateral epicondyle. **B.** The needle is redirected in a fan-like pattern over the muscle bellies.

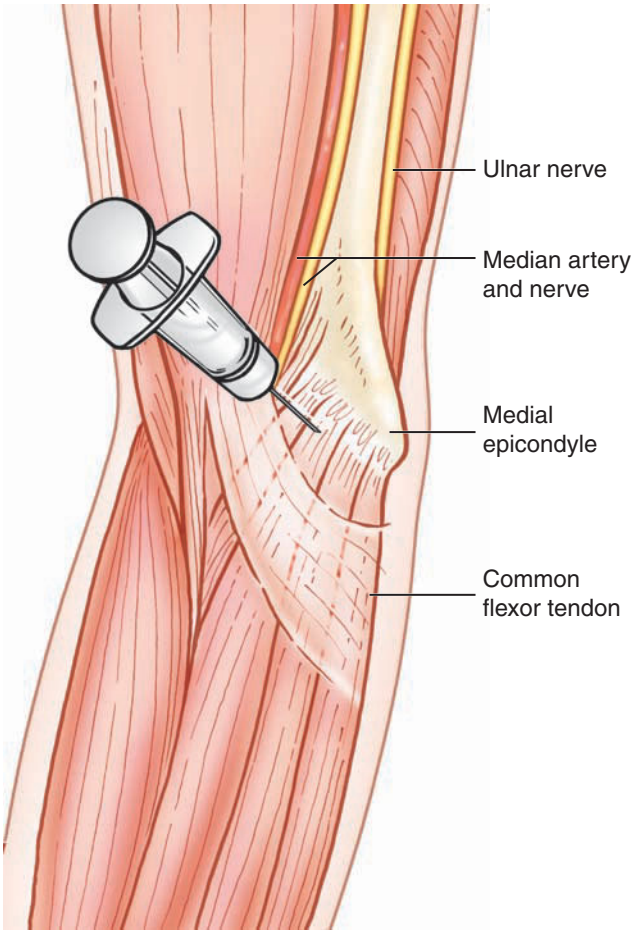

FIGURE 73-6. Injection for medial epicondylitis.

bone of the lateral condyle or radial head in children with nonfused epiphyses. Radiographs are suggested to exclude these causes.

Place the patient supine on a gurney. Place the arm in 90° of external rotation and abducted 90°. Flex the elbow 90°. Prepare a steroid–anesthetic mixture similar to that used for lateral epicondylitis. Identify by palpation the volar surface of the medial epicondyle. Insert the needle 2 cm proximal to the medial epicondyle and advance it distally to the tenoperiosteal region (**Figure 73-6**). **The ulnar nerve is better protected than the radial nerve, as it runs posterior to the epicondyle. Proximal needle insertion prevents striking the ulnar nerve.** Paresthesias and pain are indicators of nerve penetration. Inject 1.5 mL of the steroid–anesthetic mixture over the medial epicondyle while withdrawing the needle. Withdraw the needle and apply a bandage.

OLECRANON BURSITIS

Olecranon bursitis is usually sterile even though the olecranon bursa is the most frequent site of a septic bursitis. The bursa is located subcutaneously overlying the olecranon process of the ulna. Olecranon bursitis is not very painful except for the discomfort due to bursal expansion. An enlarged olecranon bursa may limit elbow extension. Studies have demonstrated that corticosteroid injection is superior to oral regimens for resolution of bursal inflammation.[13] Simple aspiration without corticosteroid injection is often followed by reoccurrence. **Since the olecranon bursa is the most common site of a septic bursitis, aspiration with fluid analysis is recommended before corticosteroid injection unless infection can be ruled out clinically.**

Seat the patient upright with their elbow flexed 90°. Fill a syringe with 30 to 40 mg of triamcinolone and 1 mL of local anesthetic solution. Insert an 18 gauge needle on an empty syringe into the most dependent aspect of the bursal sac. Aspirate the bursal fluid to drain it completely. The bursa may be "milked" by palpation and compression of the tissues toward the draining needle. Hold the needle securely. Remove the syringe while the tip of the needle remains within the bursa. Attach the syringe containing the steroid–anesthetic mixture. Inject the steroid–anesthetic mixture. Withdraw the needle and apply a bandage. Wrap the elbow region with an elastic compression bandage (Jones compression dressing) for 7 to 10 days. Instruct the patient to limit elbow movement for 7 to 10 days to prevent reaccumulation of the fluid.[14]

DEQUERVAIN'S TENOSYNOVITIS

DeQuervain's tenosynovitis is an inflammation of the tendon sheaths of the abductor pollicis longus and extensor pollicis brevis muscles as they cross the wrist (**Figure 73-7A**). The precise cause is unknown. Excessive friction from overusing the thumb and wrist such as repetitive and excessive gripping and grasping may be a possible etiology. Cases have been seen in bricklayers, golfers, those who sew, and piano players. Pain is elicited by the classic Finkelstein test, in which the patient deviates the wrist ulnarly while holding the thumb between the palms and fingers (**Figure 73-7B**). Palpation along the course of the tendon will also cause pain.

Fill a syringe with 40 mg of triamcinolone and 1 to 2 mL of mepivacaine or bupivacaine. Apply a 25 gauge needle to the syringe. Bending the needle approximately 30° at its base makes it easier to negotiate the area and insert the needle alongside the tendon.[14] Introduce the needle through the skin overlying the point of maximal tenderness. This is usually just distal to the radial styloid process (**Figure 73-8**). Inject the steroid–anesthetic mixture into the tendon sheath. **Resistance to injection signifies that the tip of the**

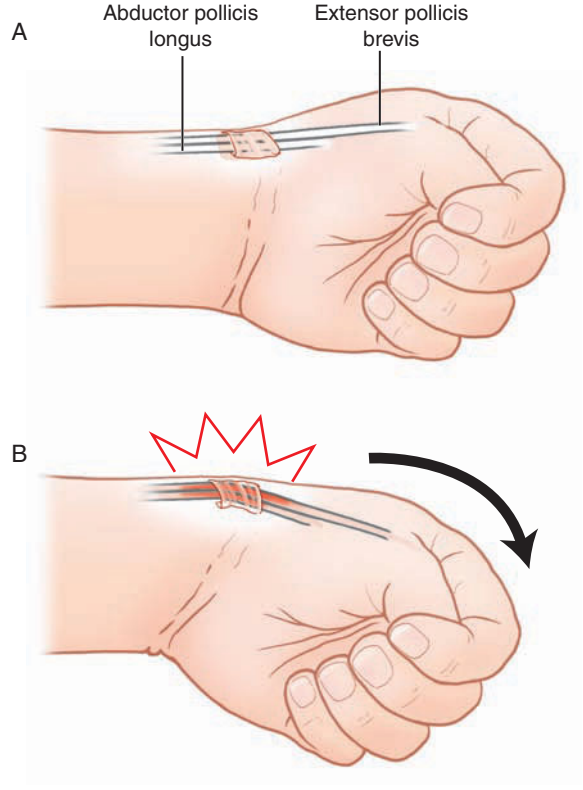

FIGURE 73-7. DeQuervain's tenosynovitis. **A.** Anatomy. **B.** Finkelstein's test.

FIGURE 73-8. Injection for DeQuervain's tenosynovitis.

needle is within the tendon. Withdraw the needle slightly and reinject, feeling for the loss of resistance. Withdraw the needle and apply a bandage. Apply a light thumb splint for approximately 10 days. The splint is especially useful at night or when there is significant activity.

TROCHANTERIC BURSITIS

Trochanteric bursitis typically affects women in the fourth to sixth decades of life. It also occurs in runners, ballet dancers, and as a form of overuse or trauma to the hip. Hip pain often prevents the patient from sleeping on the affected side. Pain is also severe with walking, especially up stairs. The deep trochanteric bursa lies between the tendon of the gluteus maximus and the greater trochanter of the femur. Another lies between the gluteus medius and the greater trochanter (**Figure 73-9**). Pain is elicited on palpation of the greater trochanter of the femur. Pain can be reproduced by hip adduction in superficial bursitis or on a resisted active abduction in deep bursitis.

The principal bursa lies between the gluteus maximus and the posterolateral prominence of the greater trochanter. Pain may radiate from the greater trochanter down the lateral or posterior thigh, mimicking sciatica or hip joint disease. In contrast to these syndromes, passive range of motion of the hip is nearly painless in the trochanteric bursitis. However, active abduction of the affected hip while the patient is lying on the unaffected side increases symptoms. Pain is also elicited by abduction and external rotation of the hip.

Place the patient prone on a gurney. Fill a syringe with 80 mg of triamcinolone and 3 to 10 mL of local anesthetic solution. Apply a 22 to 23 gauge needle on the syringe. Insert the needle at the point of maximal tenderness and aimed toward the greater trochanter. Advance the needle until the tip strikes the greater trochanter. Withdraw the needle 1 to 2 mm and inject the steroid–anesthetic mixture. Withdraw the needle and apply a bandage.

ISCHIAL BURSITIS

The ischial bursa lies between the ischial tuberosity and the overlying gluteus maximus (**Figure 73-9**). It becomes inflamed from trauma or prolonged sitting on a hard surface. Pain may radiate down the back of the thigh and mimic sciatica. Pain can be elicited by applying pressure over the ischial tuberosity.

Place the patient prone on a gurney. Fill a syringe with 30 to 40 mg of triamcinolone and 5 to 10 mL of local anesthetic solution.

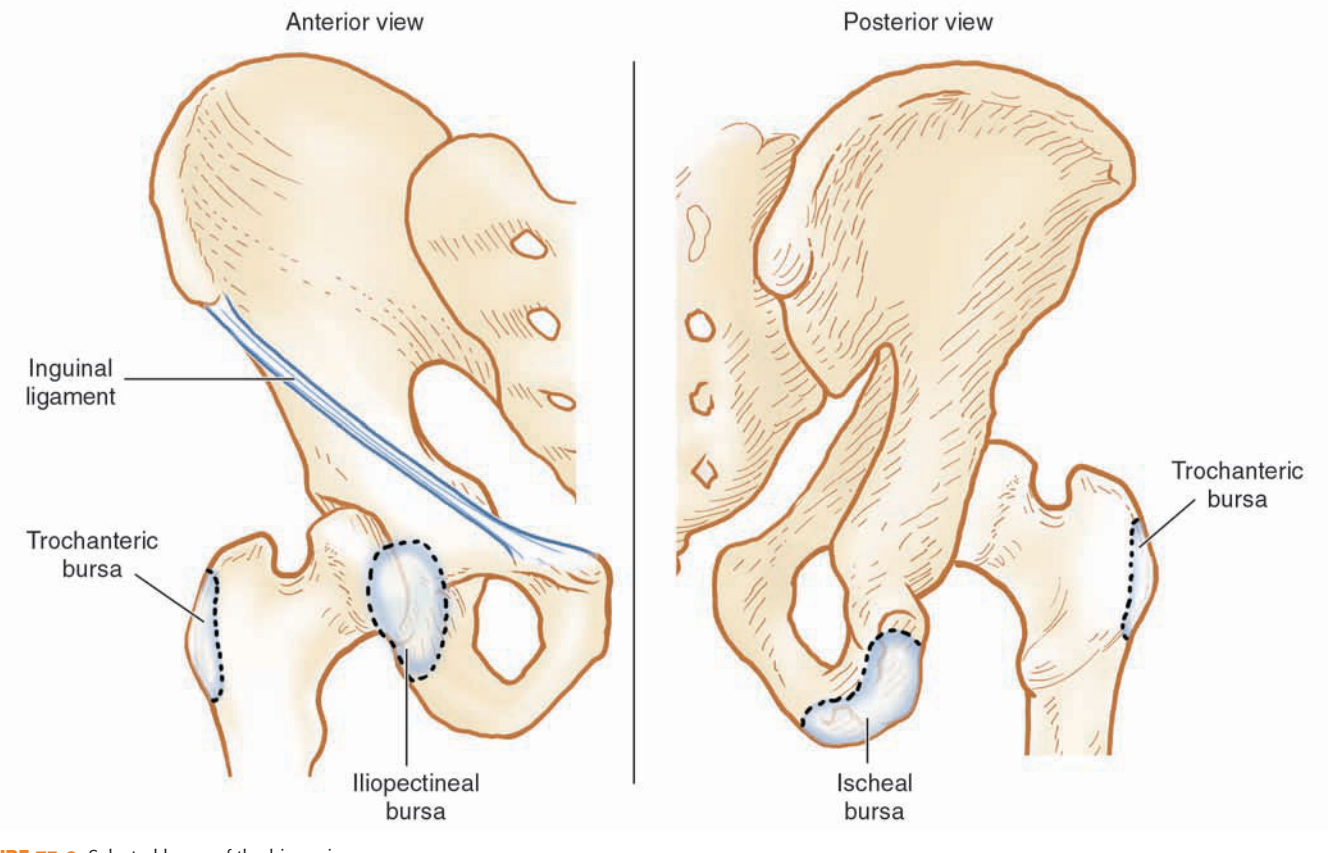

FIGURE 73-9. Selected bursa of the hip region.

Apply a 22 to 23 gauge needle to the syringe. Insert the needle over the most prominent section of the ischium. Hip flexion may facilitate palpation of the ischium in obese patients. **Care must be taken not to injure the sciatic nerve.** Striking the nerve will cause paresthesias across the buttocks and down the leg. Advance the needle until it contacts the ischial tuberosity. Withdraw the needle 2 to 3 mm and inject the steroid–anesthetic mixture. Withdraw the needle and apply a bandage.

ILIOTIBIAL BAND SYNDROME

Patients with iliotibial band syndrome present with lateral knee pain. This condition is commonly seen in cyclists, dancers, long-distance runners or walkers, and football players. These patients have a painful limp that is exacerbated with walking or running. Climbing stairs or walking up an incline will increase their pain. Tenderness is elicited with the patient lying supine and knee flexed 90°. Instruct the patient to extend their knee as you press over the lateral femoral condyle. Pain will be localized to the lateral femoral condyle. The patient will have pain at 30° of flexion as the iliotibial band slides over the condyle. A positive Rinne test occurs when the patient stands with their weight on the affected leg and flexes their knee. Pain at 30° of flexion is considered in a positive test.

Place the patient supine on a gurney. Fill a syringe with 80 mg of triamcinolone and 2 mL of local anesthetic solution. Apply a 22 to 25 gauge needle to the syringe. Typically, at 30° of flexion, the iliotibial band is at the midpoint of the lateral femoral condyle (**Figure 73-10**). Support the patient's leg in this position to bring the tendon to its most superficial point. Identify the point of maximal tenderness as the patient flexes their knee. Insert the needle perpendicular to the skin and 1 cm inferior to the point of maximal tenderness. Aim the needle superiorly. Inject the steroid–anesthetic mixture in an arc from anterior to posterior. The goal is to deposit corticosteroid in the tendon sheath and the surrounding inflamed tissues. **Resistance to injection indicates that the tip of the needle is within the tendon.** Withdraw the needle slightly and reinject, feeling for the loss of resistance. Withdraw the needle and apply a bandage.

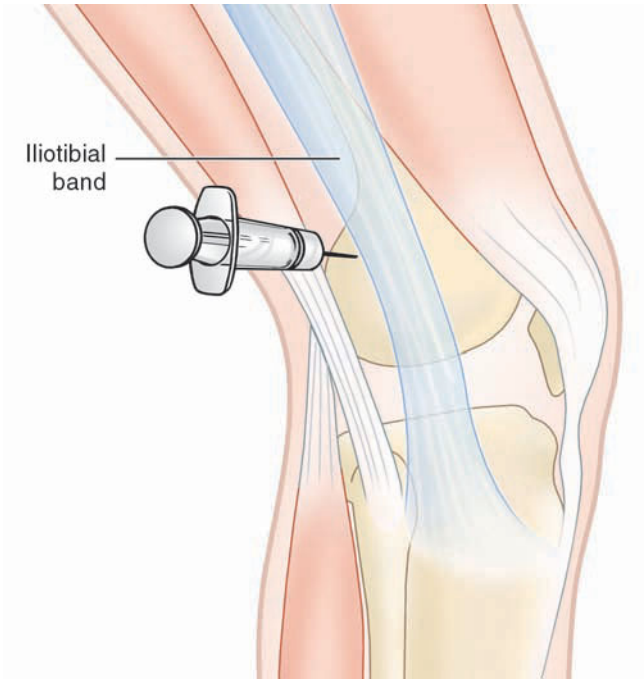

FIGURE 73-10. Injection for iliotibial band syndrome. The knee is flexed 30° to bring the tendon to its most superficial position overlying the midportion of the lateral femoral condyle.

ANSERINE BURSITIS

Anserine or pes anserine bursitis is an inflammation of the bursa located 5 cm below the medial joint line of the knee at the tibial insertion of the gracilis, sartorious, and semitendinosus muscles (**Figure 73-11**). The anserine bursa is superficial to the tibial insertion of the medial collateral ligament. The syndrome occurs predominately in overweight women with osteoarthritis of the knees. It may also be found in equestrians. The anserine bursa will be tender to palpation.

Place the patient supine with the affected leg externally rotated. Identify the anteromedial joint line of the knee. The bursa is located inferior to the joint line at the insertion of the sartorius, gracilis, and semitendinosus tendons (**Figure 73-11**). Palpate the area of maximal tenderness at this site. Fill a syringe with 40 mg of triamcinolone and 2 to 4 mL of local anesthetic solution. Apply a 23 to 25 gauge needle to the syringe. Insert the needle and direct its tip into the bursa at the point of maximal tenderness. Inject the steroid–anesthetic mixture into the bursa. Withdraw the needle and apply a bandage.

PREPATELLAR BURSITIS

Prepatellar bursitis is caused by direct pressure, such as when a person is kneeling on a firm surface. It is also known as nun's, rug cutter's, or housemaid's knee. Tenderness and/or crepitance is elicited by direct palpation overlying the patella. Extreme knee flexion causes pain. There is often a fluctuant, well-circumscribed, and warm bursal pouch overlying the patella. The prepatellar space is a common site for septic bursitis. Aspiration with fluid analysis is recommended to rule out an infection before any corticosteroid injection is considered.

Place the patient supine on a gurney with the affected knee slightly flexed. Note that the bursa is very superficial and may be entered by passing the needle just through the skin and subcuticular tissues (**Figure 73-11**). Fill a syringe with 30 to 40 mg triamcinolone and 1 to 2 mL of local anesthetic solution. Apply a 23 to 25 gauge needle to the syringe.[14] Insert the needle into the bursa at the point of maximal fluctuance. Inject the steroid–anesthetic mixture into the bursa. Withdraw the needle and apply a bandage.

INFRAPATELLAR BURSITIS

The infrapatellar bursa has two components (**Figure 73-11**). The superficial infrapatellar bursa lies between the patellar ligament and the skin. The deep infrapatellar bursa lies between the patellar ligament and the anterior tibia. Inflammation of the superficial bursa occurs due to friction from the overlying skin. Clinically, there is no pain with passive flexion. Active knee flexion and extension causes pain in the deep infrapatellar bursa. Edema and tenderness may be found on both sides of the patellar tendon.

Place the patient supine on a gurney with the affected leg and knee extended. Palpate the patellar tendon. Identify the superficial inflamed bursa. Fill a syringe with 20 mg of triamcinolone and 1 mL of local anesthetic solution. Apply a 23 to 25 gauge needle to the syringe. Insert the needle into the superficial bursa and inject the steroid–anesthetic mixture. Withdraw the needle and apply a bandage.

Patients with deep infrapatellar bursitis have maximal tenderness and swelling both medially and laterally to the patellar tendon. Fill a syringe with 30 mg of triamcinolone and 1 to 2 mL of local

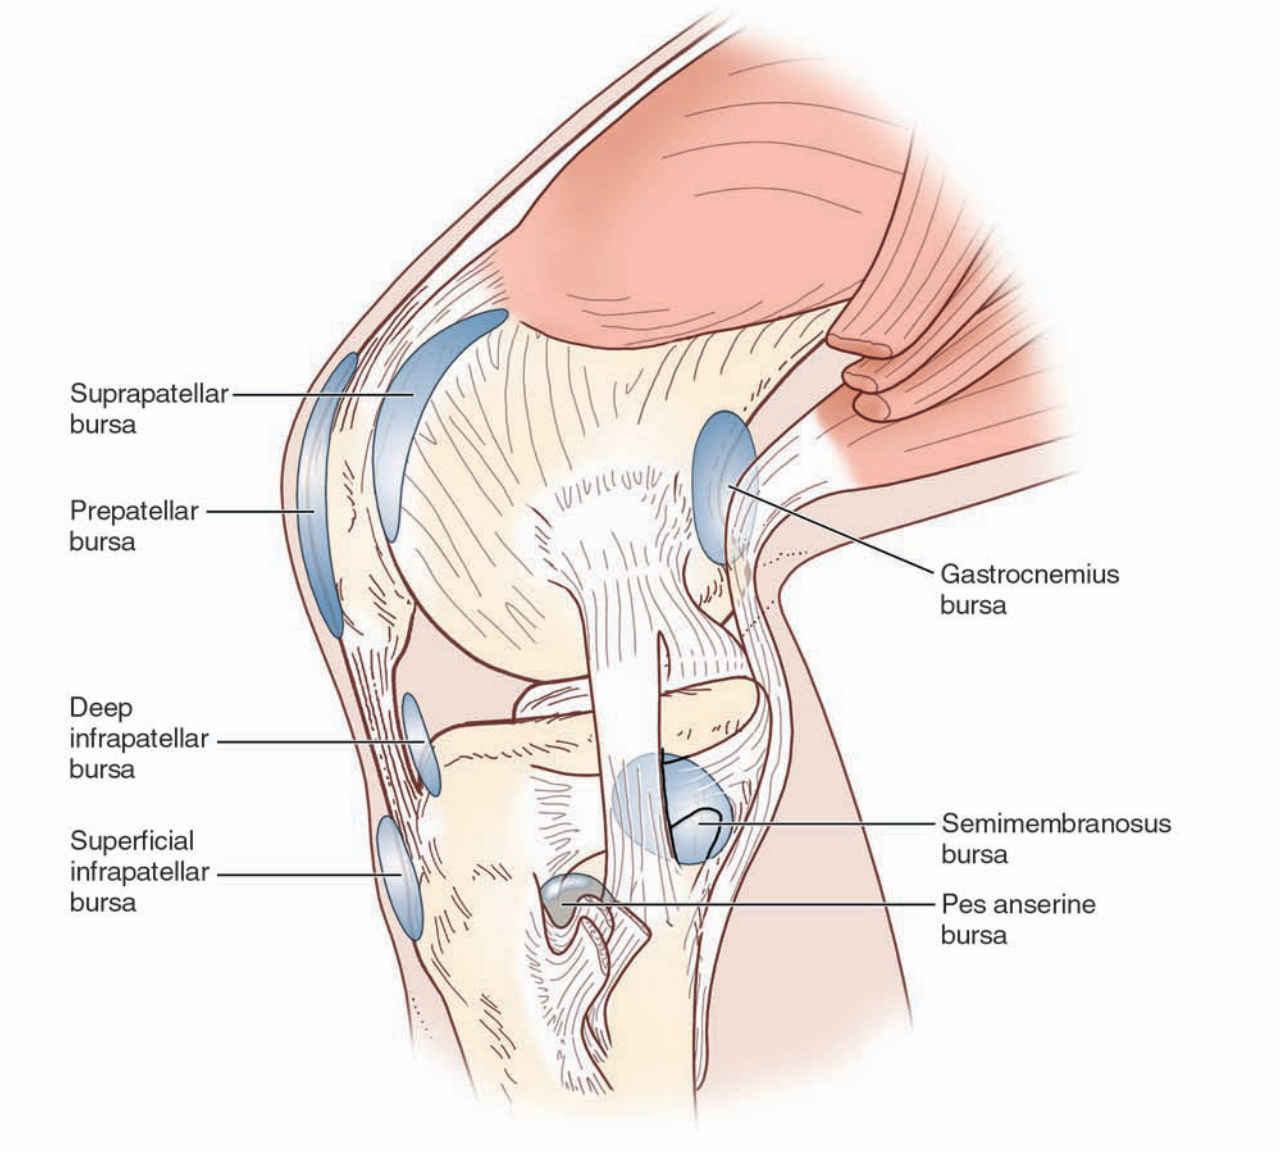

FIGURE 73-11. Bursae of the knee.

anesthetic solution. Apply a 23 to 25 gauge needle on the syringe. Insert the needle into the infrapatellar bursa, either medially or laterally to the patellar tendon. Attempt to aspirate, although fluid accumulation is minimal and usually no return will be found. Inject the steroid–anesthetic mixture. Withdraw the needle and apply a bandage.

ACHILLES TENDONITIS

Achilles tendonitis causes tightness and pain in the heel region upon first awaking. This discomfort improves with ambulation. The Achilles tendon will be tender to palpation and may be visually swollen. Corticosteroid injection around the Achilles tendon has been associated with tendon rupture.[15] Therefore, this injection is reserved for the Podiatrist, Rheumatologist, or the Orthopedic surgeon.[15]

PLANTAR FASCIITIS

Plantar fasciitis is a common problem presenting to the Emergency Department and the primary care physician. Patients typically complain of medial heel pain, particularly after standing for a long period of time. These patients have minimal to no swelling but feel acute tenderness to palpation over the calcaneal insertion of the plantar fascia. Maximum tenderness is palpated just beneath the spring ligament at the insertion of the plantar fascia on the calcaneous. Radiographs may demonstrate a calcaneal spur. However, the presence of a spur does not correlate with plantar fasciitis. Patients may have plantar fasciitis with or without a calcaneal spur. The optimal therapy for these patients is to elevate the heel with a felt heel pad inserted in the shoe. In addition, they may begin stretching exercises that are designed to stretch the plantar fascia. This often relieves the condition without an injection. In significant cases where conservative therapy is unsuccessful, injection of the calcaneal insertion of the plantar fascia with a steroid–anesthetic mixture is advocated.

Place the patient supine on a gurney with the affected leg externally rotated. Fill a syringe with 20 mg of triamcinolone and 1 mL of local anesthetic solution. Apply a 25 gauge needle on the syringe. Insert the needle into the medial aspect of the foot and aimed just anterior to the base of the calcaneous (**Figure 73-12**). Advance the needle 1.5 cm and inject the steroid–anesthetic mixture. Withdraw

FIGURE 73-12. Injection for plantar fasciitis.

the needle and apply a bandage. The patient should avoid weight bearing for 3 to 4 days and immediately begin oral nonsteroidal anti-inflammatory drugs.

ASSESSMENT

The patient must be observed for several minutes after the injection. Reexamine the patient to compare pre- and postinjection tenderness and mobility. The patient's symptoms should abate within a few minutes from the local anesthetic. Lack of relief indicates deposition of the steroid–anesthetic mixture away from the target structure. In these cases, a second attempt may be performed if the injection site can be properly identified. Otherwise, refer the patient to their primary care physician, a Rheumatologist, or an Orthopedic Surgeon for reevaluation and reassessment.

AFTERCARE

Instruct the patient to limit movement and/or weight bearing of the affected area after a corticosteroid injection. The duration of rest is dependent on the injection site. Larger and weight-bearing joints may require up to 2 to 3 weeks of rest, with range-of-motion exercises encouraged. Immobilization with splints or bandages may be necessary to prevent weight-bearing. A rehabilitation program including range-of-motion exercises, stretching, and strengthening may be recommended depending upon the chronicity and severity of the presenting condition.

COMPLICATIONS

Local infection is rare after corticosteroid joint injection and occurs from 1 in 17,000 to 50,000 injections.[1,8,16,17] A local reaction consisting of swelling, tenderness, and warmth may occur a few hours postinjection and last up to 2 days. This is known as the "postinjection flare" or "steroid flare."[9] It is self-limited, and responds to ice packs and nonsteroidal anti-inflammatory drugs. The etiology of the steroid flare is attributed to preservatives in the steroid suspension inducing a local synovitis. Steroid flares occur in approximately 2% of patients injected with corticosteroids.[1]

Tendon rupture is a theoretical complication thought to be due to corticosteroids weakening the collagen matrix. Tendon ruptures after corticosteroid injections have been reported, but direct causality has not been established.[15,18–21] Rupture is more likely if the injection is made into the tendon matrix rather than the synovial sheath, if the patient does not rest the tendon appropriately after the injection, or with multiple repeat injections.

Subcutaneous fat atrophy and atrophy of the overlying skin may develop if the steroid is injected less than 5 mm beneath the skin surface. A depigmentation in darker-skinned individuals may also occur due to superficial steroid injections. The depigmentation typically resolves spontaneously over a period of 6 months to 1 year.

SUMMARY

Local corticosteroid injections are useful diagnostic and therapeutic adjuncts for the Emergency Physician. Many patients with an inflammatory bursitis or tendonitis will benefit greatly from these simple and effective injections. Mastery of the techniques is quite easy. They require a familiarity with the indications, the local anatomy, and the injectable corticosteroid preparations. Complications associated with the injection of a steroid–anesthetic mixture are minimal if it is not injected into an infected space.

74 Compartment Pressure Measurement

Matt Kleinmaier and Sanjeev Malik

INTRODUCTION

The ability to diagnose a compartment syndrome is a critical skill for the Emergency Physician (EP). Early identification of a compartment syndrome can enable the appropriate treatment and may facilitate limb salvage. A compartment syndrome begins when an imbalance of volume and pressure within a myofascial compartment results in diminished blood flow.[1] A compartment syndrome has been classically described in the early literature as a Volkmann ischemic contracture following vascular insufficiency in the forearm.[3]

A compartment syndrome can occur in almost any muscle group that is contained within a confined fascial space. Common locations include the leg, forearm, and gluteal area. There are many causes of a compartment syndrome. These include protracted muscle ischemia secondary to necrosis from a contusion, swelling secondary to volume overload states or a fracture, or a thrombus in a vessel that traverses the compartment. In the Emergency Department (ED), a compartment syndrome is most commonly associated with long bone fractures or blunt trauma.[2] Most compartment syndromes are caused by trauma; 58% of all cases are due to fractures of the tibia or forearm.[27] Other etiologies for a compartment syndrome include complications from a coagulopathy, dialysis, surgery, or states of obtundation (**Table 74-1**).[4–6]

Identifying a compartment syndrome in a timely fashion can be challenging. The sensitivity and specificity of manual palpation to identify a compartment syndrome is 24% and 55%, respectively.[34] Manual palpation has a positive predictive value of 19% and a negative predictive value of 63%.[34] **Thus, manual palpation cannot be used to rule in or rule out a compartment syndrome. The hallmark symptom is persistent and progressive pain that is disproportionate to the underlying cause.** The pain typically increases with passive motion. **A catastrophic mistake is to attribute the etiology of the patient's pain solely to the underlying problem, such as the fracture or trauma.**[7,8] Other signs and symptoms associated with a compartment syndrome occur late in the course and include paresthesias of the involved nerve, paralysis of the involved muscle group, pallor of the skin, and diminished pulses.[9] Waiting for the development of all the clinical signs and symptoms is an invitation for permanent and dangerous sequelae, including muscle necrosis and possible loss of a limb. **Measurement of elevated**

TABLE 74-1 Common Causes of a Compartment Syndrome

Anticoagulation therapy or coagulopathy
Bleeding into compartment
Burns which involve muscle
Exercise-induced (chronic exertional compartment syndrome)
External compression
Iatrogenic closure of fascial injuries
Immobility
Improper casting or tight dressings
Infusion of fluids into muscle compartment (blown forearm IV)
Nephrotic syndrome (lower extremity swelling)
Reperfusion injury after prolonged OR positioning or tourniquet use
Seizures (increased capillary permeability)
Trauma
Long bone fractures
Blunt trauma (Crush injury)
Vascular injury
Venous thrombus

tissue pressure within the muscle compartment is currently the most common objective means of diagnosing this syndrome. Compartment pressure measurement provides objective support for the diagnosis of a clinically suspected compartment syndrome, leading to the appropriate treatments designed to salvage the afflicted limb.

Numerous methods have been evaluated to diagnose a compartment syndrome.[35] The inflammatory biomarkers and proteins released from damaged muscle are either late markers or nonspecific to distinguish between muscle injury from trauma versus a compartment syndrome. MRI is not reliable or specific to identify the early changes of a compartment syndrome. Pulsed phase-locked loop (PPLL) ultrasound identifies subtle movements of the fascia and may be helpful in the diagnosis. Further investigations using this technology are required before it can be used clinically. Radionuclide imaging is not feasible in the acute setting of the ED due to its lack of specificity, the complexity of the procedure, the time required for testing, and the inability to perform repeated measurements. Near-infrared spectroscopy measures changes in oxygenated hemoglobin and tissue perfusion. Further investigations using this technology are required before it can be used clinically in the diagnosis of a compartment syndrome. Pulse oximetry cannot be used to measure intracompartmental oxygenation. It can measure if distal blood flow is present but is limited due to collateral circulation and the loss of pulses being a late finding for a compartment syndrome. Laser Doppler flowmetry measures microvascular perfusion and has potential in the future when more clinical information regarding its use becomes available. Tissue ultrafiltration requires the extraction of tissue fluid and the time consuming measurement of biomarkers. Differences in vibratory sensation using a 256 cycle tuning fork show some promise in the diagnosis of a compartment syndrome. It cannot be used in young children, patients that cannot appropriately communicate, and those with an altered sensorium. Tissue hardness measurement techniques evaluate skin surface pressure and are in the early stages of testing. Direct nerve stimulation is not for the early evaluation of a compartment syndrome because nerve damage is a later finding. Finally are the invasive techniques to measure compartment pressure, which are the focus of this chapter.

ANATOMY AND PATHOPHYSIOLOGY

The anatomy of a compartment syndrome is variable, as it can occur in any enclosed muscle group. Any muscle tissue that is confined in space by fascia, skin, or any external forces (e.g., casting material) is a potential site for the development of a compartment syndrome. The muscles, nerves, and vasculature within the affected muscle group are all potentially compromised by a prolonged ischemic state followed by swelling. A basic knowledge of the anatomy of commonly affected compartments is necessary to successfully and safely perform compartment pressure measurement.

The initial imbalance of a compartment syndrome occurs between the volume and pressure within the myofascial compartment. The arterial inflow and venous outflow diminish as either intracompartmental volume or pressure increases. The blood begins to be shunted via capillaries into the muscle tissue. This compensatory shunting of blood further disturbs the volume–pressure balance, resulting in impaired tissue oxygenation.[2,9,10]

The extent of the tissue damage is determined by the duration of ischemia. Numerous experimental studies have documented a lack of muscle viability after 6 to 8 hours of total ischemia and a lack of nerve viability after 8 hours of total ischemia.[11,12] Thus, reversing the ischemia well before this time period is crucial to restoring tissue function. The definitive factor in the development of a compartment syndrome is the alteration of the pressure gradient between arterial and venous flow. Measurement of the intracompartmental pressures is used to determine the extent of ischemia.

The pressure of a healthy muscle compartment ranges between 0 and 8 mmHg.[13] Although there is no absolute value that determines the presence of a compartment syndrome, values above 30 to 35 mmHg are considered abnormal and should be the cutoff point for performing a fasciotomy.[9,14,15] Although this value is referred to commonly, several studies confirm that a compartment syndrome does not develop definitively at or above this pressure threshold.[16,17] A prospective study of patients with isolated lower leg fractures without clinical signs of compartment syndrome showed significant elevations in compartment pressure compared to the contralateral normal leg (35.5 ± 13.6 mmHg in the injured leg vs. 16.6 ± 7.5 mmHg in the control leg; $P = 0.0001$).[33] Other studies use a compartmental pressure that is within 10 to 30 mmHg of the patient's diastolic pressure as one of the indications for a fasciotomy.[2,11] Finally, a measurement that is within 10 to 30 mmHg of the patient's mean arterial pressure is also suggested as an indication for a fasciotomy.[18] **Nonetheless, if the compartmental pressure is 30 mmHg or greater, one must consider the development of a compartment syndrome and the need to perform a fasciotomy.**

Studies have investigated the correlation between perfusion pressure (diastolic blood pressure minus compartment pressure, also known as delta pressure) and compartment syndrome, with compartment syndrome suggested if delta pressure is less than 30 mmHg.[2,11,27] In equivocal cases, newer adjunctive and noninvasive testing such as T2-weighted MRI[28] and near-infrared spectroscopy[28,29] may be helpful if available. Despite advances in testing, there is as yet no gold standard for diagnosis, and compartment syndrome remains a clinical and operative diagnosis.

A compartment syndrome can occur in any muscle group. This includes the hand, foot, thigh, arm, and intercostal spaces, to name a few. This chapter reviews the anatomy of the two most common sites of a compartment syndrome, the leg and the forearm.

LOWER EXTREMITY: LEG

The lower leg consists of four distinct muscle compartments: anterior, lateral, deep posterior, and superficial posterior (**Figure 74-1**). A general understanding of the components of each compartment is important.[19,20]

The anterior compartment contains the four extensor muscles of the leg. These muscles function together to dorsiflex the foot. The deep peroneal nerve travels through this compartment to innervate the extensors and provide sensory innervation to the web space

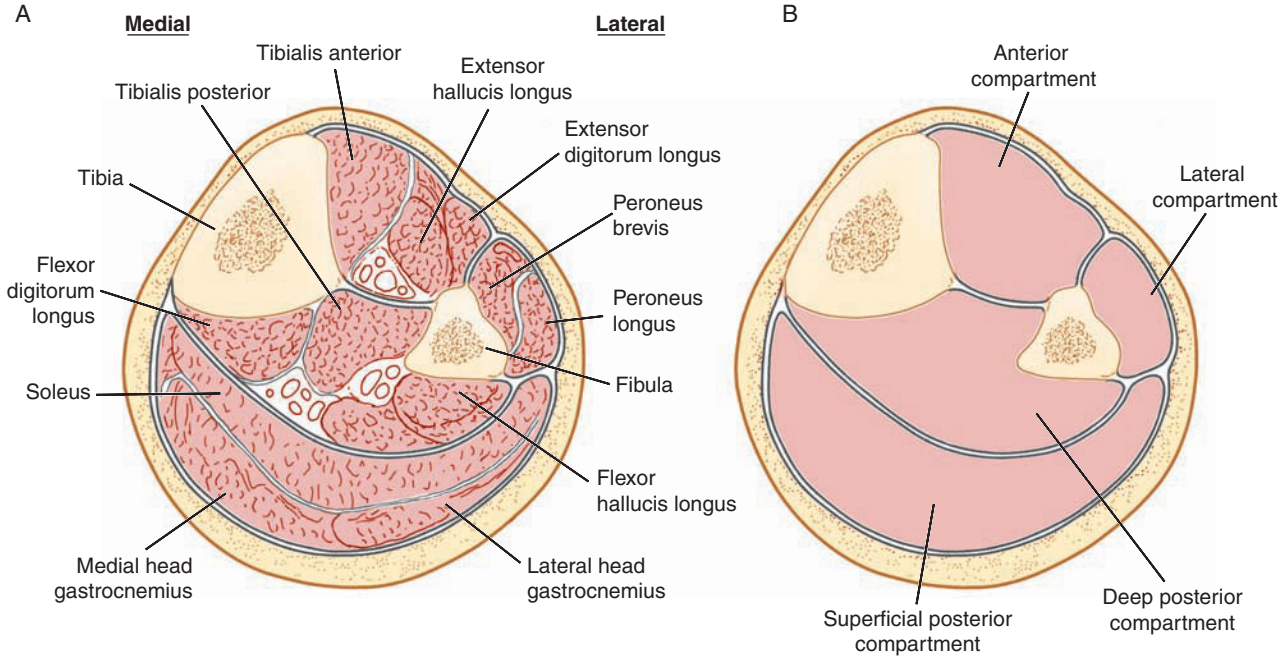

FIGURE 74-1. Cross section through the middle of the right leg demonstrating the four compartments. The size and proportion of the compartments change as one travels proximally or distally from this middle section. **A.** The anatomy. **B.** The compartments.

between the first and second toes. The anterior tibial artery travels through this compartment and provides bloodflow to its contents.

The lateral compartment contains the peroneus longus and brevis muscles. Their chief function is to evert the foot, with some consequent abduction and plantarflexion of the foot. The major nerve in the lateral compartment is the superficial peroneal nerve to supply motor innervation to the compartment muscles and sensory innervation to the lower leg and dorsum of the foot.

A fascial layer divides the posterior muscle group into superficial and deep compartments. The superficial posterior compartment contains the muscles of plantarflexion (gastrocnemius, soleus, and plantaris tendons). No major nerves or blood vessels travel in the superficial compartment. The deep posterior compartment contains the four deep flexor muscles (flexor digitorum longus, flexor hallucis longus, tibialis posterior, and popliteus). This group of muscles contributes to inverting and adducting the foot in addition to flexing the toes and foot. The primary sensory innervation is from the tibial nerve, which courses through the deep posterior compartment. The tibial nerve supplies most of the muscles of the posterior compartment before dividing into several branches that provide sensory innervation to the sole of the foot. The posterior tibial artery and the peroneal artery are also contained within this compartment.

Although any of these compartments can suffer from ischemia, **the deep posterior compartment and the anterior compartment have the highest incidence of developing a compartment syndrome.**[17] It is difficult to simply observe the patient in the face of a normal compartmental pressure when they clinically present with increasing pain and the features suggestive of a compartment syndrome. **Thus, multiple compartmental syndrome readings must be taken when the suspicion is high and the compartmental pressures are normal.**

UPPER EXTREMITY: FOREARM

The forearm consists of three compartments that are interconnected at various levels (**Figure 74-2**).[20,21] This interconnection is significant because release of the pressure in one compartment will reduce some of the pressure into the adjacent compartments. **The volar compartment is most at risk for development of a compartment syndrome in traumatic injuries of the forearm.**

The forearm includes the volar, dorsal, and mobile wad compartments (**Figure 74-2**). The volar compartment contains all of the hand and forearm flexor muscles, the median and ulnar nerves, and the radial, ulnar, and common interosseous arteries. The mobile wad contains the brachioradialis, the extensor carpi radialis brevis, and the extensor carpi radialis longus muscles. No major arteries or nerves are contained within this compartment. The radial artery and a branch of the radial nerve may sometimes lie between the mobile wad and the volar compartment. The dorsal compartment contains the hand and forearm extensor muscles, the posterior interosseous artery, and the posterior interosseous nerve.

INDICATIONS

The earliest and most reliable indication for measuring compartment pressures is the development of increasing pain in a tense and swollen muscle group.[2] This pain tends to be disproportionate to the underlying cause (e.g., fracture, soft tissue contusion, thrombus, etc.). Pain that increases with passive motion of the affected muscles is also an indication for compartmental pressure measurement. Sensory deficits and paresis of the affected muscles are two late findings for the development of compartment syndrome.[9] **It is important to remember that the presence of palpable pulses and capillary refill do not rule out an evolving acute compartment syndrome.** The absence of pulses may suggest arterial injury or hypovolemia. One must measure and monitor all compartments at risk if the patient is obtunded or unreliable. This usually refers to the forearm and lower leg compartments in the multiple trauma patient.

Have a very low threshold for measuring pressures within a muscle compartment. Compartmental pressures must be measured if a compartment syndrome is considered as a diagnosis. Do not rely solely on the compartmental pressure measurements

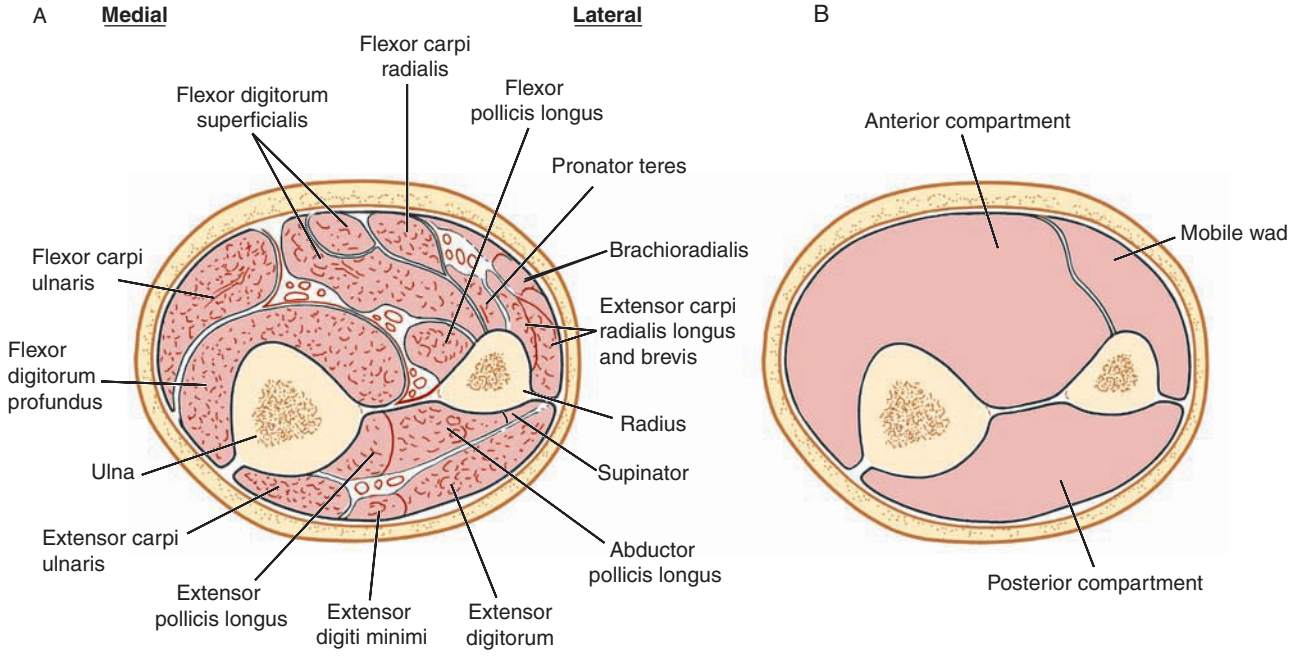

FIGURE 74-2. Cross section through the middle of the right forearm demonstrating the dorsal and volar compartments separated by the line of the radius, the ulna, and the interosseous membrane. **A.** The anatomy. **B.** The compartments. The mobile wad forms a distinct muscle compartment coursing along the radius.

to make a decision regarding the need for fasciotomy. A compartment syndrome is primarily a clinical diagnosis. Pressure measurements should be taken in each compartment at risk, in at least two sites within the compartment. If concern persists, serial measurements or continuous pressure measurement should be performed even if initial pressures are normal or only mildly elevated. Compartment pressures should be interpreted in the clinical context of the patient; normal compartment pressures do not rule out the diagnosis.

CONTRAINDICATIONS

There are no absolute contraindications to the measurement of compartment pressures. Given the importance of prompt diagnosis, compartment pressure measurements should be performed while evaluating for coexistent traumatic injuries. The EP can still assess the compartmental pressures even though the patient may be undergoing other invasive and/or surgical procedures. **Time is of the essence. Postponing compartmental pressure measurements or a fasciotomy may lead to irreversible damage to the affected extremity.**

EQUIPMENT

General Supplies

- Povidone iodine or chlorhexidine solution
- 4 × 4 gauze squares
- Sterile drapes or towels

Needle (Whiteside) Manometer Technique

- 18 gauge needles, 1.5 in. long
- 20 mL syringe
- Three-port, four-way stopcock
- Intravenous extension tubing
- Sterile saline
- Mercury manometer

Stryker Monitor System

- Stryker pressure monitor unit
- Sterile quick pressure monitor set (single use, contains: needle, syringe, diaphragm chamber)

Arterial Manometer Technique

- 18 gauge needle or Angiocath
- Sterile saline
- Arterial line tubing and manometer (identical to that used for arterial line)

PATIENT PREPARATION

Explain the risks and benefits of the procedure to the patient and/or their representative. Discuss the low risk of infection or bleeding, and the possibility of obtaining erroneous values. Written informed consent should be obtained from the patient and/or their representative if possible. If the patient is unable to consent and no representative is available, proceed after documentation of the medical necessity.

Wash away any blood, dirt, or debris on the patient's skin. Apply povidone iodine or chlorhexidine solution to the skin around the puncture sites. The measurement of compartment pressures is considered a sterile procedure and the EP should don a hat, mask, sterile gloves, and a sterile gown. Create a sterile field with either surgical towels or drapes. Identify the landmarks for needle insertion and mark the skin puncture sites.

The exact location at which to measure the intracompartmental pressures is not clearly defined. There were no clearly established guidelines for determining the appropriate location for compartmental pressure measurements in patients with fractures prior to the recent study of Heckman et al.[24] The results of their study suggest that measurements must be performed at the level of the fracture as well as locations proximal and distal to the zone of the fracture. A 5 cm distance was used from the fracture site to the proximal and distal needle insertion sites. In the absence of a fracture, insert the needle at the point of maximal tightness of the compartment, as

TABLE 74-2 Needle Insertion Sites for the Compartments of the Leg

Compartment	Needle insertion site	Insertion depth (cm)
Anterior	1 cm lateral to the anterior tibial ridge and directed perpendicular to the long axis of the leg	1.0–3.0
Lateral	Just anterior to the posterior border of the fibula and directed toward the fibula	1.0–1.5
Superficial posterior	3 cm medial or lateral to a vertical line drawn through the midcalf	2.0–4.0
Deep posterior	Just posterior to the medial border of the tibia, directed posterolaterally and toward the posterior border of the fibula	2.0–4.0

TABLE 74-3 Needle Insertion Sites for the Compartments of the Forearm

Compartment	Needle insertion site	Insertion depth (cm)
Anterior	1.5 cm medial to a vertical line drawn through the middle of the forearm	1.0–2.0
Mobile wad	Perpendicular to the long axis of the radius and into the muscles lateral to the radius	1.0–1.5
Posterior	1 to 2 cm lateral to the posterior aspect of the ulna	1.0–2.0

well as in at least two other sites within the compartment. General anatomic landmarks for needle insertion into the various compartments of the lower leg and forearm are described in **Tables 74-2 & 74-3**, and graphically depicted in **Figure 74-3**. **The authors recommend using the highest measured intracompartmental pressure in making the decision for further intervention.**

TECHNIQUES

Several techniques for measuring compartmental pressures have been developed. Some use isolated intracompartmental pressure measurements while others monitor pressure continuously. Obtaining isolated intracompartmental pressure measurements is most important in the ED. Whitesides et al. described the needle manometer method utilizing a manual manometer and a saline–air meniscus in standard IV tubing connected to a 16 gauge needle.[22] Stryker (Stryker Instruments, Kalamazoo, MI) introduced an electronic system consisting of a reusable digital pressure monitor and a single-use measurement set with a needle, diaphragm chamber, and sterile saline flush.[23] More recently, a technique involving a 16 gauge angiocatheter or needle connected by arterial line tubing to a standard manometer has been described.[30] While all three of these methods will be discussed in this chapter, recent data suggest that the Stryker method and the arterial manometer method are significantly more accurate, are more convenient, and require only a small number of components readily available in most EDs than the needle manometer method.[31,32]

While each of these techniques may be performed with a standard straight needle, all are more accurate if used with a special side-ported needle or slit catheter, if available.[32] Similar measurement systems that introduce a wick or slit catheter into the tissue have been shown to be equally effective. For simplicity's sake, explanations of these techniques have been omitted, as they are rarely performed.

NEEDLE MANOMETER TECHNIQUE

Begin by setting up the system (**Figure 74-4A**). Attach the hub of a 20 mL syringe to the middle port of a three-way stopcock. Attach one end of the intravenous extension tubing to one of the ports of the stopcock. Attach an 18 gauge needle to the free end of the intravenous extension tubing. Insert a second 18 gauge needle into a container of sterile normal saline to release the vacuum. Insert the 18 gauge needle attached to the intravenous extension tubing into the normal saline so that the needle port is well immersed. Open

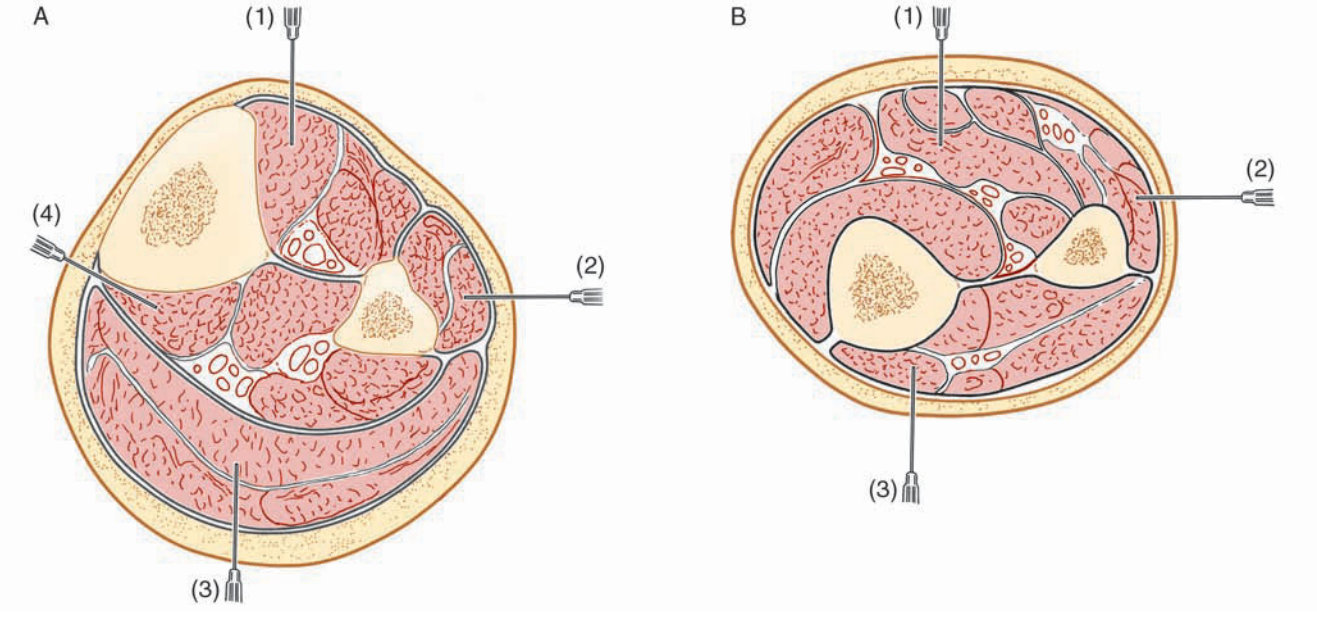

FIGURE 74-3. Needle insertion sites to measure intracompartmental pressures. **A.** The leg compartments: anterior (1), lateral (2), superficial posterior (3), and deep posterior (4). **B.** The forearm compartments: anterior (1), mobile wad (2), and posterior (3).

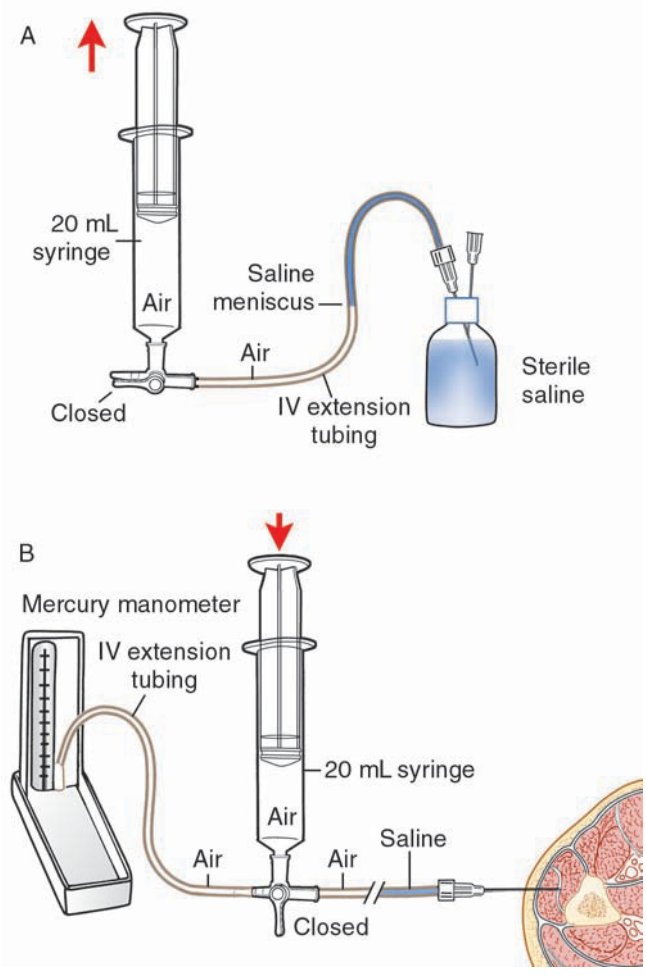

FIGURE 74-4. The needle manometer technique. **A.** The initial system setup. **B.** The final system should form a closed system of space from the manometer through the tissue space.

the stopcock ports only to the syringe and the extension tubing. Aspirate the saline to fill one-half of the length of the intravenous extension tubing. **Make sure that no bubbles enter the system.** Turn the stopcock valve so that the port to the saline is closed.

Attach a second piece of intravenous extension tubing to the remaining open port of the stopcock (**Figure 74-4B**). Attach the opposite end of this tubing to a manometer or arterial pressure monitor. Remove the 20 mL syringe from the system and aspirate 15 mL of air into the syringe. Reattach the syringe to the stopcock. Remove the extension tubing with the 18 gauge needle from the saline container.

Insert the 18 gauge needle into the affected muscle compartment (**Figure 74-4B**). Turn the stopcock valve so that all three ports are open. Position the intravenous extension tubing with the normal saline so that the meniscus of the saline–air interface is exactly level with the tip of the needle inserted into the patient's tissue. **The position of the saline–air interface in relation to the tip of the needle is important for an accurate intracompartmental pressure measurement.**

The saline–air interface will form a meniscus when the needle is in the patient. The meniscus will be convex-shaped away from the patient when the tissue pressure is greater than the pressure within the system (**Figure 74-5A**). **Depress the plunger of the syringe gradually and delicately to increase the pressure within the system.** The shape of the meniscus begins to flatten as the plunger is

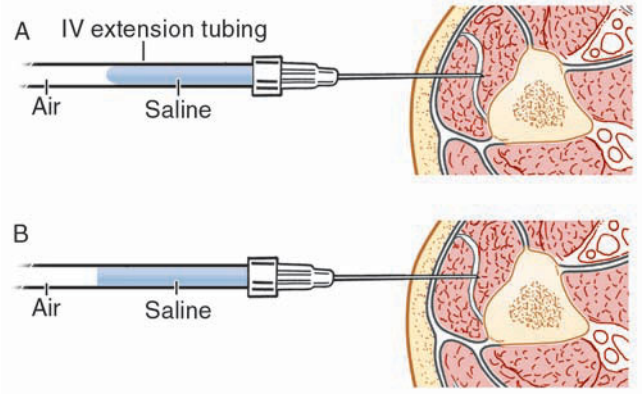

FIGURE 74-5. The air–saline interface. **A.** The air–saline meniscus will form a convex shape away from the patient when the tissue pressure is greater than the pressure of the system. **B.** The meniscus will flatten out when the pressure within the system equals that of the tissue.

depressed. **The point where the meniscus is flat and the saline column begins to move equals the pressure within the compartment (Figure 74-5B).** Note and document the pressure on the manometer.

It is important to equilibrate the system between measurements. With the needle still positioned in the tissue, pull back on the syringe plunger until the manometer reads 0 mmHg. Withdraw the needle from the tissue. This will prevent any saline from being deposited in the tissue. The same needle can then be reinserted in another location to obtain additional pressure measurements if sterile technique was used throughout the procedure.

The needle puncture sites will bleed. It is important to complete the procedure by properly dressing these puncture wounds. Apply gauze over the puncture sites and tape it in place.

STRYKER METHOD

The Stryker intracompartmental pressure monitor system is a self-contained device that is convenient, accurate, and relatively easy to use (**Figure 74-6**). The unit should be kept in a secure, yet easily accessible location. The pressure monitor is a battery operated, reusable unit with a digital display (**Figure 74-6A**). The quick pressure monitor pack is a disposable, single-patient-use kit that contains a needle, the diaphragm chamber, and a saline-filled syringe (**Figure 74-6B**).

Turn the pressure monitor unit on. The digital display should read 0 to 9 mmHg. The steps for setting up the system must be performed using sterile technique. Take the diaphragm chamber from the quick pressure monitor pack. This chamber ensures sterility between the system and the patient. Place the 18 gauge, 2.5 in side-ported needle firmly on the smaller tapered stem of the diaphragm chamber (**Figure 74-7A**). **This needle must remain sterile.** Uncap the 3 mL syringe filled with sterile normal saline and screw it onto the larger stem of the diaphragm chamber (**Figure 74-7A**). Open the clear plastic lid of the monitor unit. Place the needle–diaphragm chamber–syringe unit on the monitor such that the diaphragm chamber sits in the well (**Figure 74-7B**). Push down gently so that the diaphragm chamber is firmly and evenly positioned on the monitor. Close the cover so that a snap is heard at the latch site.

Hold the monitor unit so that the needle is at a 45° angle from the horizontal. Depress the plunger of the syringe to pass saline through the diaphragm chamber and needle until saline drips from the tip of the needle. This will remove any air within the system. Position the needle next to the skin at the angle needed for insertion.

FIGURE 74-6. The Stryker intracompartmental pressure monitor system. **A.** The Stryker pressure monitor unit. Note the power switch, zero button, and digital readout. Under the clear plastic cover, the round well will secure the disposable drum, while the syringe will clip into the plastic bracket at right. **B.** The quick pressure monitor pack contains (*from left to right*): an 18 gauge, 2.5 in side-ported needle, the diaphragm chamber, and a 3 mL syringe filled with sterile saline.

Press the "zero" button on the pressure monitor. The display should read "00" after a few seconds. **Insert the needle into the desired compartment at the same angle used during the zeroing process (Figure 74-8).** Slowly inject 0.3 mL of saline into the compartment. This volume of fluid is used to equilibrate with the interstitial fluids. Wait a few seconds as the system is measuring the compartmental pressure. The final compartmental pressure measurement will be displayed on the digital screen. Remove the needle from the patient.

Reset the system to zero before taking additional measurements. This is accomplished by positioning the needle at a new site and desired angle of insertion and pressing the zero button. This must be repeated between each measurement. Apply bandages over the skin puncture sites.

An optional indwelling slit catheter set is also available for use on the Stryker pressure monitor. This set substitutes a slit catheter, breakaway needle, and extension tubing for the side-ported needle. The slit catheter is intended to be left within the patient so that multiple sequential intracompartmental pressure measurements may be obtained. This is not intended for use in the ED.

ARTERIAL MANOMETER TECHNIQUE

The third method of checking compartment pressures in the ED requires only an 18 gauge needle or angiocatheter, arterial line tubing, and an arterial manometer set up as if for an arterial line. For a one-time reading, use a straight or side-port needle. If continuous

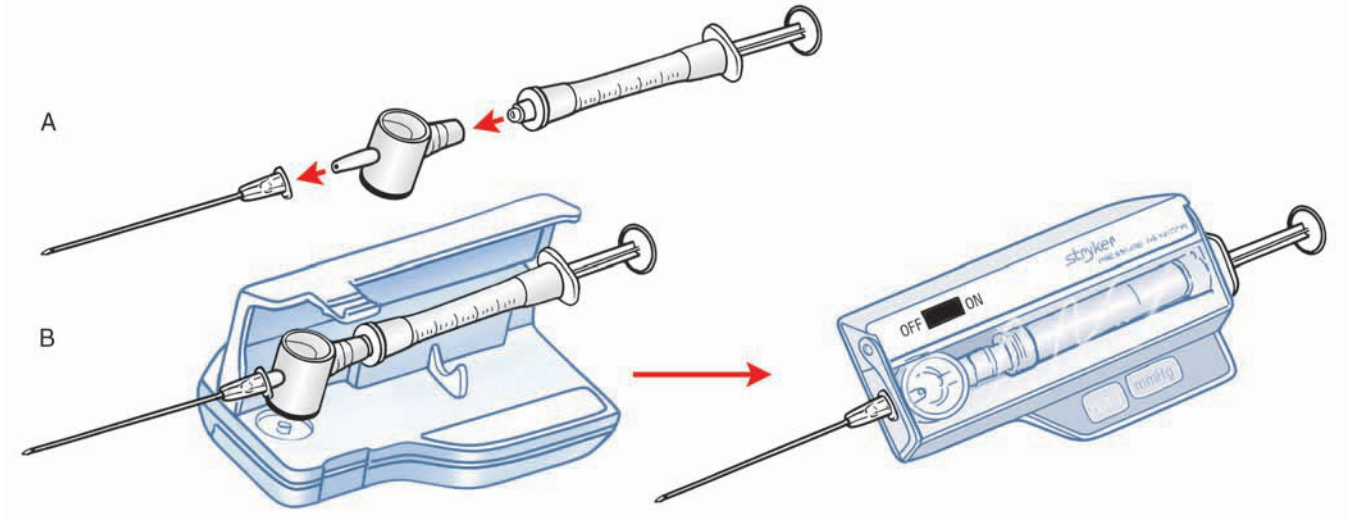

FIGURE 74-7. Assembly of the Stryker system. **A.** The contents of the quick pressure monitor pack are assembled. **B.** The assembled needle–diaphragm–syringe is placed onto the monitor unit.

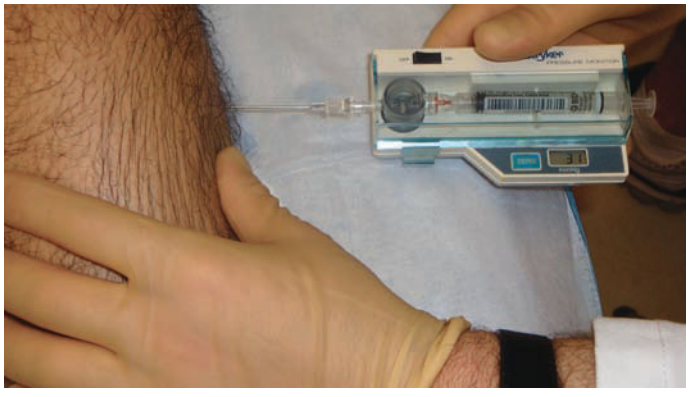

FIGURE 74-8. The needle is inserted into the desired compartment and the pressure measurement read on the digital display.

compartment pressure monitoring is preferable, use an 18-gauge angiocatheter. Attach the desired needle or angiocatheter to the end of the arterial line tubing, which leads to the prepared arterial manometer. Flush the entire line with sterile saline. Place the tip of the needle adjacent to the skin insertion site and zero the system. Insert the needle into the compartment and slowly infuse 0.3 mL of sterile saline to equilibrate the system with the interstitial pressure. The manometer will provide continuous real-time measurement of the compartment pressure for as long as the needle or angiocatheter remains in place.

AFTERCARE

Control any bleeding from the skin puncture sites with direct pressure. Apply gauze and tape dressings to all puncture sites. Perform and document a repeat neurovascular exam of the extremity distal to the procedure site.

COMPLICATIONS

There should be no complications for the patient if sterile technique is maintained throughout this procedure. Inserting a needle into a tissue compartment introduces the theoretical risk of infection or damage to the nerves or vessels. No study has shown this to be a significant complication.

A realistic complication of the procedure is obtaining erroneous values. The greatest risk to the patient is if an artificially low pressure is obtained and the needed fasciotomy is not performed. Although false high-pressure readings may also be obtained, the consequences of receiving an unnecessary fasciotomy are less disastrous.

It is important to understand how the mechanics of the needle-manometer system can alter the pressure readings. Injection of normal saline into the tissue will raise the pressure reading. The manometer reading will not accurately reflect the pressure of the compartment if the needle is inserted into a tendon rather than the muscle. A piece of tissue from the compartment can obstruct the needle and lead to erroneous pressure measurements. Failing to match up the saline–air meniscus with the level of the needle in the tissue can produce false pressure measurements as well.

One must take multiple pressure measurements around the injury site. To decide whether or not to perform a fasciotomy on an isolated pressure reading is to proceed without all the necessary data. It becomes difficult to simply observe the patient when they clinically present with increasing pain and features suggestive of a compartment syndrome when the compartmental pressure measurement is normal. Thus, multiple readings must be taken when suspicion is high and the compartment pressures are read as normal.

SUMMARY

A compartment syndrome is a well-documented phenomenon. The clinical presentation is variable and changes over time. It is a difficult clinical diagnosis that is critical for the EP to make in a timely fashion. While the most common sites are the lower leg and forearm, compartment syndrome can occur in any muscle compartment of the body. Determining the pressure within a compartment is a fundamental and essential tool to aid in this diagnosis. Many methods exist for the measurement of compartment pressures. Use of the traditional needle manometer system, the Stryker pressure monitor kit, and the arterial manometer are three established techniques that can easily be performed in the ED. These techniques represent the standard of practice in most EDs. Other methods using noninfusing catheter tips and emission tomography are under investigation as potentially noninvasive procedures.[25,26] Any concern for a compartment syndrome should be followed up with an emergent Orthopedic Surgeon or General Surgeon consultation in the ED, as continuous observation and repeated measurements are often indicated. Pressures over 30 mmHg or within 30 mmHg of the diastolic blood pressure warrant an emergent evaluation for a possible fasciotomy and limb salvage.

75 Fasciotomy

Justin Mazzillo, Sobia Ansari, and Eric F. Reichman

INTRODUCTION

A compartment syndrome is a serious and sometimes catastrophic entity that can lead to irreversible local and systemic damage.[1] It typically results from increased interstitial pressure in a closed and confined space that leads to inadequate perfusion and impaired function of the tissues contained within that space. Locally, a compartment syndrome may lead to loss of function, contractures, rhabdomyolysis, infection, and amputation. This can be followed by systemic complications such as renal failure, sepsis, and possibly death.[2] Common causes of a compartment syndrome include circumferential burns, constrictive dressings, crush injuries, electrical injuries, exercise, external compression of a limb, external trauma to the extremity, open or closed fractures, reperfusion after a vascular insult, snakebites, and tight fitting casts or splints (**Table 74-1**).[1–20]

The difficulty in diagnosing a compartment syndrome is that the physical examination is a poor indicator of the degree of microcirculatory compromise.[3] The diagnosis requires a high level of suspicion on the part of the Emergency Physician. Refer to Chapter 74 regarding the complete details of a compartment syndrome. **Maintaining a low threshold for performing a fasciotomy can be the safest course for the patient. The prognosis is more favorable if a fasciotomy is performed soon after the onset of symptoms.** If delayed, there may be little or no benefit to performing a fasciotomy.

ANATOMY AND PATHOPHYSIOLOGY

The anatomy of a compartment syndrome is variable, as it can occur in any enclosed muscle group. Any muscle tissue that is confined in space by fascia, skin, or any external forces (e.g., casting material) is a potential site for the development of a compartment syndrome.

The muscles, nerves, and vasculature within the affected muscle group are all potentially compromised by a prolonged ischemic state followed by swelling. A basic knowledge of the anatomy of commonly affected compartments is necessary to successfully and safely perform a fasciotomy.

The initial imbalance of a compartment syndrome occurs between the volume and pressure within the myofascial compartment. The arterial inflow and venous outflow diminish as either intracompartmental volume or pressure increases. The blood begins to be shunted via capillaries into the muscle tissue. This compensatory shunting of blood further disturbs the volume–pressure balance, resulting in impaired tissue oxygenation.

Skeletal muscles, major nerves, and major blood vessels of the extremities are contained within a noncompliant connective tissue membrane known as the investing or deep fascia. Connective tissue septa from the investing fascia to the bones of the extremities form compartments within the extremity. Each fascial compartment has a relatively constant range of pressure within it in which perfusion is maintained.[3] Under normal circumstances, the compartment pressure is ≤10 to 12 mmHg. Any of the previously mentioned insults may set off a cascade of events. This includes edema, hemorrhage, and/or external compression. The pressure within the compartment begins to rise. A critical pressure is reached within the compartment and perfusion is impaired. This results in altered metabolic processes, muscle cell death, cell wall dysfunction, and vascular compromise. This eventually leads to extravasation of intracellular contents and edema within the enclosed space, further raising compartment pressures.[4]

Increased intracompartmental pressure, from edema or hemorrhage within the compartment or from external compression, affects perfusion. Compartmental perfusion is a dynamic process, which is maintained by arterial blood pressure and limited by the absolute compartment pressure. Elevated compartmental pressure leads to venous outflow obstruction and eventually tissue ischemia.

Skeletal muscle and peripheral nerves can survive under ischemic conditions for up to 4 hours before irreversible damage begins to occur. At 6 hours of ischemia, muscle and nerve injury may still be reversible. Ischemia for greater than 8 hours, however, will lead to irreversible damage to muscles and nerves.[5] The resulting ischemic contractures of the extremities were described over 100 years ago by Richard Von Volkmann and are now referred to as "Volkmann's ischemic contracture." Treatment of a compartment syndrome with a fasciotomy was first suggested in 1906 by Bardenheuer.[6]

The pertinent anatomy for each fasciotomy described is included in the respective techniques section. Refer to Chapter 74 for the details of the anatomy, pathophysiology, evaluation, and diagnosis of a compartment syndrome.

Clinical signs of a compartment syndrome consist of the 5 "Ps" for any region at risk. These include pain out of proportion to exam, paresthesias, pallor, pulselessness, and paralysis. Some may choose to include poikilothermia as the sixth "P."[4] These clinical findings are generally late findings and may be completely absent early in the course of the disease process. Measure the compartment pressures when any signs or a clinical suspicion exists for a compartment syndrome. Refer to chapter 74 for the complete details of compartment pressure measurement.

INDICATIONS

Classically, it has been taught that a fascial compartment with an absolute pressure of greater than 30 mmHg will require a fasciotomy. Other factors besides the absolute compartmental pressure contribute to tissue perfusion and should be taken into account when deciding to perform a fasciotomy. Hypertension may be protective of perfusion whereas hypotension may further compromise perfusion.[1] More recently, a "delta *P*" or ΔP of less than 30 mmHg has been suggested as a better indication for performing a fasciotomy.[3] The ΔP is calculated as the difference between the diastolic blood pressure and the absolute or measured compartment pressure.

Maintaining a low threshold for performing a fasciotomy can be the safest course in patients who are at risk of extremity ischemia.[7] Any patient with the appropriate history and any of the clinical signs of a compartment syndrome should be considered a candidate for a fasciotomy. Strongly consider performing a fasciotomy if the patient has a fascial compartment with a $\Delta P < 30$ mmHg. An absolute compartment pressure ≥30 mmHg, or ≥20 mmHg if the patient is hypotensive, combined with any clinical signs of a compartment syndrome is an indication for a fasciotomy. The prognosis is favorable if the fasciotomy is performed within 30 hours of symptom onset.[8] If delayed longer, there is usually little or no benefit. This is particularly true if the fasciotomy is performed greater than 2 days after the onset of symptoms.

CONTRAINDICATIONS

A fasciotomy in the setting of a true compartment syndrome has few absolute contraindications. Any life-threatening conditions must first be addressed. If performed beyond the third or fourth day after symptom onset, there is a high incidence of severe infections.[8] A fasciotomy should not be performed if the Emergency Physician is not familiar with the local anatomy or the technique.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Face mask and cap
- Sterile gloves and gown
- Sterile drapes or towels
- Equipment for compartment pressure measurement (refer to Chapter 74)
- 4 × 4 gauze squares
- # 10 scalpel blade on a handle
- Tissue forceps
- Metzenbaum scissors
- Curved forceps
- Surgical retractors
- Kerlix dressings
- Splint material

PATIENT PREPARATION

Perform and document a thorough neurological and vascular examination of the affected extremity.[1] Remove any constrictive dressings, casts, and/or splints that may be contributing to the increased compartment pressures. Place the patient supine on the gurney so that the limb at risk is at heart level. If time is permissible and a Surgeon is available, it may be more appropriate to perform the fasciotomy in the Operating Room by an experienced Surgeon. This is often not possible and the fasciotomy must be performed in the Emergency Department.

Inform the patient and/or their representative of the risks, benefits, complications, and aftercare associated with a fasciotomy. The procedure must be performed using strict aseptic technique.

The Emergency Physician and any assistants must be wearing sterile gloves, a sterile gown, a face mask, and a cap. Clean the extremity of any blood, dirt, and debris. Apply povidone iodine or chlorhexidine solution to the extremity and allow it to dry. Apply sterile drapes or towels to isolate the extremity and form a sterile field. Collect and place all required supplies on a bedside table covered with a sterile drape. Using a sterile marking pen, draw the incision lines onto the skin prior to making any incisions.

A fasciotomy is a painful procedure. If the patient is conscious, some form of analgesia is required. The infiltration of local anesthetic solution provides appropriate analgesia. Ensure that the toxic dose of the selected local anesthetic solution is not exceeded (Chapter 123). Alternatives include a regional nerve block (Chapter 126) or procedural sedation (Chapter 129).

TECHNIQUES

THE ARM

The arm consists of three compartments (**Table 75-1 & Figure 75-1**).[9] The anterior compartment contains the biceps, brachialis, and coracobrachialis muscles. The posterior compartment contains the triceps muscle. The proximal anterolateral arm contains the deltoid compartment.

A fasciotomy of the arm requires two longitudinal incisions. Decompress the anterior compartment with a longitudinal incision over the entire anterior surface of the arm overlying the biceps muscle (**Figures 75-1 & 75-2A**). Decompress the posterior compartment with a longitudinal incision on the posterior surface of the arm overlying the triceps muscle (**Figures 75-1 & 75-2B**). Use a #10 scalpel blade to cut through the skin and subcutaneous tissues down to the level of the investing fascia. Carefully cut the fascia parallel to the skin incision with a scissors. The fascial incision should be the same length of the skin incision. **Use caution so as not to cut the muscle itself.**

A fasciotomy of the deltoid compartment muscle may occasionally be indicated. The deltoid muscle has three heads that are separated by septae. Therefore, it is often necessary to decompress each muscle belly.[10] Begin the skin incision over the anterior origin of the deltoid muscle (**Figure 75-3**). Extend the incision superiorly and laterally, going just lateral to the acromion process. Continue the incision posteriorly along the origins of the posterior deltoid muscle. Use a #10 scalpel blade to cut through the skin and subcutaneous tissues down to the level of the investing fascia. **The cutaneous branch of the axillary nerve becomes superficial inferior and posterior to the acromion and continues anteriorly over the lateral deltoid muscle. It should not be cut when performing a fasciotomy.** It may be necessary to decompress each fascial compartment. Carefully cut open the fascia of the anterior deltoid muscle with a scissors. **Use caution so as not to cut the muscle itself.** Measure the compartment pressure in the remaining two compartments. Sometimes, decompressing one compartment allows the remaining compartment(s) to spontaneously decompress. If elevated, incise the fascia of the second compartment. Measure the pressure of the remaining compartment. If elevated, incise the fascia of that compartment.

THE FOREARM

The forearm is one of the most common regions afflicted by a compartment syndrome.[1,11,12] The forearm consists of three compartments that are interconnected at various levels. This interconnection is significant because release of the pressure in one compartment will reduce some of the pressure in the adjacent compartments. **The volar compartment is most at risk for development of a compartment syndrome in traumatic injuries of the forearm.**[11] This is followed by the dorsal compartment then the lateral compartment. The lateral compartment is the easiest compartment to decompress because it is located superficially.[5]

The forearm includes the volar, dorsal, and mobile wad compartments (**Figure 75-4**). The contents of each forearm compartment are listed in **Table 75-2**. The volar compartment contains all of the hand and forearm flexor muscles, the median and ulnar nerves, and the radial, ulnar, and common interosseous arteries. The mobile wad contains the brachioradialis, the extensor carpi radialis brevis, and the extensor carpi radialis longus muscles. No major arteries or nerves are contained within this compartment. The radial artery and a branch of the radial nerve may sometimes lie between the mobile wad and the volar compartment. The dorsal compartment contains the hand and forearm extensor muscles, the posterior interosseous artery, and the posterior interosseous nerve.

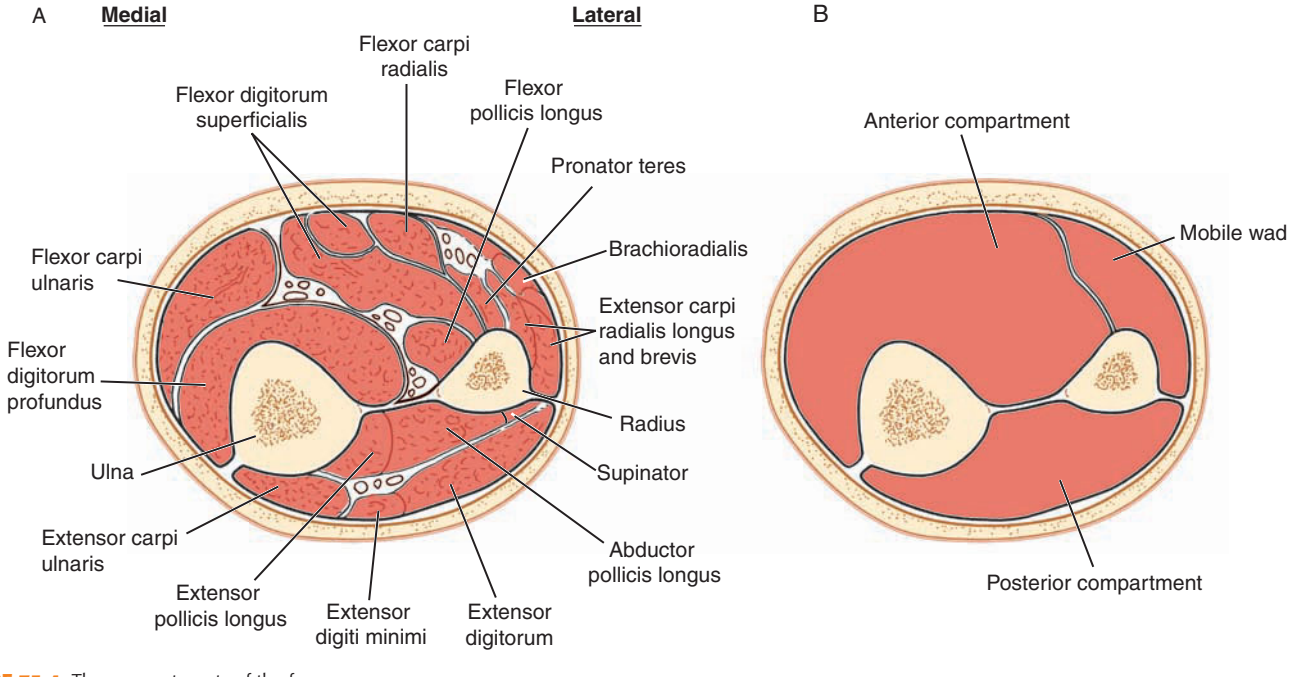

FIGURE 75-4. The compartments of the forearm.

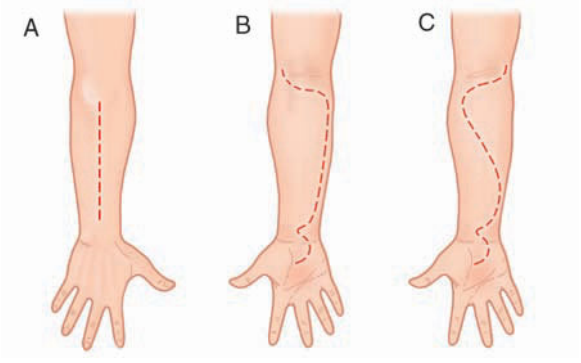

FIGURE 75-5. Fasciotomy incisions for the forearm. **A.** The dorsal incision. **B.** The anterior volar-ulnar incision. **C.** The volar curvilinear incision.

The volar and dorsal compartments can be further subdivided into superficial and deep muscles. Evaluation of the deep muscles becomes important when these muscles are preferentially injured. This includes electrical injury as the bone transmits thermal injury to adjacent muscles, crush injuries, sepsis, and prolonged external pressure on the forearm.

Decompression of the volar compartment can lead to the simultaneous decompression of the other compartments. Thus, a volar fasciotomy is generally performed first.[11] There are multiple approaches to making the incision for a forearm fasciotomy (**Figure 75-5**). This section chapter will describe the volar-ulnar incision for the anterior fasciotomy (**Figure 75-5B**). Some authors feel that this incision is associated with the least amount of iatrogenic injury.[1,12,13]

Place the patient supine with their arm supinated on a bedside table to decompress the volar compartment. Begin the incision proximally and laterally to the antecubital fossa. Extend the incision transversely and distally across the antecubital fossa until it reaches the anteromedial aspect of the antecubital fossa. Continue the incision distally on the anteromedial surface of the forearm toward the wrist. Just proximal to the wrist, extend the incision in an S-shape toward the radial aspect of the forearm while remaining just proximal to the wrist. **Do not extend the incision as lateral as the radial artery pulse.** Continue the incision back medially to the midline of the wrist. Continue down the midline of the wrist and make a turn along the thenar crease. **Be sure to incise deep enough to include the superficial fascia along the length of the entire forearm without cutting into the muscles or tendons.**

Identify the median nerve proximally. Release the bicipital aponeurosis at the level of the antecubital fossa and overlying the median nerve. Retract the flexor carpi ulnaris muscle medially and the flexor digitorum superficialis muscle laterally. Follow the median nerve all the way to the carpal tunnel. Decompress the median nerve at the carpal tunnel. **Be careful not to injure the ulnar artery, ulnar nerve, and the palmar cutaneous branch of the median nerve.** Incise the superficial palmar fascia in the midline followed by incising the transverse carpal ligament in the midline.

At this point, the superficial forearm contents are completely open and the deep contents of the volar compartment are exposed. Inspect the flexor digitorum profundus, flexor pollicis longus, and pronator quadratus muscles. Using aseptic technique, measure the pressures within the deep muscles to determine whether the fascia covering these muscles needs to be incised. If the muscle pressures are greater than 15 to 20 mmHg, incise the deep fascial coverings.

The major disadvantage to the volar-ulnar incision is that the mobile wad is not easily accessible via this incision. If the mobile wad is at risk, it may be reached through the dorsal incision (**Figure 75-5A**) as described below. It may also be reached through a different volar approach such as the volar-curvilinear incision (**Figure 75-5C**).

If a fasciotomy is indicated for the dorsal compartment, place the patient prone if not contraindicated and their arm extended on a bedside table. If the patient is supine, completely flex the supinated arm so that the dorsal surface is exposed. Make the incision along a line between the lateral epicondyle of the humerus and the distal radioulnar joint (**Figure 75-5A**). Be sure to incise the fascia along the entire length of the incision. **It is important to avoid incising too deep at the wrist and cutting the extensor retinaculum.** If the skin is adequately undermined, the mobile wad will be accessible via this approach.

Although the carpal tunnel does not contain muscle bellies and is thus not a true compartment, it can achieve acute compartment syndrome physiology.[10] Some authors recommend routinely decompressing the carpal tunnel during a forearm fasciotomy while others maintain that doing so is of limited benefit.[7,14] This decision is left to the Physician performing the fasciotomy. Many important structures run through the carpal tunnel including the median nerve. Structures within the carpal tunnel become compromised at pressures greater than 40 mmHg. The signs and symptoms will be similar to a chronic carpal tunnel syndrome, but more severe.

A carpal tunnel release can be performed as part of the forearm fasciotomy as described above or as an isolated procedure. To perform an isolated carpal tunnel release, begin the skin incision on the proximal portion of the hand between the thenar and hypothenar creases.[10,14] Extend the incision proximally toward the flexor crease of the wrist. Make a slight ulnar deviation of the incision so that the flexor crease is not crossed at a 90° angle. This will prevent injury to the palmar branch of the medial nerve as it courses between the palmaris longus and the flexor carpi radialis tendons. Reflect the skin edges to identify the superficial palmar fascia and the transverse carpal ligament. Make a longitudinal midline incision though the superficial palmar fascia and the transverse carpal ligament.

THE HAND

There are 11 compartments in the hand. This includes the midpalm, hypothenar, thenar, adductor pollicis, four dorsal interosseous, and three palmar or volar interosseous compartments (**Figure 75-6 & Table 75-3**).[10] Each hand compartment is completely isolated from

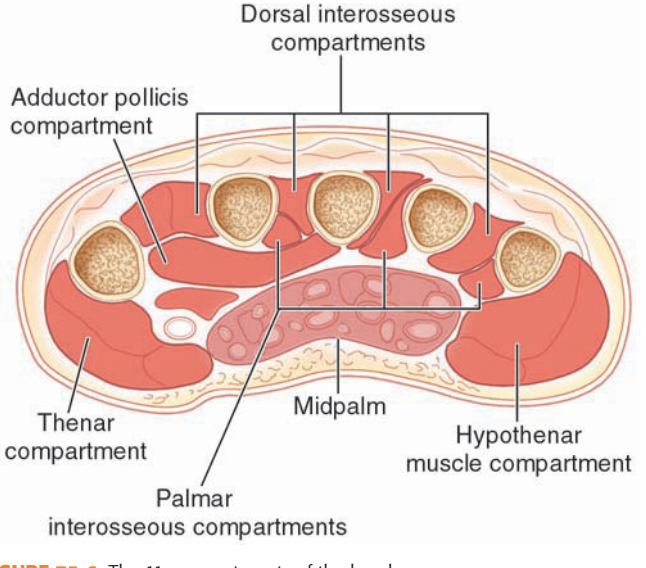

FIGURE 75-6. The 11 compartments of the hand.

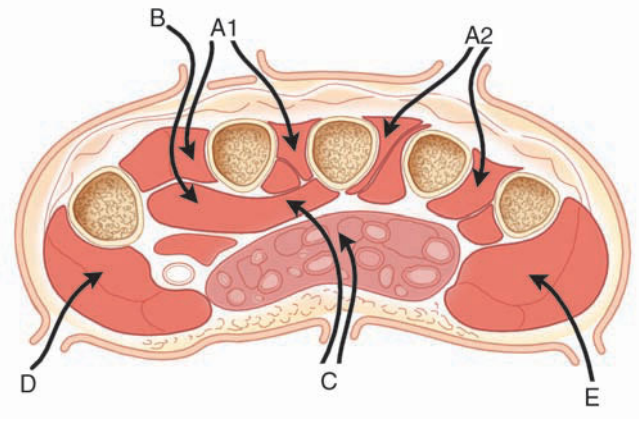

FIGURE 75-7. Fasciotomy incisions for the hand. **A.** Dorsal and palmar interosseous compartments. **B.** The adductor pollicis compartment. **C.** The midpalm compartment. **D.** The thenar compartment. **E.** The hypothenar compartment.

the others. Decompression or release of one compartment will not help to decompress any of the others. The pressures required to cause an acute compartment syndrome in a hand compartment may be as low as 15 to 20 mmHg.

Decompress the dorsal interosseous, palmar interosseous, and adductor compartments through dorsal incisions (**Figure 75-7**). Decompress the first and second dorsal interosseous compartments with a 3 to 4 cm long incision over the second metacarpal (**Figure 75-7A(1)**). Extend the incision into the fascia on both sides of the metacarpal to access the compartments. Continue deeper, using gentle blunt dissection, to access the adductor compartment on the radial aspect and the first palmar interosseous compartment on the ulnar aspect (**Figure 75-7B**). Decompress the third and fourth dorsal interosseous compartments with a 3 to 4 cm long incision over the fourth metacarpal (**Figure 75-7A(2)**). Incise the fascia on both sides of the metacarpal to access the compartments. Use gentle blunt dissection to access the second palmar interosseous compartment on the radial aspect and the third palmar interosseous compartment on the ulnar aspect.

To perform a fasciotomy of the thenar compartment, make a 3 to 4 cm long longitudinal skin incision over the thenar muscles on the lateral aspect of the hand, just volar to the first metacarpal (**Figures 75-7D & 75-8**). Continue the incision through the subcutaneous tissues until the thenar muscle fascia is visible. Carefully incise the fascia with a scissors. **Be careful to not cut the underlying muscle.**

To access the hypothenar compartment, make a 3 to 4 cm long longitudinal incision along the ulnar aspect of the fifth metacarpal over the hypothenar muscles (**Figures 75-7E & 75-8**). Continue the incision through the subcutaneous tissues until the hypothenar muscle fascia is visible. Carefully incise the fascia with a scissors. **Be careful to not cut the underlying muscle.**

The midpalm compartment of the hand is located between the thenar and hypothenar compartments (**Figure 75-6**). Make a 3 to 4 cm long longitudinal incision in the middle of the hand, between the thenar and hypothenar muscles (**Figure 75-7C**). If a fasciotomy of the forearm or carpal tunnel has already been performed, that incision can be extended distally to gain access to the fascia of the midpalm compartment. Continue the incision through the subcutaneous tissues until the fascia is visible. Carefully incise the fascia with a scissors. **Be careful to not cut the underlying muscle.**

THE DIGITS

The digits do not contain muscle bellies or true fascial compartments (**Table 75-4 & Figure 75-8**). The ligaments and restrictive skin create a contained compartment that can exhibit large pressure

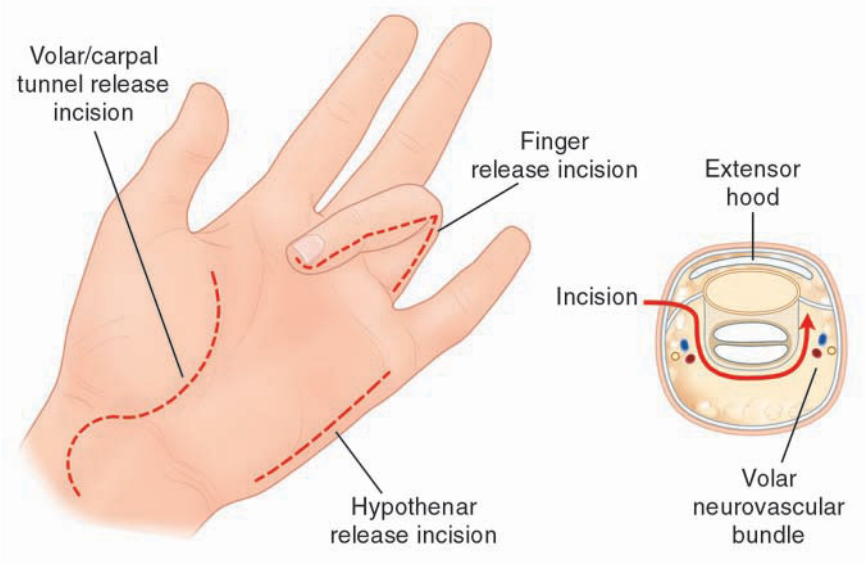

FIGURE 75-8. Fasciotomy incisions for the hand and fingers.

TABLE 75-4 The Compartments of the Digits and Their Contents

Compartment	Contents
Digits	Common palmar digital arteries Proper palmar digital arteries Proper palmar digital nerves Tendons Ligaments

increases, thus resulting in a compartment syndrome.[10] Cleland's and Grayson's ligaments are constrictive ligaments that encircle the finger and overlie the neurovascular bundles (**Figure 75-9**). Measurement of pressures in these "pseudocompartments" is very difficult. The indications for decompression are based more on clinical findings and suspicion. The fingers and toes have very similar anatomy and are managed in the same manner.

A fasciotomy of the digit is performed using a single midaxial longitudinal incision along the length of the digit. Make the incision along the ulnar aspect of the index, long, and ring fingers and along the radial aspect of the thumb and small fingers (**Figure 75-8**). **Be careful to avoid injuring the underlying neurovascular bundle.** Identify the neurovascular bundle and release any constrictive fascial bands from Cleland's or Grayson's ligaments (**Figure 75-9**). Continue dissecting along the palmar aspect of the flexor tendon sheath and release any vertical bands of connective tissue. If severe swelling is present with dysfunction of both the ulnar and radial neurovascular bundles, a second longitudinal incision can be placed on the opposite side of the digit to decompress the underlying neurovascular bundle.

THE THIGH

A compartment syndrome of the thigh is not common, despite how commonly femur fractures occur.[15] The pressure at which a compartment syndrome of the thigh develops is not known. A case report of three patients who developed a thigh compartment syndrome in association with a femur fracture noted that two of the patients had significant arterial bleeding into the thigh and the third had prolonged extrinsic compression of the leg. The Emergency Physician will need to rely on clinical signs and symptoms, measured pressures, as well as the mechanism of injury to make the diagnosis of a thigh compartment syndrome.

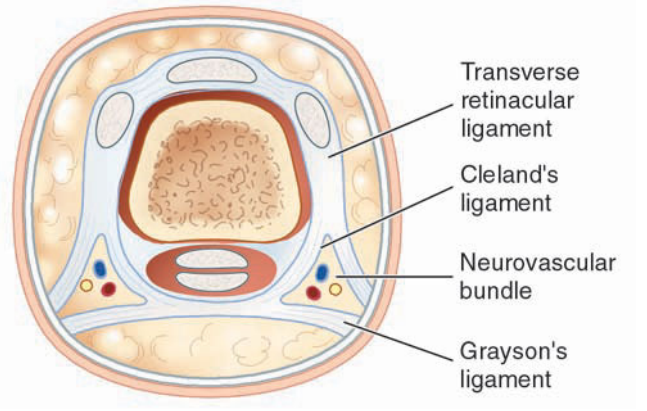

FIGURE 75-9. Cross section through a digit.

The thigh contains three compartments. These are the anterior, medial, and posterior compartments (**Figure 75-10**). They are separated from each other by intermuscular septa. The lateral intermuscular septum is the thickest of the three and separates the anterior and posterior compartments. The contents of the compartments are listed in **Table 75-5**.

Place the patient supine with their foot pointing upward. Expose the thigh from the iliac crest to the lateral epicondyle.[8] Begin the incision just distal to the intertrochanteric line and extend it to the lateral epicondyle (**Figure 75-11A**). Expose the iliotibial band, a thickening of the investing fascia, by subcutaneous dissection. Release the anterior compartment of the thigh by making an incision in the iliotibial band that parallels the skin incision. Retract the vastus lateralis muscle medially to expose the lateral intermuscular septum (**Figure 75-11B**). Make a 1.5 cm incision in the lateral intermuscular septum using Metzenbaum scissors. Extend the incision proximally and distally to decompress the posterior compartment. Once the anterior and posterior compartments have been decompressed, determine the pressure in the medial/adductor compartment. If the pressure is elevated, make a separate medial incision to release this compartment.

THE LEG

The leg is the most common location for a compartment syndrome.[1,6] A tibial fracture is the most common injury leading to a

leg compartment syndrome.[17] The lower leg consists of four distinct muscle compartments: anterior, lateral, deep posterior, and superficial posterior (**Figure 75-12**).[8,16] A detailed list of the contents of each compartment is noted in **Table 75-6**.

The anterior compartment contains the four extensor muscles of the leg. These muscles function together to dorsiflex the foot. The deep peroneal nerve travels through this compartment to innervate the extensors and provide sensory innervation to the web space between the first and second toes. The anterior tibial artery travels through this compartment and provides bloodflow to its contents.

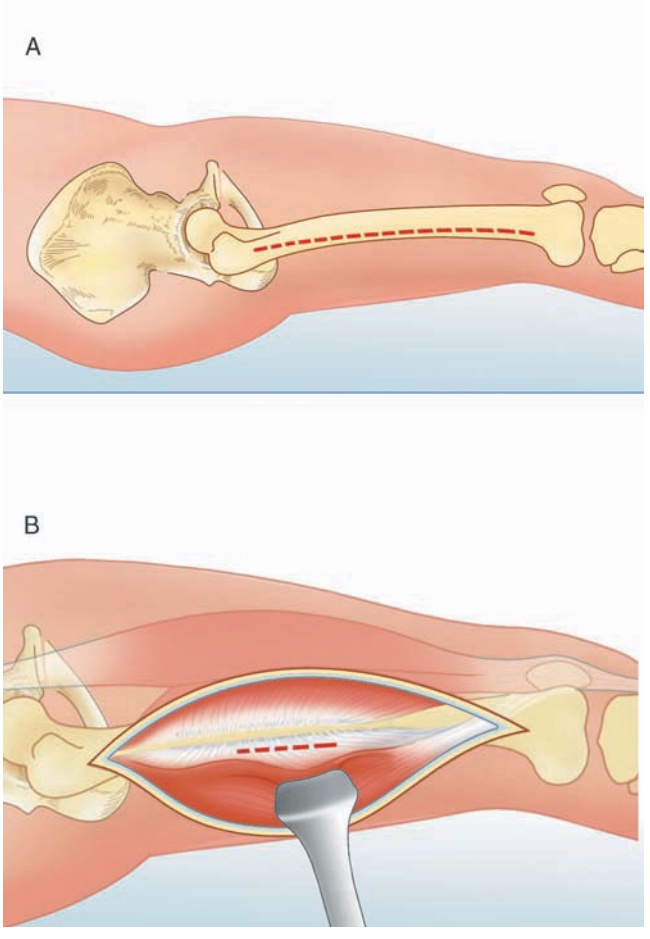

FIGURE 75-11. Fasciotomy of the thigh. **A.** The fasciotomy incision. **B.** The vastus lateralis muscle is retracted to expose the lateral intermuscular septum.

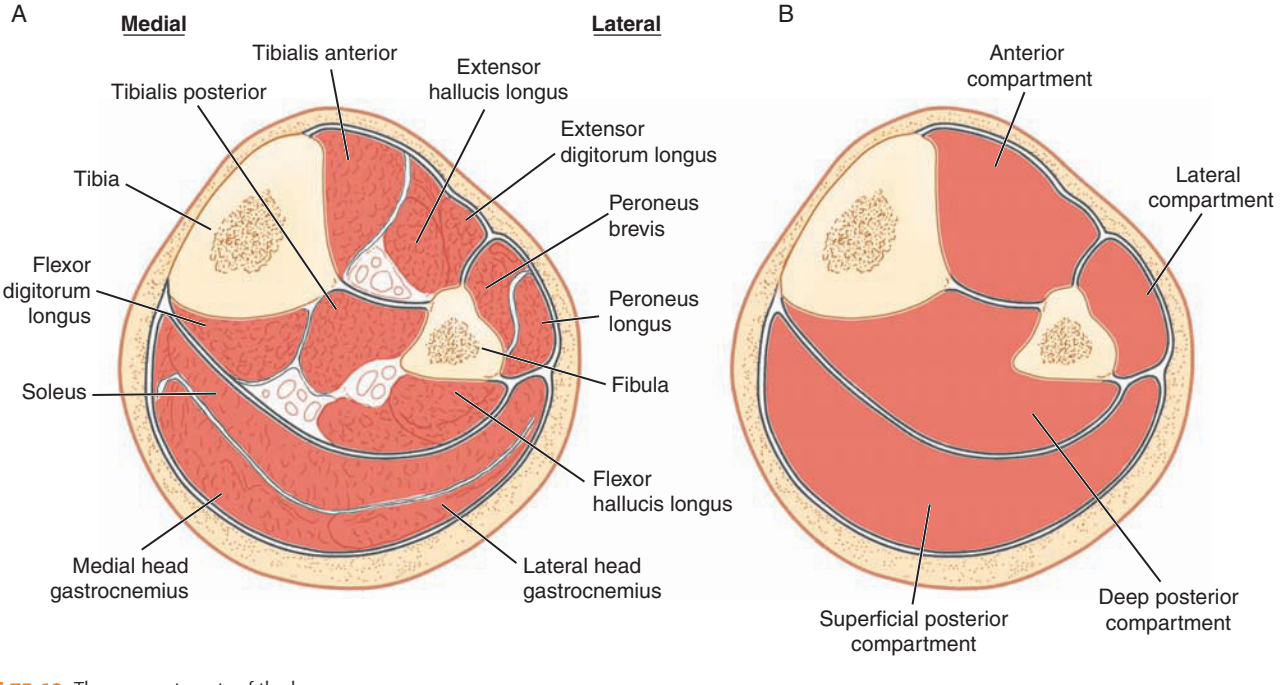

FIGURE 75-12. The compartments of the leg.

TABLE 75-6 The Compartments of the Leg and Their Contents

Compartment	Contents
Anterior	Tibialis anterior muscle
	Extensor hallucis longus muscle
	Extensor digitorum communis muscle
	Anterior tibial artery and vein
	Deep peroneal nerve
Lateral	Peroneus longus muscle
	Peroneus brevis muscle
	Superficial peroneal nerve
Superficial posterior	Gastrocnemius muscle
	Soleus muscle
	Plantaris muscle
	Sural nerve
Deep posterior	Tibialis posterior muscle
	Flexor hallucis longus muscle
	Flexor digitorum longus muscle
	Posterior tibial artery and vein
	Peroneal artery and vein
	Tibial nerve

The lateral compartment contains the peroneus longus and brevis muscles. Their chief function is to evert the foot, with some consequent abduction and plantarflexion of the foot. The major nerve in the lateral compartment is the superficial peroneal nerve to supply motor innervation to the compartment muscles and sensory innervation to the lower leg and dorsum of the foot.

A fascial layer divides the posterior muscle group into superficial and deep compartments. The superficial posterior compartment contains the muscles of plantarflexion (gastrocnemius, soleus, and plantaris tendons). No major nerves or blood vessels travel in the superficial compartment. The deep posterior compartment contains the four deep flexor muscles (flexor digitorum longus, flexor hallucis longus, tibialis posterior, and popliteus). This group of muscles contributes to inverting and adducting the foot in addition to flexing the toes and foot. The primary sensory innervation is from the tibial nerve, which courses through the deep posterior compartment. The tibial nerve supplies most of the muscles of the posterior compartment before dividing into several branches that provide sensory innervation to the sole of the foot. The posterior tibial artery and the peroneal artery are also contained within this compartment.

Although any of these compartments can suffer from ischemia, **the deep posterior compartment and the anterior compartment have the highest incidence of developing a compartment syndrome.**[21] It is difficult to simply observe the patient in the face of a normal compartmental pressure when they clinically present with increasing pain and the features suggestive of a compartment syndrome. **Thus, multiple compartmental syndrome readings must be taken when the suspicion is high and the compartmental pressures are normal.**

If the physical examination of the leg reveals clinical concern for a compartment syndrome of only one compartment, then a single-incision fasciotomy can be performed. However, in cases of prolonged limb compression or severe trauma, a double-incision fasciotomy for decompression of all compartments will be required.[16,18]

Perform an anterolateral incision to decompress the anterior and lateral compartments. Make a 20 to 25 cm long longitudinal incision between the fibular shaft and tibial crest (**Figure 75-13A**).[1] The incision will thus be located over the anterior intermuscular septum, allowing access to both the anterior and lateral compartments (**Figure 75-13C**). Undermine the skin edges to expose more of the fascial covering. Make a small transverse incision through the fascia at the midpoint of the incision to expose the intermuscular septum. **Be cautious not to cut the superficial peroneal nerve that lies just lateral to the septum.** Instruct an assistant to retract the skin edges. Open the anterior compartment using Metzenbaum scissors. Extend the facial incision longitudinally, both distally and proximally, the length of the skin incision. Next decompress the lateral compartment by incising the fascia longitudinally in a similar manner.

Perform a posteromedial incision to decompress the posterior compartments. The two posterior compartments can be decompressed with one skin incision (**Figure 75-13C**). Make a 20 to 25 cm long longitudinal incision 2 to 3 cm posterior to the posterior tibial margin (**Figure 75-13B**). Undermine the skin and subcutaneous

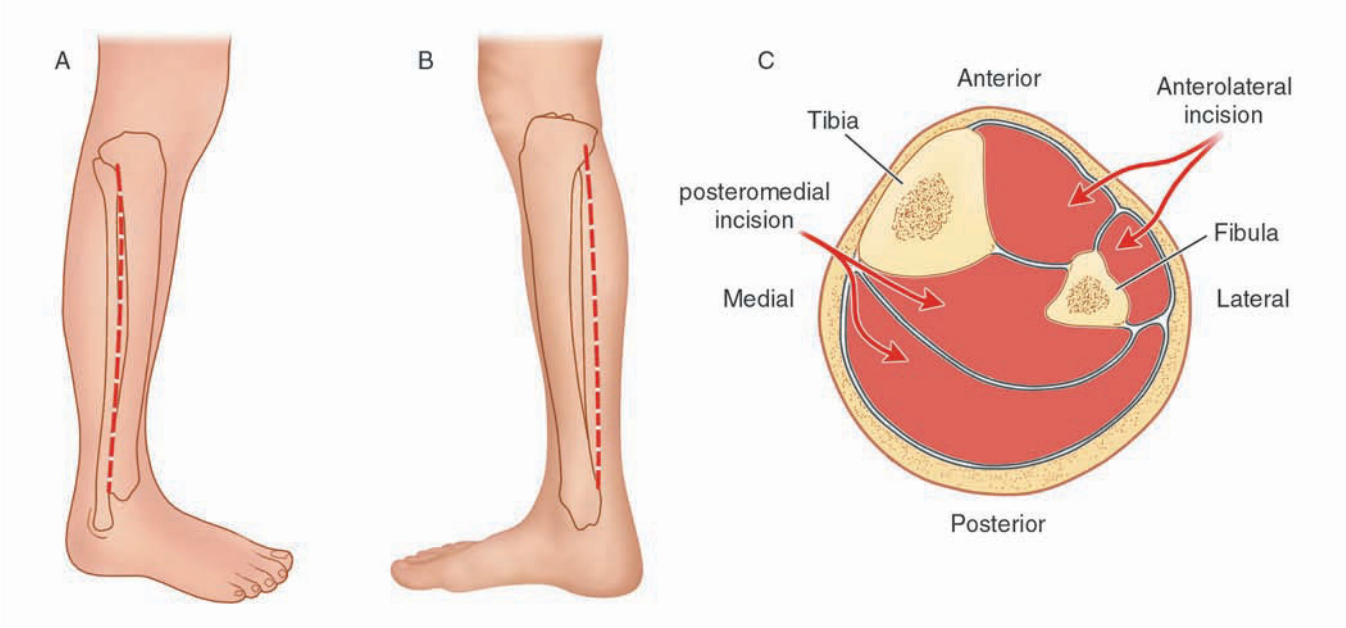

FIGURE 75-13. Fasciotomy incisions for the leg. **A.** The anterolateral incision. **B.** The posteromedial incision. **C.** Cross section through the leg demonstrating the fasciotomy incisions.

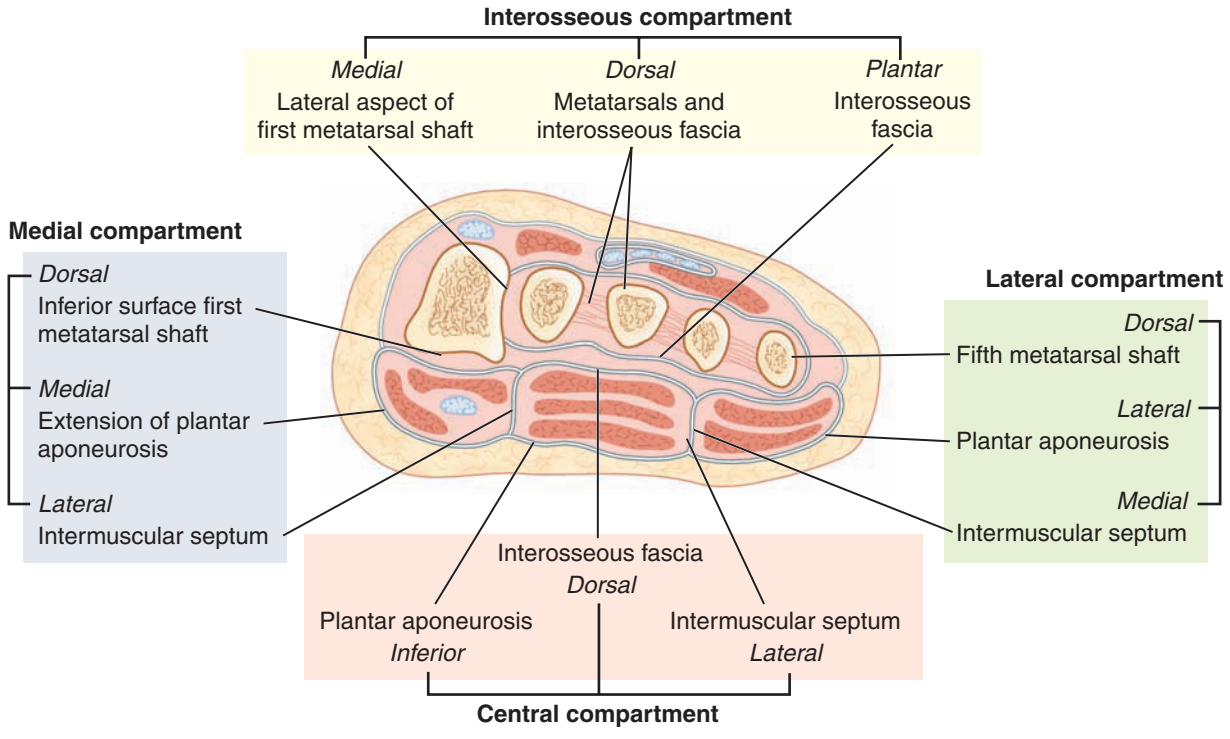

FIGURE 75-14. The compartments of the foot.

tissues on both sides of the incision. Instruct an assistant to retract the skin and subcutaneous tissue on both sides of the incision. Incise the fascia transversely to expose the septum dividing the deep and superficial posterior compartments. Decompress the superficial posterior compartment. Make a longitudinal incision posterior to the intramuscular septum, extending the length of the skin incision. Decompress the deep posterior compartment. Make a longitudinal incision starting from the anterior edge of the initial transverse incision. Extend this incision both proximally and distally.

THE FOOT

The number of compartments within the foot is a matter of controversy (**Figure 75-14**).[19] It was initially believed that there were four compartments. Further research has shown that up to nine compartments exist. Subsequent studies have shown that the barriers between many of these compartments break down at pressures greater than 10 mmHg, far less than that required to cause a compartment syndrome. For the sake of this chapter, we will divide the nine compartments into four groups: the intrinsic compartment that contains the four muscles between the first and fifth metatarsals, the medial compartment, the central compartment, and the lateral compartment.[20] A list of the contents of each compartment is noted in **Table 75-7 & Figure 75-14**.

There are two main incisions used to access the compartments of the foot and both approaches can potentially reach all of the compartments. The most popular approach is the medial approach (**Figure 75-15A**). Make the skin incision starting just below the medial malleolus. Continue the incision distally along the inferior border of the first metatarsal, but superior to the abductor muscle. Retract the skin edges. Identify the neurovascular bundle and retract it out of the way. Incise the fascia of the medial compartment. Continue incising laterally through the medial intermuscular septum of the medial compartment. The remaining compartments can be accessed by blunt dissection with a clamp or by performing additional incisions via the dorsal approach.

The dorsal approach can also be used to access all of the compartments but is best to access the interosseous compartments and the lateral compartment (**Figure 75-15B**). This approach is superior to the medial approach in the setting of metatarsal or Lisfranc fractures. Make the first incision along the medial aspect of the second metatarsal. Make the second incision along the lateral aspect of the fourth metatarsal. Incise the superficial fascia of each compartment and elevate the muscles off the bone for more effective decompression. Use a clamp to bluntly dissect, access, and decompress the remaining compartment (**Figure 75-14B**). The lateral compartment can be accessed and decompressed via the space between the fourth and fifth metatarsals. The central compartment can be accessed and decompressed via the spaces between the second and third and the third and fourth metatarsals. The medial compartment can be accessed and decompressed via the space between the first and second metatarsals.

ASSESSMENT

Aseptically measure all compartment pressures after each fasciotomy. As previously mentioned, many compartments communicate and a fasciotomy of one compartment may relieve the

pressure in others and obviate the need for additional fasciotomies. **After the fasciotomy is complete, compartment pressures should be measured again to ensure successful decompression.** Check multiple readings throughout the same compartment.[1] If compartment pressures are still elevated, ensure that the fascia is completely incised and consider increasing the length of the fasciotomy.

AFTERCARE

Once decompressed, the wound is left open. Apply sterile saline-soaked gauze into the incisions followed by a nonrestrictive and bulky dressing wrapped around the limb. The dressing should be loose and allow the wound to easily drain.[12] Splint the limb to prevent contractures. In cases where the decompressed limb has a fracture, the limb must be splinted so that the fractured bones are in appropriate alignment.[13] Consult the appropriate Surgeon (e.g., Hand, Orthopedic, Plastic, or Trauma) to manage the patient. The decision to administer prophylactic antibiotics should be made in consultation with the Surgeon. Admit the patient for further surgical care.

COMPLICATIONS

The goal of surgical decompression is to open the tight fascial layers.[13] Minimizing the length of the skin incisions or limiting the number of compartments decompressed will lead to substandard results. Continued edema and postischemic hyperemia in the first hours after a decompression can lead to increased compartment pressures in adjacent compartments that were not decompressed.

There is a significant risk of an iatrogenic injury to arteries, nerves, tendons, and veins during the fasciotomy.[1] A thorough understanding of the local anatomy and the procedure will help to minimize these injuries. Adequate visualization using proper overhead lighting and proper retraction will further minimize injury.

The diagnosis of a compartment syndrome may be delayed because of a missed diagnosis or because the patient does not present immediately to the Emergency Department. The Emergency Physician may be faced with a situation in which the muscles of the limb are in varying stages of ischemia, irreversible injury, and contracture. In these cases, performing a fasciotomy may predispose the limb to secondary infection with subsequent gram-negative sepsis.[12] The Emergency Physician must weigh the risks and benefits before proceeding. Consider consulting a Surgeon to assist in the decision to perform a fasciotomy.

Infection after a fasciotomy is a definite possibility. While the use of aseptic technique is mandatory, it does not prevent subsequent infections. The presence of crush injuries, myonecrosis, poor perfusion, preexisting peripheral vascular disease, and the patient immune status can predispose the site to an infection. The decision to use of broad-spectrum prophylactic antibiotics should be made in consultation with a Surgeon.

Hemorrhage is often minimal when performing a fasciotomy. Most hemorrhage can be controlled with direct pressure. Small subcutaneous blood vessels transected during the procedure can be controlled with electrocautery or figure-of-eight sutures.

SUMMARY

Emergency Physicians must have an understanding of the signs and symptoms of a compartment syndrome. Always maintain a high level of suspicion in patients presenting with limb injuries. The technique itself is quite simple as long as the incision is made in the proper location. Performing a fasciotomy in a timely fashion can prevent serious and irreversible consequences.

76 Extensor Tendon Repair

Jaime Harper, Stanley Harper, and Ramasamy Kalimuthu

INTRODUCTION

The Emergency Physician (EP) commonly encounters lacerations or trauma to the dorsum of the hand and forearm. In evaluating these patients, the possibility of extensor tendon lacerations must be considered. The extensor mechanism of the hand and forearm is typically disrupted in association with penetrating trauma. It must be remembered, however, that blunt trauma, such as sudden forced flexion, can also result in injury to the extensor tendons. Performing an extensor tendon repair is an important skill in the EP's surgical armamentarium.

Although the diagnosis of an extensor tendon injury must be identified at the initial examination, the timing of the tendon repair is not a critical aspect of its management. Successful repair of extensor tendons may be accomplished acutely, or within a 7 day window following the injury.[1] One should also be aware that at some

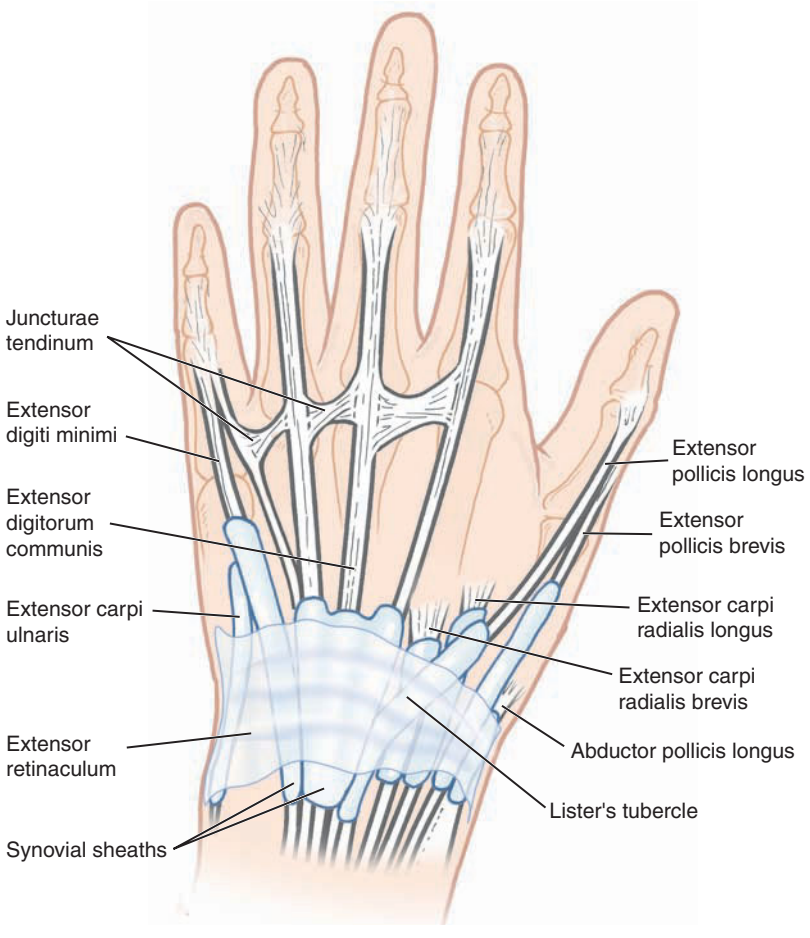

FIGURE 76-1. The extensor tendons of the hand begin just proximal to the extensor retinaculum. After exiting from under this encasing sheath, the tendons form an interconnected network as they cross the dorsum of the hand.

anatomic sites, splint immobilization of the damaged tendon can produce a similar outcome to surgical reapproximation. This is most evident in the conservative management of a mallet finger injury.

Repair of an extensor tendon by an EP requires them to have a familiarity with the anatomy of the region and be skilled in the surgical technique. Although complications of tendon repair are more frequently associated with flexor tendons, follow-up studies of extensor tendon repairs reveal similar pitfalls and problems.[2] Adhesions, loss of length, and diminished flexion can all complicate the repair of an extensor tendon.[3]

The anatomy of the extensor mechanism prevents tendon retraction far from the site of a laceration or partial disruption.[4] This is mostly due to the tethering of tendons by multiple interconnections as the tendons cross the dorsum of the hand. Additionally, the tendons over the dorsum of the hand are ensheathed in a paratenon layer of tissue. This covering is extrasynovial, thus containing the cut ends of the tendons in a tissue layer that prevents their wide separation. These properties frequently allow both ends of a lacerated extensor tendon to be located with local wound exploration, at which point they may be safely repaired.

The techniques for extensor tendon repair originate in studies of flexor tendons. **The goal of extensor tendon repair is to restore tendon continuity and function while minimizing interference from the repair itself.** The suture techniques of Kessler and Bunnell are two of the methods traditionally used in this repair. Modifications of these original methods have resulted in the greatest outcome measurements of tendon strength.[5] **Facility with these two suture techniques, as well as the anatomy, is essential to the repair of any extensor tendon in the Emergency Department (ED).**

ANATOMY AND PATHOPHYSIOLOGY

The extensor tendon mechanism is an intricate system of pulleys and levers coursing along the dorsum of the forearm, wrist, and hand.[6,7] The function of these tendons is to extend the fingers and wrist from a flexed position. This finger motion is complemented by the actions of the intrinsic hand muscle groups (i.e., lumbricals and interossei).

The elegant anatomy of the hand extensor mechanism is best appreciated in diagrammatic representation (**Figure 76-1**). The forearm tendons pass through the extensor retinaculum of the wrist to travel across the dorsum of the hand to each of the fingers. The extensor tendons are reinforced in the fingers by the lateral bands of the intrinsic hand muscles to form a complex tendon that inserts into the distal phalanx (**Figure 76-2**).

Knowledge of the anatomy of the extensor mechanism reveals certain salient points. The extensor retinaculum of the wrist is a complicated structure of fibrous canals through which the tendons pass and whose repair necessitates a Hand Surgeon's intervention. The paucity of soft tissue covering the dorsum of the hand makes the tendons quite vulnerable to penetrating trauma. The extensor tendons of the fingers are interconnected across the dorsum of the hand by the juncturae tendinum. This interconnection of tendons distributes the work of extension among the involved fingers. Redundancy is built into the extension of the first and small fingers with the presence of two separate extensor systems. An isolated tear of the extensor tendon of the index or small finger, therefore, may not result in lack of function because of the contributing band from the extensor digitorum communis

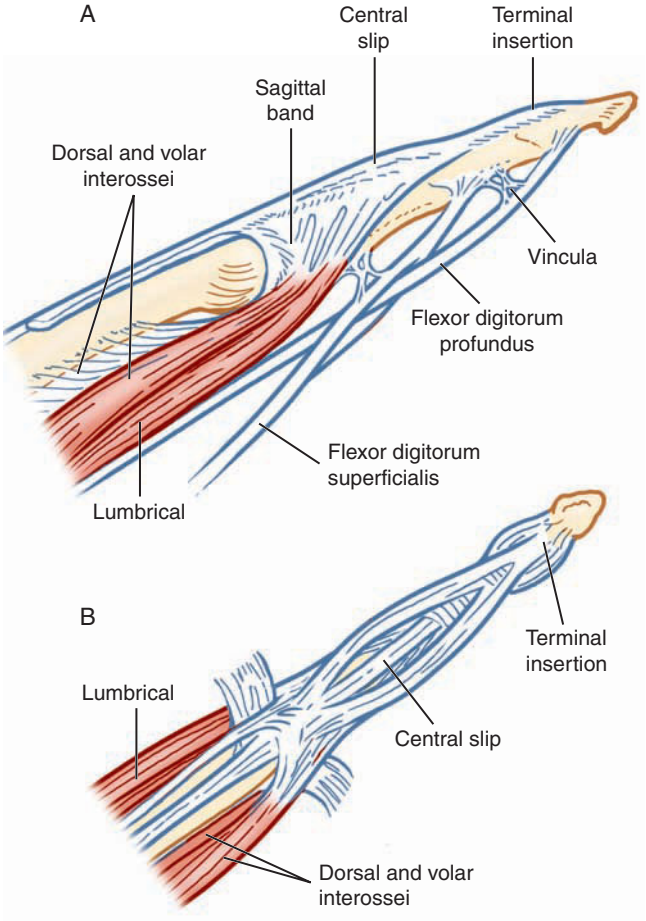

FIGURE 76-2. The central extensor tendons of the digits are reinforced and aided by the lateral bands of the interosseous and lumbrical muscles. The extensor tendon is tethered to the joint surface by a sagittal band, which forms a protective hood. **A.** Lateral view. **B.** Superior view.

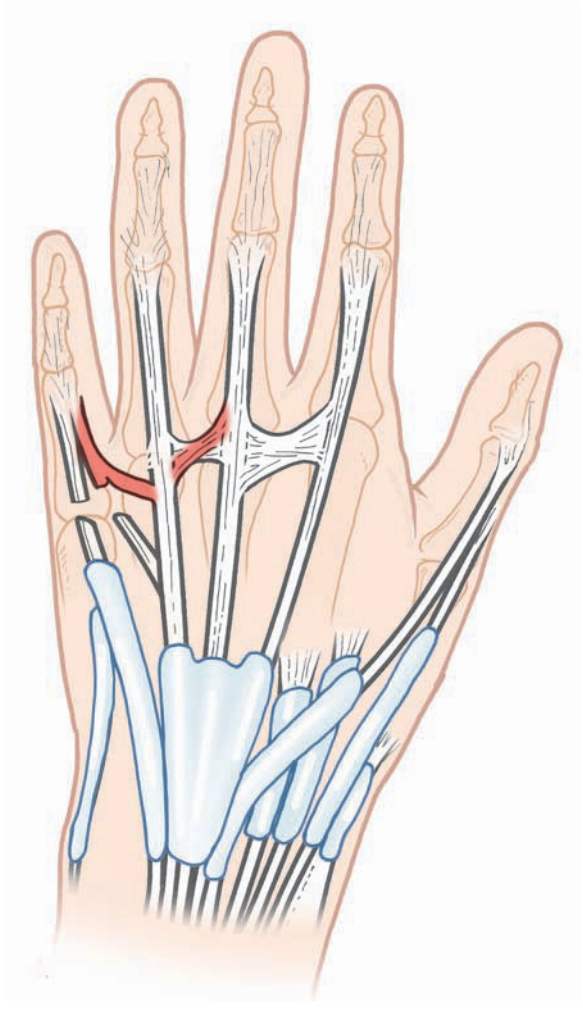

FIGURE 76-3. Division of an extensor tendon in the dorsum of the hand may still allow for full finger extension because of the communicating juncturae tendinum.

(**Figure 76-3**). It is important to realize that there is great anatomic variability in the detailed distribution of these tendons.

The location of an extensor tendon injury is important in determining whether tendon repair in the acute ED setting is feasible. A range of eight zones defines the location of an extensor tendon injury (**Figure 76-4**). The zone chart first described by Kleinert and Verdan helps to classify and organize the modes of repair.[8] The odd-numbered zones refer to areas over the joints, while the even-numbered zones refer to the bony areas. Although any zone can undergo injury and repair, the outcome is variable, depending upon the suture technique and the mode of rehabilitation.

INDICATIONS

The decision to surgically repair a lacerated extensor tendon is multifactorial. One must consider the extent of the tendon laceration, the involvement of other tissues (e.g., bone or joint space), and the location of the tendon injury. Studies that define a minimum laceration width that requires tendon repair have not been performed. **It is generally accepted that a laceration greater than 50% of the tendon width requires surgical repair.**[1] A tendon that has a laceration less than 50% of its width will usually heal with conservative management. **One must put the finger through its entire range of motion to confirm normal function and movement of the affected tendon prior to making the decision as to whether conservative management is appropriate.** A lacerated tendon that is associated with significant overlying skin loss, joint space penetration, or a bony fracture will require repair by an Orthopedic or Hand Surgeon.

Defining the location of the tendon injury according to the Kleinert zone system guides one in deciding what tendon lacerations can be safely repaired in the ED. Although there are no published guidelines on where these procedures should be performed, a thorough understanding of the extensor tendon's anatomy and a good dose of common sense are imperative.

The following zones and types of injury represent sites where extensor tendon repair in the ED is feasible with minimal complications. The thickness of the extensor pollicis longus allows for a core-type suture in zone 2 of the thumb. The broad configuration of the extensor tendon allows for a core-type suture in zone 4 of all digits. Isolated involvement of the extensor tendon allows for a core-type suture unless the joint is involved (rare) in zone 5 of the fingers. Isolated involvement of the extensor tendon allows for a core-type suture and good prognosis in zone 6 of the hand.

CONTRAINDICATIONS

There are definite contraindications to repairing an extensor tendon in the ED. First and foremost, the lack of skill on the part of the EP performing this repair may result in loss of function or may

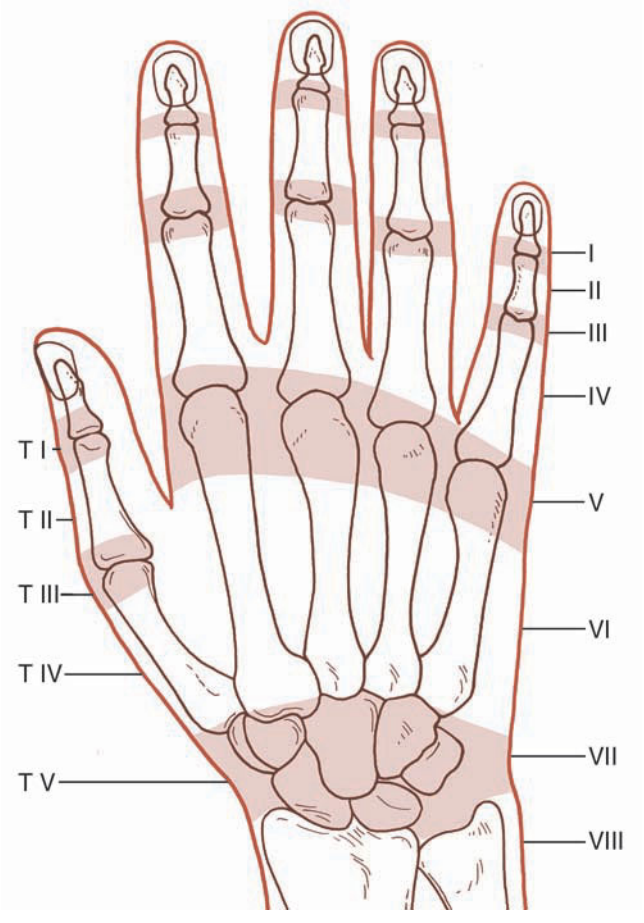

FIGURE 76-4. The extensor tendons of the hand are easily classified by the Kleinert zone system. The odd numbers represent joint spaces. The even numbers represent long bones. Note that the thumb zones are distinct from the other digits.

further compromise the patient's result. Consult an Orthopedic or Hand Surgeon if any doubt exists. The skin wound can be closed loosely, the hand splinted, and the patient referred for delayed repair. Surgical repair of the tendon is not recommended if less than 50% of the tendon is lacerated and the finger functions as well as the corresponding finger on the unaffected opposite hand. The presence of a bony fracture, an open joint space, or the lack of adequate soft tissue or skin covering are contraindications to repairing an extensor tendon in the ED. A tendon laceration as a result of a human bite wound is an absolute contraindication to closure and repair of the injury. The management and rehabilitation of these wounds necessitate consultation with the appropriate surgical specialist.

The Kleinert zone chart can be used to help determine the suitability of repairing an extensor tendon in the ED. The following zones on the forearm, wrist, and hand represent areas where wound care, skin closure, and splinting are highly recommended until an Orthopedic or Hand Surgeon can perform definitive surgical repair. Extensor tendon remnants may be too short in zone 1 of all digits. Except in the thumb, extensor tendons of the fingers that are very thin in zone 2 should not be repaired. Actual or potential joint or lateral band involvement in zone 3 of all digits should not be repaired. Actual or potential joint or sagittal band involvement in zone 5 of all digits should not be repaired. Actual or potential extensor retinaculum involvement in zone 7 should not be repaired. The actual or potential need for a tendon transfer in zone 8 requires an Orthopedic or Hand Surgeon.

EQUIPMENT

Digital or Hand Anesthesia

- Povidone iodine or chlorhexidine solution
- 10 mL syringe
- 25 to 27 gauge needle, 2 in. long
- Local anesthetic solution without epinephrine

Extensor Wound Irrigation and Preparation

- 250 to 500 mL of sterile saline or Ringer's lactate solution
- Irrigation set
- 60 mL syringe
- 16 gauge angiocatheter
- Intravenous tubing
- Personal protective equipment
- Blood pressure cuff, preferably automatic
- Overhead lamp or source of intense lighting

Extensor Tendon and Skin Repair

- Sterile surgical towels
- 4 × 4 gauze squares
- Forceps
- #11 blade disposable scalpel
- Needle driver
- Nonabsorbable, synthetic, and braided suture (4-0, 5-0, and 6-0 Ethibond or Mersilene)
- Nylon suture (4-0 and 5-0) for skin closure

Wound Dressing and Splint

- Topical antibiotic ointment
- Gauze squares
- Elastic gauze bandage
- Splinting materials

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the planned procedure to the patient and/or their representative. The broad risks to the procedure include, but are not limited to, bleeding, infection, nerve damage, additional tendon damage, temporary or permanent stiffness, and a need for additional operations in the future. Additionally, alternative forms of therapy should be discussed. Upon receiving verbal or written consent, the physician may proceed with prepping and positioning the patient.

Place the patient in a supine and comfortable position to minimize movement during the course of the procedure. Place the involved hand on a bedside procedure table ideally at the heart level so that the patient's arm is resting comfortably. Temporarily diminish arterial blood flow with either a digital tourniquet or a blood pressure cuff applied to the arm if vascular bleeding is active and obscures the site of repair. Padding should be applied under the tourniquet. The maximum tourniquet time should be less than 2 hours.[8] Any surgical procedure that takes this long should not be performed in the ED.

Anesthesia to the affected area can be accomplished with either a digital or wrist block. The choice of procedures depends upon the location and extent of the injury. Descriptions of these procedures can be found in Chapter 126, Regional Anesthesia. Once the patient has adequate anesthesia, the wound can be debrided and copiously

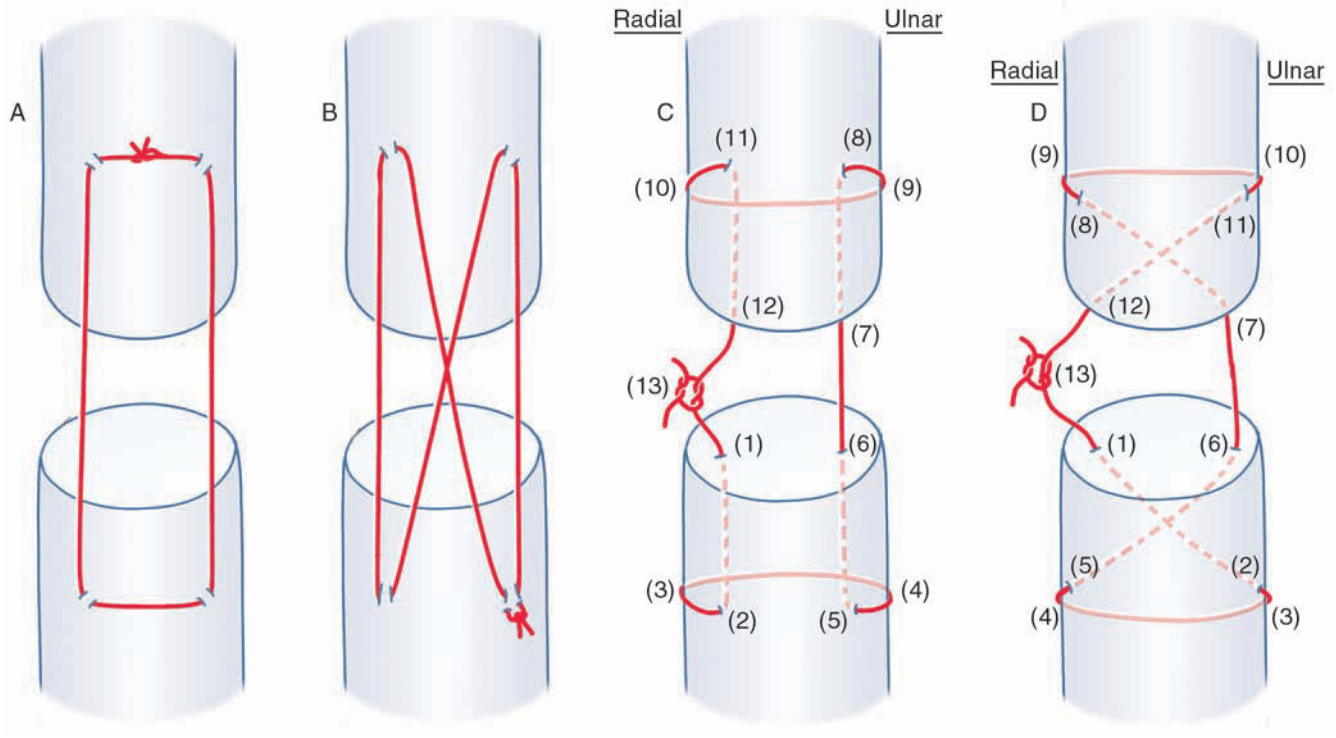

FIGURE 76-5. Suture techniques for extensor tendon repair. **A.** Mattress stitch. **B.** Figure-of-eight stitch. **C.** The modified Kessler stitch. The numbers represent the sequence of steps. **D.** The modified Bunnell stitch. The numbers represent the sequence of steps.

irrigated with 250 to 500 mL of sterile saline (if no open joint is involved). Following irrigation, the wound is considered sterile. All techniques must be aseptic from this point forward. Apply sterile drapes or towels to delineate a sterile field. Place a sterile drape over the bedside procedure table. Lay out the required instruments and suture material on the bedside procedure table.

TECHNIQUES

Many techniques are used to repair lacerated tendons. All of the original techniques were described with reference to flexor tendons. These techniques have been extended to include the repair of the extensor tendons. Four common suture techniques used for a "core" repair of the extensor tendon include the mattress stitch, the figure-of-eight stitch, the modified Bunnell stitch, and the modified Kessler stitch (**Figure 76-5**). No single stitch is optimal for any one zone of injury. The type of stitch must be individualized based on the properties of the tendon at the site of injury. While evidence exists that the modified Kessler and Bunnell stitches produce the greatest strength for a core-type tendon repair,[5] they may not be best suited for extremely thin tendons (such as in zones 4 or 6). Instead, a figure-of-eight or mattress stitch may be necessary. The Bunnell and Kessler techniques are more useful in round, thicker tendons such as the flexor tendons or more proximal extensor tendons.[5,10]

MODIFIED KESSLER STITCH

This "core" stitch is designed to place the direction of force perpendicular to the longitudinal axis of the tendon (**Figure 76-5C**). If the force of the suture is placed in the tendon's longitudinal axis, there is a tendency for the suture to pull through and shred the tendon.

Identify the two ends of the lacerated extensor tendon. **Handle the cut ends with maximal care. Blindly or bluntly grabbing the ends traumatizes the tendons and compromises the repair.** A retracted tendon can be held in place with a needle piercing it perpendicularly. Judiciously debride the tendon ends if they are jagged or dirty. This can be performed with a fresh 11-blade scalpel, cutting down against a wooden tongue depressor. **Do not remove too much length from the tendon.** Place the affected digit and wrist in maximum extension to facilitate approximation of the tendon ends.

Hold one end of the tendon gently with your fingers or a stitch. Introduce the needle into the cut end of the tendon (**Figure 76-5C(1)**). The entrance point should be about one-third of the diameter of the tendon, beginning on either its ulnar or radial side. For simplicity, we begin on the radial side. Pass the suture approximately 1 cm through the length of the tendon and exit dorsally (**Figure 76-5C(2)**). Wrap the suture around the tendon (**Figure 76-5C(3)**). Reenter the radial side of the tendon perpendicularly and 1 to 2 mm closer to the tendon end (**Figure 76-5C(3)**). Pull the suture straight through the tendon to exit on its ulnar side (**Figure 76-5C(4)**). Wrap the suture around the tendon (**Figure 76-5C(5)**). Enter the dorsal aspect of the ulnar half of the tendon (**Figure 76-5C(5)**). This entrance stitch must line up with the first dorsal stitch (**Figure 76-5C(2)**). Pass the needle through the length of the tendon to exit the end of the tendon (**Figure 76-5C(6)**). The needle must exit on the ulnar one-third of the tendon.

Repeat the same stitch on the opposing piece of the tendon. Pass the needle into the ulnar one-third of the tendon (**Figure 76-5C(7)**). Pass the suture approximately 1 cm through the length of the tendon and exit dorsally (**Figure 76-5C(8)**). Wrap the suture around the tendon (**Figure 76-5C(9)**). Reenter the ulnar side of the tendon perpendicularly and 1 to 2 mm closer to the tendon end (**Figure 76-5C(9)**). Pull the suture straight through the tendon to exit its radial side (**Figure 76-5C(10)**). Reenter the dorsal aspect of the radial half of the tendon (**Figure 76-5C(11)**). The stitch must line up with the previous dorsal stitch (**Figure 76-5C(8)**). Pass the

needle through the length of the tendon to exit the end of the tendon (**Figure 76-5C(12)**). The needle must exit on the radial one-third of the tendon.

The two free ends of the suture should be on the radial side of the tendon. Apply tension to the two free ends of the suture to gently approximate the ends of the lacerated tendon. **Do not apply so much force that the ends bunch up.** Secure the stitch with a knot that will remain buried between the tendon ends (**Figure 76-5C(13)**).

MODIFIED BUNNELL STITCH

This stitch follows the same principle as the Kessler stitch. It incorporates a crossing of the suture in its pathway (**Figure 76-5D**). Remember to minimize the handling of the tendon in performing this stitch. **Instrumentation of the tissue is detrimental to its nutritional supply and can lead to adhesions.** Ideally, one should immobilize the tendon ends with one's fingers or a single suture.

Enter the tendon end on the radial half and at approximately one-third of the diameter of the tendon (**Figure 76-5D(1)**). Pass the needle diagonally through the tendon and exit on the ulnar side (**Figure 76-5D(2)**). Wrap the suture around the tendon (**Figure 76-5D(3)**). Reenter the tendon on its dorsal half (**Figure 76-5D(3)**). Pass the needle directly through the tendon to exit the dorsal surface of the radial aspect of the tendon (**Figure 76-5D(4)**). Enter the radial side of the tendon (**Figure 76-5D(5)**). Cross the suture diagonally through the tendon to exit its ulnar end (**Figure 76-5D(6)**). The needle must exit through the ulnar one-third of the tendon end.

Repeat the same stitch on the opposing piece of the tendon. Pass the needle into the ulnar one-third of the tendon (**Figure 76-5D(7)**). Pass the needle diagonally through the tendon and exit on the radial side (**Figure 76-5D(8)**). Wrap the suture around the tendon (**Figure 76-5D(9)**). Reenter the tendon on its dorsal half (**Figure 76-5D(9)**). Pass the needle directly through the tendon to exit the dorsal surface of the ulnar aspect of the tendon (**Figure 76-5D(10)**). Wrap the suture around the tendon (**Figure 76-5D(11)**). Enter the ulnar side of the tendon (**Figure 76-5D(11)**). Cross the suture diagonally through the tendon to exit the radial end of the tendon (**Figure 76-5D(12)**). The needle must exit through the ulnar one-third of the tendon end.

The two free ends of the suture should be on the radial side of the tendon. Pull gently on the suture ends to approximate the ends of the lacerated tendon. **Do not apply so much force that the ends bunch up.** Secure the stitch with a knot, which will remain buried within the tendon ends (**Figure 76-5D(13)**).

AFTERCARE

Close the overlying skin with nylon suture, ideally everting the skin edges with a horizontal mattress suture. Apply topical antibiotic ointment. Apply 4 × 4 gauze squares to cover the wound. Apply an elastic bandage for protection. Splint the extremity to immobilize the repaired tendon and its associated muscle belly.

The patient may be discharged home with follow-up arranged within 24 to 48 hours with an Orthopedic or Hand Surgeon. Instruct the patient to elevate the extremity. They should return to the ED immediately if there is increased pain, numbness or tingling in the digits, if the digits become cold or blue, or if a fever develops. Pain can be controlled by the use of nonsteroidal anti-inflammatory drugs supplemented with an occasional narcotic analgesic.

Static immobilization may not be the optimal postoperative management for extensor tendon repairs. The affected tendon may benefit from early mobilization exercises or dynamic splinting depending upon the zone of injury. Dynamic extension splinting may produce fewer complications and less postoperative adhesions.[11–13] Tendon injuries in zones 1 to 4 can be temporarily immobilized in extension until follow-up by an Orthopedic or Hand Surgeon determines the definitive splinting management. Tendon injuries in zones 5 to 8 can be placed in a temporary static splint with the wrist in 30° of extension, the MCP joints in 15° of flexion, and the interphalangeal joints in full extension.

The aftercare of extensor tendon lacerations necessitates close follow-up by an Orthopedic or Hand Surgeon for the evaluation of tendon function, wound evaluation, and rehabilitation strategies. **Proper aftercare and hand rehabilitation is crucial to ensure successful results of a tendon repair.**

COMPLICATIONS

Surgical repair of any open wound or tendon laceration can result in unforeseen infections. Careful instructions for wound care and follow-up evaluations are important for early detection and treatment of tissue infection.

Failure of the tendon repair can be due to several etiologies. Disruption of the surgical repair, the formation of adhesions, and joint stiffness can produce an inadequate outcome.[9] It is rare to encounter these complications in the ED. Nonetheless, they are real complications that both the EP and patient must discuss before proceeding with the repair procedure.

SUMMARY

The repair of an extensor tendon laceration can and does occur in the ED. While the literature and authors have found that the use of the Bunnell and Kessler stitches for the repair of extensor tendon injuries produces good results, the mattress technique and figure-of-eight stitch may be more useful in the thinner extensor tendons. Effective communication with an Orthopedic or Hand Surgeon is imperative in optimizing the patient's outcome. Even if the tendon repair does not occur in the ED, the wound must be irrigated, explored, and closed for delayed surgical repair by an Orthopedic or Hand Surgeon. Postoperative rehabilitation is crucial to ensure an optimal outcome. Splinting in the ED should only be a temporizing immobilization procedure until rehabilitation therapy occurs.

77 Arthrocentesis

Eric F. Reichman, John Larkin, and Brian Euerle

INTRODUCTION

Arthrocentesis is the insertion of a needle into a joint cavity for the removal of synovial fluid and/or the injection of pharmaceutical agents into the joint cavity. Fluid can be aspirated from almost any joint. Arthrocentesis is used to diagnose and make treatment decisions regarding a joint. Obtaining synovial fluid is safe, simple, relatively pain free, inexpensive, and extremely beneficial to the patient.

Arthrocentesis may be diagnostic or therapeutic. Diagnostically, it is performed to identify the cause of an acute arthritis, to identify an intraarticular fracture, to identify the causes of an effusion, or to give a therapeutic trial of pharmaceuticals. It can also be therapeutic by relieving pain from elevated intraarticular pressure, to drain septic or crystal-laden fluid, or to inject pharmaceuticals. Ultrasound (US)-guided joint aspiration is a supplemental technique that improves several aspects of the arthrocentesis procedure.

TABLE 77-1 General Principles for Arthrocentesis

Know the anatomical relationships
Avoid piercing any tendons
Do not damage articular cartilage
Do not penetrate bone
Use sterile technique
Provide adequate analgesia
Place the joint in slight flexion
Apply distal traction to small joints
Apply compression to large joints
Enter the extensor surface
Use US guidance if available

Synovial fluid analysis will provide unique and valuable information about the affected joint.[32] It is the only method to definitively diagnose or rule out a septic arthritis. The fluid should be analyzed for the presence of crystals. A white blood cell count and differential may help identify the causes of an effusion. A Gram's stain can be quickly performed to identify bacteria in the synovial fluid. Bedside gross analysis of the fluid's physical properties such as clarity, viscosity, and color has been shown to be a reliable clinical predictor of a potentially septic joint.[30] A culture of the synovial fluid should be performed to definitively identify any microbiologic pathogen in the joint.

There are several general principles that should be followed when performing an arthrocentesis (**Table 77-1**). The Emergency Physician (EP) must know the anatomical relationships around the joint. The needle should go around and not through any tendons. Avoid piercing the articular cartilage, which is avascular and may not heal. Do not bounce the needle off the bone, as this is extremely painful for the patient. Insert the needle through the extensor surface of the joint. The synovial cavity is closest to the skin over the extensor surface of the joint. The extensor surface has fewer tendons and ligaments than the flexor surface. Most of the blood vessels and nerves are located on the flexor surface of the joint. Using the extensor surface of the joint for the procedure will avoid potential injury to these structures. Place the joint in slight flexion to maximize the size of the joint cavity. Apply distal in-line traction to the small joints of the wrists, hands, and feet to enlarge the joint cavity. This allows the needle to more easily enter the small joint spaces. Compression of large joints will mobilize peripheral fluid. This is helpful when the volume of synovial fluid is small. Compression may be applied manually or with an elastic bandage.

It is critical to use sterile technique to prevent the infection of a nonseptic joint as well as to ensure the joint fluid is uncontaminated for microbiological cultures. Sterile drapes, sterile gloves, and face masks are not needed to perform the procedure.[1–3] It is necessary to wear gloves to prevent transmission of blood-borne diseases to the EP.[1,4] The skin should be cleansed and prepped in the usual manner. The needle may then be grasped, with clean gloves, at the hub and inserted. As long as the skin and needle are not handled, sterile gloves are not required. This is sometimes difficult to master if the EP has little practice with the technique of arthrocentesis. It may be better to err on the side of conservatism and use sterile gloves and drapes; particularly with inexperienced EPs and in training situations.

US has been used by Interventional Musculoskeletal Radiologists and Rheumatologists to guide needles for joint injections and aspirations.[44,45] US guidance allows these procedures to be performed in a safer manner because the needle is less likely to injure nerves, tendons, and blood vessels. US also allows a comparison with the asymptomatic opposite-side joint. As bedside ultrasonography has become more commonly used in the ED, more EPs are appreciating and reporting on the benefits of its use in guiding arthrocentesis.[46–51] Arthrocentesis is commonly performed on the shoulder, elbow, hip, knee, and ankle joints. It may also be performed on other joints. US guidance can be a useful adjunct in all of these procedures.

There are several possible approaches for the use of US-guided arthrocentesis in the ED. Knee arthrocentesis is commonly performed with a high success rate using only the landmark-palpation technique. Many EPs feel comfortable performing this procedure without the routine use of US guidance. Wiler and colleagues compared US-guided versus standard landmark techniques for knee arthrocentesis and found that US guidance did not improve overall success.[50] Others may use US guidance in cases anticipated to be difficult, such as small effusions or prior joint surgery. Some EPs feel that US guidance improves the safety of arthrocentesis and thus choose to use it whenever an arthrocentesis is performed. This approach is especially appealing in light of the fact that US is noninvasive and does not add any risk to the procedure.

INDICATIONS

Arthrocentesis is indicated to evaluate the cause of an arthritis or a joint effusion (**Table 77-2**).[4–7] All patients presenting with an acute monoarthritis or an acute nontraumatic effusion should undergo arthrocentesis when the diagnosis is not clear based upon the history and physical examination. Analysis of the synovial fluid is essential to help differentiate inflammatory from noninflammatory causes of joint disease. **Arthrocentesis is the only reliable method to confirm the presence of an infectious agent as the cause of an arthritis.** The presence of crystals within the synovial fluid can diagnose gout or pseudogout from other crystal-induced arthritides. **Always keep in mind that two or more types of arthritis can coexist in a patient or in a single joint.[4]**

Arthrocentesis may be therapeutic.[8] A large effusion, regardless of the cause, stretches the joint capsule, causing pain and limiting range of motion. Removal of the fluid will decrease pain and increase the joint's range of motion. An effusion caused by inflammation or sepsis contains numerous mediators of inflammation. Removal of this synovial fluid will help to relieve the patient's discomfort. The removal of purulent fluid will decrease the number of organisms in the joint cavity and, theoretically, may limit further joint destruction.

Injection of therapeutic agents into nonseptic joints is commonly performed in the Emergency Department (ED). Local anesthetic solutions may be injected to relieve pain. A joint examination after trauma may be limited secondary to pain. Injection of local anesthetic solutions can relieve pain and allow an examination for ligamentous and joint instability. Corticosteroids are injected into joints to control inflammation and arthritis pain.

TABLE 77-2 The Indications for Performing an Arthrocentesis

To evaluate a monoarticular arthritis
To diagnose and treat a traumatic arthritis
To diagnose an intraarticular fracture
To diagnose an intraarticular ligamentous disruption
To relieve pain
To diagnose inflammatory versus noninflammatory disorders
To identify the cause of an effusion
To rule out an infection
To identify a crystal-induced arthritis
To inject therapeutic agents

Sometimes, corticosteroids and local anesthetic solutions are combined into one syringe and injected intraarticularly. The local anesthetic provides immediate pain relief and assures the EP of proper needle placement.

Arthrocentesis can be used to diagnose and treat traumatic arthritides. The traumatic event is usually acute, obvious, and followed by joint pain and swelling. Occasionally, the trauma is minimal or remote and not recalled by the patient. A traumatic effusion can be grossly bloody and, if acute, may contain a large amount of red blood cells. The bloody synovial fluid represents an intraarticular fracture or a disruption of an intraarticular structure. An intraarticular fracture may be suspected based on mechanism of injury and yet radiographic findings may be negative. The synovial fluid may then be evaluated for fat globules, which are released from the marrow cavity of the fractured bone, which confirm the presence of an intraarticular fracture.

The temporomandibular joint is a highly specialized joint that has a unique set of problems associated with it. Arthrocentesis can be an easy, minimally invasive, and efficient procedure used to solve some of these issues. Degenerative joint disease and joint lock are two examples of conditions that are amenable to therapeutic arthrocentesis, although much debate still exists concerning efficacy and therapeutic value of this procedure.

CONTRAINDICATIONS

There are no absolute contraindications to arthrocentesis. All contraindications are relative. The risks and benefits of the procedure should be evaluated and a decision made with the informed consent of the patient. **If a septic joint is suspected, it should be aspirated despite the presence of any relative contraindication. The benefit of the procedure outweighs any relative contraindication when compared to the morbidity of an undiagnosed septic arthritis.**

The presence of a suspected or known skin cellulitis, or other infection overlying the joint, is a relative contraindication. A dermatitis or skin lesion overlying the joint should also be avoided. The skin or subcutaneous tissue can harbor organisms that may contaminate the joint when the needle passes through the dermatitis or skin lesion. Often, an alternative site can be found to perform the arthrocentesis and avoid the above obstacles. If the needle is inserted into the joint through any potential or obvious source of infection, antibiotic treatment is required due to the theoretical risk of introducing an infection into the joint cavity.[5] In these cases, patients should be admitted for 23 hours of intravenous antibiotics whose spectrum covers skin flora.

Infections after arthrocentesis, in previously sterile joints, have been reported in bacteremic patients.[5] It is not clear whether the source of the septic arthritis was from the arthrocentesis or bacteremia coincidentally seeding the joint. It is recommended to avoid arthrocentesis in any patients with bacteremia or sepsis except to rule out a septic arthritis.

Patients may be coagulopathic due to heparin or Coumadin therapy, factor deficiencies, liver dysfunction, or many other causes. When possible, the coagulopathy should be reversed prior to arthrocentesis. Unfortunately, this is not always possible or practical. An experienced EP can safely perform the procedure without reversing the coagulopathy. Use the smallest needle gauge possible (i.e., 22 or 23 gauge) to aspirate the joint fluid. Avoid injury to the articular cartilage by identifying the anatomic landmarks prior to the procedure. Do not bounce the needle off any bony surfaces.

The procedure may be difficult in some patients. In the morbidly obese, it may be difficult to identify anatomic landmarks. The standard needle may be too short to enter the joint cavity. A spinal needle may be required to perform an arthrocentesis in an obese patient. Uncooperative patients require sedation and/or restraint prior to performing the procedure.

A prosthetic joint increases the risk of a septic arthritis. Arthrocentesis is technically more difficult secondary to scar formation and alteration of the normal anatomic relationships. **Joints that contain a prosthesis should be aspirated only to rule out a septic arthritis. Arthrocentesis for other reasons, including joint injection, should be referred to a consultant.**

Corticosteroids are instilled into joints for a variety of conditions. If the patient has no response to the injection within a few weeks, it may be repeated. If multiple injections cause no improvement, an alternative form of therapy should be explored.[9] Multiple injections into a joint increase the risk of complications.

EQUIPMENT

- Clean gloves
- Gauze squares
- Povidone iodine or chlorhexidine solution
- Sterile skin marking pen
- Local anesthetic (injectable, vapor coolant, or ice)
- 25 to 27 gauge needle
- 3 mL syringe
- Needles to aspirate fluid (18/20/22 gauge)
- Syringes to aspirate fluid (1/3/5/10/20/30/60 mL)
- Hemostat
- Specimen tubes
- Culturettes or culture tubes

Optional Equipment

- US machine
- US gel
- US transducers (5 to 10 MHz)
- Sterile US probe covers

Arthrocentesis should be performed with a needle of sufficient bore to allow the aspiration of thick fluid, fluid with debris, or purulent fluid. An 18 to 20 gauge needle is recommended for large joints (i.e., shoulder, elbow, ankle, knee, and hip). A 22 to 23 gauge needle is recommended for all other joints. Using too small a needle makes the procedure technically more difficult and more painful for the patient.

A high-frequency (5 to 10 MHz) linear array transducer is preferred for arthrocentesis and should be used whenever possible.[44] If this type of transducer is not available, or if more depth of field is required, a curvilinear array may be used. Cavalier and colleagues reported using color Doppler and a sterile needle guide attached to the transducer when performing US-guided arthrocentesis in children.[52] Doppler was used to localize the blood vessels so that they could be avoided by the needle. While Doppler may occasionally provide additional anatomic information, it is not routinely used when performing an arthrocentesis. The use of a needle guide depends on the personal preference of the sonographer.

PATIENT PREPARATION

A complete history and physical examination should be performed prior to the arthrocentesis. The affected joint should be thoroughly assessed. Inspect the skin overlying the joint for breaks, infection, old scars, prior incisions, superficial lesions, or any wounds. Palpate the joint to identify any warmth, tenderness,

or effusion. Evaluate the joint for any crepitation, deformity, ligamentous instability, or limitations in motion.

As with any nonemergent procedure, consent should be obtained from the patient or their representative. Ideally, the consent should be documented in the medical record and signed by the patient. Some prefer to note on the patient's chart "indications, risks, and benefits were discussed with the patient" rather than having the patient sign a consent form.[4,10] The following is a sample consent for performing an arthrocentesis (which may be written on the medical record and signed by the patient):

Arthrocentesis involves inserting a small needle into your_____joint. The skin is anesthetized prior to the procedure. Ordinarily, the procedure has no significant complications. Occasionally, a patient may experience bleeding into the joint, infection of the joint or skin, pain, bruising, nerve injury, or an allergic reaction to the medications administered. These complications are minimized by the use of sterile technique and proper techniques.

Position the patient based on the specific joint to be aspirated and the approach to be used. Expose the joint and surrounding areas. Identify the anatomic landmarks required for proper needle placement. The landmarks may be difficult to identify on a swollen and tender joint. Compare the "affected" joint to the "normal" joint on the opposite side of the body. Identify the joint and a landmark on the normal joint and transfer this to the affected joint. Clean any dirt and debris from the skin. Scrub the needle insertion site with povidone iodine or chlorhexidine solution and allow it to dry.

Apply anesthesia to the skin and subcutaneous tissue using 1% lidocaine, topical vapor spray, or ice.[11] The administration of some form of local anesthesia is recommended but not required.[4,12] The most common local anesthetic used is a short-acting injectable anesthetic solution of 1% lidocaine. **Do not inject the local anesthetic solution deeper than the subcutaneous tissues**. Deep injections may instill anesthetic solution into the joint cavity, which may interfere with the synovial fluid analysis. There is disagreement if the additional needle stick to administer the anesthesia causes as much discomfort as aspiration without any anesthesia. This decision is specific to each patient and EP.

Alternative methods of anesthesia include ice and topical vapor coolants. A sterile drape may be placed over the prepped skin and a bag of ice water placed over the drape. Remove the ice water bag and drape after 5 minutes and perform the procedure. Ethinyl chloride topical vapor coolant may be used as an anesthetic. Spray the solution onto the area of skin in which the needle will be inserted. Apply the spray from 6 in. above the skin. Spray until the skin turns white and frosty. This usually takes 5 to 10 seconds. Immediately perform the procedure, as the anesthesia lasts only 30 to 60 seconds.

TECHNIQUES

THE BASIC TECHNIQUE

The general procedure preferred by one of the authors and the editor (EFR) will be described. Some may prefer to insert the needle into the joint space and then attach the syringe. Specifics will be addressed with each individual joint.

Apply the needle to the syringe and break the resistance. This avoids any sudden and painful movements of the needle within the joint cavity. Stretch the skin over the site where the needle will be inserted. Penetrate the skin briskly with the needle and enter the joint cavity. Gently aspirate synovial fluid. If bone is encountered, slightly withdraw the needle and re-advance it in a different direction. If no fluid is obtained, reevaluate the joint to determine if an effusion is present, if another site is more appropriate for the procedure, or if another physician may offer a different perspective. For diagnostic aspirations, it is not necessary to aspirate all of the fluid from the joint. Synovial fluid analysis can be performed on 1 to 5 mL of fluid.

If additional fluid is to be removed after the original syringe is filled, or if pharmaceuticals are to be injected into the joint, do not remove the needle from the joint cavity. Grasp the hub of the needle with a hemostat. Remove the syringe and attach the second syringe. Continue to aspirate fluid or inject the desired pharmaceutical. Remove the needle when the procedure has been completed. Apply a bandage to the skin. Transfer the synovial fluid into appropriately labeled tubes or containers. Document the procedure in the medical record. A sample procedure note is described below:

After informed consent, the skin overlying the_____joint was cleaned and prepped with povidone iodine/chlorhexidine solution. The skin was anesthetized with (_____mL of_____% lidocaine, ethyl chloride vapor coolant, ice for_____minutes). Using sterile technique, an_____gauge needle was inserted on the (supero-/infero-,medial/lateral/inferior/superior) surface of the joint. It was directed (supero-/infero-,medially/laterally/inferiorly/superiorly). _____mL of fluid was obtained. It was (thin, thick, yellow, clear, straw-colored, bloody, purulent, with debris, without debris). No complications were noted.

The joint was injected with_____mL of_____% (name of local anesthetic) and/or_____mL of_____%_____(name of corticosteroid). No complications were noted.

THE BASIC US TECHNIQUE

The acoustic windows used for US-guided arthrocentesis are the soft tissues overlying the joint. The transducer is most commonly oriented across a joint so that the bones on each side of the joint are visualized and the joint space between them. Bone is highly reflective of US waves and the cortex is seen as a bright white echogenic line on the US image. Synovial fluid will be seen as an anechoic line or hypoechoic collection within the joint space. When visualized longitudinally, the needle will appear as a narrow, linear hyperechoic structure with a posterior reverberation artifact (**Figure 77-1**). When visualized transversely, the needle appears as a small hyperechoic round object.[45]

The general procedure and technique depend on whether the static or dynamic method is used. Using the static technique, manipulate the US transducer over the joint until the optimal spot for needle entry is found based on fluid accessibility and a needle path that avoids major blood vessels, nerves, and tendons. Mark the skin on the midpoint of each side of the US transducer. Rotate the transducer 90° and repeat the process. Connect the two sets of lines to form an "X" that marks the spot for needle entry (**Figure 77-2**). Set aside the US transducer, prepare the skin in a sterile manner, and proceed with the arthrocentesis using the standard landmark-based technique.

The dynamic or real-time method is slightly more demanding technically but offers the advantage of allowing visualization of the needle and needle tip.[44] Prepare the patient's skin in a sterile manner. Place a sterile probe cover over the US transducer and apply sterile US gel to the skin. Place the transducer over the joint in the appropriate orientation and manipulate it until the synovial fluid is visualized. Inject a local anesthetic agent into the skin and subcutaneous tissue along the projected course of the arthrocentesis needle. In many cases, it is possible to observe the infusion of the anesthetic agent on the US image.[44] Advance the needle through the skin and soft tissue and direct it toward the synovial fluid. The needle can be advanced either longitudinally or transversely to the axis of the US transducer. The longitudinal axis allows visualization of the entire needle along its path and is the technique utilized by most EPs. Visualization in the transverse axis allows only one

FIGURE 77-1. Longitudinal view of a needle approaching a joint effusion.

cross-sectional area of the needle to be seen so it can be difficult to identify the needle and its tip. Regardless of orientation, continue to advance the needle until its tip is visible within the synovial fluid. Aspirate the synovial fluid. It is often possible to watch the synovial fluid diminish in size as it is aspirated.

TEMPOROMANDIBULAR JOINT ARTHROCENTESIS

Landmarks The landmarks for temporomandibular joint (TMJ) arthrocentesis are found by first drawing a line on the patients face from the corner of the eye to the ipsilateral tragus (canthal-tragus line). Mark the point 10 mm from the tragus along the line and 0.5 mm below the line. This marks the superior compartment. Mark a second point 20 mm from the tragus along the line and 1 mm below the line. This marks the superior compartment.

Patient Positioning Place the patient sitting upright with their jaw held slightly open.

Needle Insertion and Direction Use two 21-gauge needles to access the joint space compartments. Insert the first needle at the first mark and advance it into the joint space. Inject 2 to 3 mL of sterile saline to insufflate the joint space. Insert and advance the second needle at the second point and into the joint space. Correct placement is confirmed when the saline flows out the needle.[41]

Remarks Arthrocentesis of this joint is a unique solution to a specialized TMJ disorder called closed lock, in which the patient's jaw is felt to be locked and will not open greater than 20 to 25 mm. It is theorized to be the result of small adhesions and nongliding of the intraarticular disk in the TMJ space. Arthrocentesis and subsequent lavage can relieve the symptoms of closed lock.

Joint Injection Once the two needles are in place in the superior compartment, massive lavage with normal saline or lactated ringers solution can be achieved with the first needle as input and the second needle as output. Continuous fluid can be infused and removed using a 10 mL syringe or attaching IV tubing to each needle.[42]

FIGURE 77-2. The "X" marks the spot for needle entry.

STERNOCLAVICULAR JOINT ARTHROCENTESIS

Landmarks The sternal end of the clavicle and the suprasternal notch are the landmarks for this joint (**Figure 77-3**). The joint can be palpated just medial to the sternal end of the clavicle and just lateral to the suprasternal notch.

Patient Positioning Place the patient supine on a stretcher with their arm hanging over the edge of the table (**Figure 77-3A**). Abduct the arm 90°. Externally rotate the arm so that the palm faces upward. This position maximally opens the sternoclavicular joint to allow easy access.

Needle Insertion and Direction Insert a 23 gauge needle through the anterior joint surface and perpendicular to the skin (**Figure 77-3B**). Advance the needle to a depth of 2 to 5 mm.

Remarks This joint is often involved with degenerative arthritis. Septic arthritis is commonly seen in intravenous drug abusers who inject drugs into the great vessels; also known as "pocket shooting." This joint may only contain 0.25 to 0.50 mL of fluid.

Joint Injection A maximum volume of 1 mL may be instilled into this joint. A maximum dose of 10 mg of corticosteroids may be instilled into this joint.

ACROMIOCLAVICULAR JOINT ARTHROCENTESIS

Landmarks The acromioclavicular (AC) joint is very superficial (**Figure 77-4**). Palpate the clavicle and move laterally until a prominence is felt. This is the AC joint. Have the patient move their arm to confirm the joint location.

Patient Positioning Place the patient sitting upright on a stretcher with the affected arm hanging by their side. A weight may be placed in the patient's hand to distract and open the joint space.

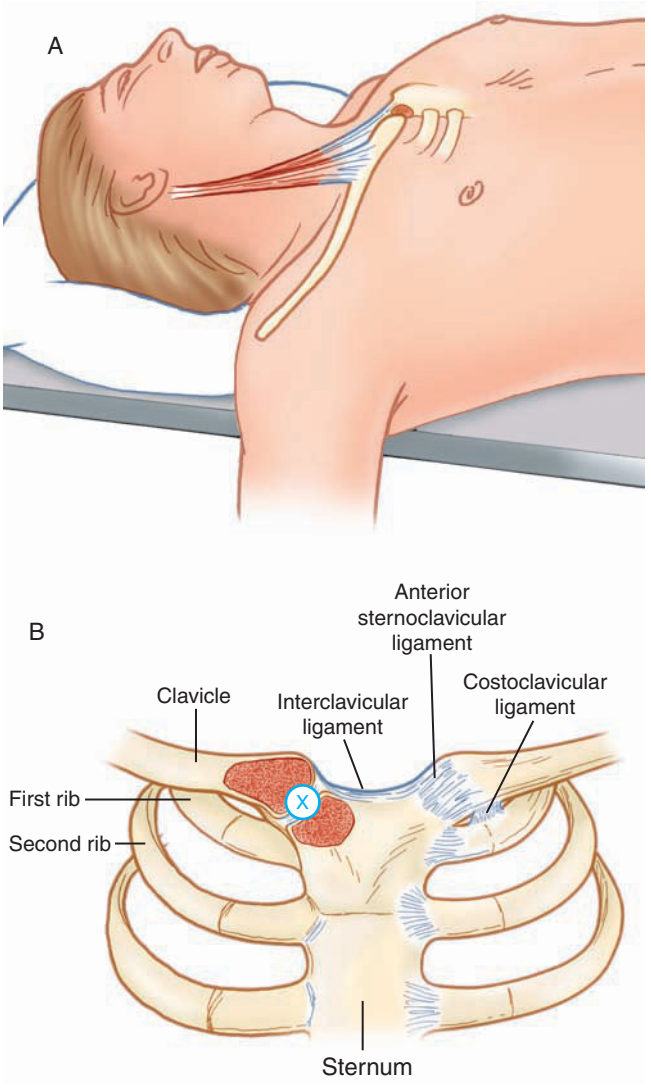

FIGURE 77-3. Sternoclavicular joint arthrocentesis. **A.** Patient positioning. **B.** Anatomy and needle insertion. The site of needle insertion is represented by an "⊗".

Needle Insertion and Direction Insert a 22 gauge needle through the superior surface of the AC joint and perpendicular to the skin (**Figure 77-4**). Advance the needle to a depth of 3 to 5 mm.

Remarks The AC joint is very superficial. It has a dense, thick capsule anteriorly that is lacking on its superior surface. The joint may contain only 0.25 to 0.50 mL of fluid.

Joint Injection A maximum volume of 1.5 mL may be instilled into this joint. A maximum dose of 10 mg of corticosteroids may be instilled into this joint.

GLENOHUMERAL JOINT (SHOULDER) ARTHROCENTESIS, ANTERIOR APPROACH

Landmarks Palpate the coracoid process of the scapula (**Figure 77-5**). It will be found below the lateral third of the clavicle. Internally rotate and adduct the humerus. Palpate the groove between the coracoid process and the humeral head. This groove is the landmark for introduction of the needle.

Patient Positioning Place the patient sitting upright or supine on a stretcher. Flex the elbow 90°. Internally rotate and adduct the arm.

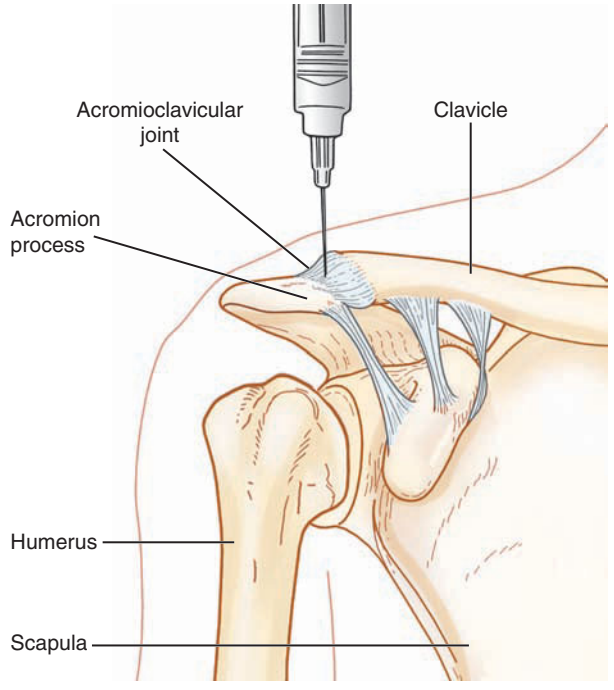

FIGURE 77-4. Acromioclavicular joint arthrocentesis.

In the proper position, the forearm is resting against the patient's abdomen.

Needle Insertion and Direction Insert an 18 gauge needle perpendicular to the skin and into the groove just lateral to the coracoid process (**Figure 77-5B**). Aim the needle directly posterior. Advance the needle until a loss of resistance is felt as the joint cavity is entered.

Ultrasound Probe Placement With the patient positioned as above, place the US probe inferior and lateral to the coracoid process.

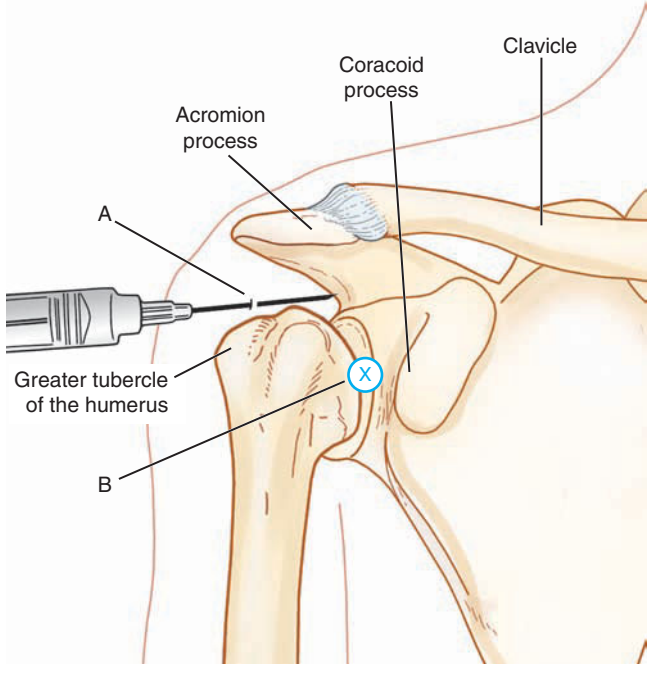

FIGURE 77-5. Shoulder joint arthrocentesis. **A.** Lateral approach. **B.** Anterior approach. The site of needle insertion is represented by an "⊗".

Rotate the probe so that the marker is cephalad and angled medially toward the patient's head. The curve of the humeral head will appear different than the flat portion of the glenoid, and between these hyperechoic surfaces lies the V-shaped hypoechoic joint space.

Remarks This approach is the simplest yet most painful of the three approaches. The needle must penetrate the tendons of the coracobrachialis, subscapularis, biceps, and pectoralis major muscles in addition to the very tough anterior joint capsule. The major disadvantage of this approach is the possible (but rare) penetration of the brachial plexus or the axillary vessels with the needle. The patient can view the large needle as it approaches the skin and this may increase their anxiety level. The posterior approach is preferred when using US guidance.[44]

Joint Injection A maximum volume of 15 mL may be instilled into this joint. A maximum dose of 30 mg of corticosteroids may be instilled into this joint.

GLENOHUMERAL JOINT (SHOULDER) ARTHROCENTESIS, LATERAL APPROACH

Landmarks Identify the acromion process of the scapula (**Figure 77-5**). A groove can be found just inferior to the lateral surface of the acromion and above the greater tubercle of the humerus.

Patient Positioning Place the patient sitting upright on a stretcher with the affected arm hanging by their side. A weight may be placed in the patient's hand to distract and open the joint cavity.

Needle Insertion and Direction Insert an 18 gauge needle into the midpoint of the groove (**Figure 77-5A**). Direct the needle medially and slightly posterior. Advance the needle to a depth of 2.5 to 3 cm.

Remarks Immediately below the deltoid muscle is the subacromial bursa. This bursa does not communicate with the shoulder joint. The needle must be inserted 2.5 to 3 cm to ensure the needle is in the shoulder joint and not in the subacromial bursa. The anterior or posterior approach to shoulder arthrocentesis avoids this potential problem.

Joint Injection A maximum volume of 15 mL may be instilled into this joint. A maximum dose of 30 mg of corticosteroids may be instilled into this joint.

GLENOHUMERAL JOINT (SHOULDER) ARTHROCENTESIS, POSTERIOR APPROACH

Landmarks Identify the spine of the scapula (**Figure 77-6**). Follow the spine laterally until it turns anterior to become the acromion process. This posterior border of the acromion process is the landmark for this technique. Locate the coracoid process of the scapula, just inferior to the lateral third of the clavicle.

Patient Positioning Place the patient sitting upright on a stretcher. Place the palm of the hand of the affected shoulder on the anterior surface of the opposite shoulder. The arm and forearm should be held against the chest. This position maximally opens the posterior joint space.

Needle Insertion and Direction Place the nondominant thumb on the posterior border of the acromion process. Place the nondominant index finger on the coracoid process. Insert an 18 gauge needle 1 to 2 cm below the thumb and parallel to the floor (**Figure 77-6**). Aim the needle toward the tip of the index finger, approximately 30° medially. Advance the needle to a depth of 2 to 3 cm.

US Probe Placement Position the patient as described above. Place the US transducer across the posterior aspect of the shoulder in a transverse orientation (**Figure 77-7**). The marker may be directed medially or laterally. The echogenic cortex of the humeral head is visible along with the adjacent glenoid rim (**Figure 77-8**). The joint fluid is visible as an anechoic area between these two bony structures (**Figure 77-8**). Insert and advance the needle from the lateral edge of the US transducer, oriented along the long axis of the transducer, and into the joint fluid.

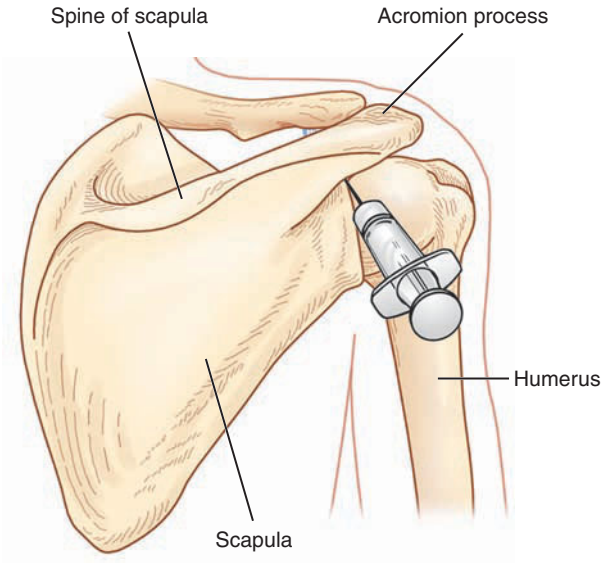

FIGURE 77-6. Posterior approach for shoulder joint arthrocentesis.

Remarks This is felt by some physicians to be the preferred approach to shoulder arthrocentesis. The needle will pierce the deltoid and infraspinatus muscles and avoid the tendons of the rotator cuff. This approach avoids the anxiety associated with the patient observing the large needle and syringe used for the procedure during the anterior or lateral approach. The posterior joint capsule is much thinner and more easily penetrated than the anterior joint capsule. There are no significant neurovascular structures that may be injured from this approach.

FIGURE 77-7. In the posterior approach to the shoulder, the US transducer is placed in a transverse orientation.

FIGURE 77-8. US image of the posterior shoulder. The hypoechoic joint fluid (*asterisk*) is located between the echogenic cortices of the humeral head (*arrow*) and the glenoid rim (*arrowhead*).

Joint Injection A maximum volume of 15 mL may be instilled into this joint. A maximum dose of 30 mg of corticosteroids may be instilled into this joint.

HUMERORADIOULNAR JOINT (ELBOW) ARTHROCENTESIS, LATERAL APPROACH

Landmarks The lateral epicondyle of the humerus, the radial head, and the tip of the olecranon process of the ulna are the landmarks for this joint (**Figure 77-9A**). Flex the elbow 45° and pronate the hand. Pronation of the hand stretches the radial collateral ligament, moves the radial nerve out of the needle's path, and widens the synovial cavity. Identify the depression between the landmarks. The depression is located proximal to the radial head in the area where no bony structures are palpated.

Patient Positioning Place the patient sitting upright or supine on a stretcher. Flex the elbow 45° and pronate the hand. This position widens the joint cavity and avoids any neurovascular structures.

Needle Insertion and Direction Insert a 22 gauge needle perpendicular to the skin and into the depression just proximal to the radial head (**Figure 77-9A**). Advance the needle to a depth of 0.75 to 2.0 cm.

Remarks This is the preferred approach for elbow arthrocentesis. It avoids tendons and neurovascular structures, thereby reducing the risk of complications.[13]

Joint Injection A maximum volume of 5 mL may be instilled into this joint. A maximum dose of 20 mg of corticosteroids may be instilled into this joint.

HUMERORADIOULNAR JOINT (ELBOW) ARTHROCENTESIS, POSTERIOR APPROACH

Landmarks Identify the top of the olecranon process of the ulna and the triceps muscle insertion into the olecranon process (**Figure 77-9B**). Find the point just proximal to the top of the olecranon and just lateral to the triceps insertion. This point is the landmark for insertion of the needle.

Patient Positioning Place the patient sitting upright on a stretcher. Flex the elbow 90° with the hand supinated. The forearm and hand should be resting on a tabletop or on the patient's leg.

Needle Insertion and Direction Approach the joint from the posterolateral surface with the needle parallel to the radial shaft. Insert a 22 gauge needle perpendicular to the skin at the landmark (**Figure 77-9B**). Advance the needle to a depth of 1 cm.

US Probe Placement Position the patient as described above. Place the US transducer along the posterior elbow in a longitudinal orientation, with the marker toward the shoulder (**Figure 77-10**). This produces an image with the humerus located to the left, the olecranon located to the right, the olecranon fossa at the bottom, and the triceps tendon passing from side to side across the top of the screen (**Figure 77-11**). Keep the US transducer in the same orientation and slide it laterally to move off the triceps tendon. The joint effusion will be visualized in or adjacent to the olecranon fossa (**Figure 77-11**). Be sure to avoid the ulnar nerve which passes over the medial epicondyle, by choosing a location as far lateral as possible.[33,34] Advance the needle over the superior edge of the US transducer and into the synovial fluid.

Remarks Potential complications include needle penetration of the triceps tendon or the radial nerve. This approach is reserved for patients in whom the lateral approach is contraindicated.

Joint Injection A maximum volume of 5 mL may be instilled into this joint. A maximum dose of 20 mg of corticosteroids may be instilled into this joint.

HUMERORADIOULNAR JOINT (ELBOW) ARTHROCENTESIS, POSTEROLATERAL APPROACH

Landmarks Identify the lateral surface of the olecranon process of the ulna and the lateral epicondyle of the humerus (**Figure 77-9C**). Find the indentation just lateral to the olecranon and just distal to the lateral epicondyle. This point is the landmark for the insertion of the needle.

Patient Positioning Place the patient sitting upright on a stretcher. Flex the elbow 90° with the hand supinated. The forearm and hand should be resting on a tabletop or on the patient's leg.

Needle Insertion and Direction Approach the joint from the posterolateral surface with the needle parallel to the radial shaft. Insert a 22 gauge needle perpendicular to the skin at the landmark (**Figure 77-9C**). Advance the needle to a depth of 1 cm.

Remarks This approach is an alternative when the lateral approach is contraindicated.

Joint Injection A maximum volume of 5 mL may be instilled into this joint. A maximum dose of 20 mg of corticosteroids may be instilled into this joint.

RADIOCARPAL JOINT (WRIST) ARTHROCENTESIS

Landmarks Identify the lunate bone (**Figure 77-12**). Palpate the middle (third) metacarpal and follow it proximally until a

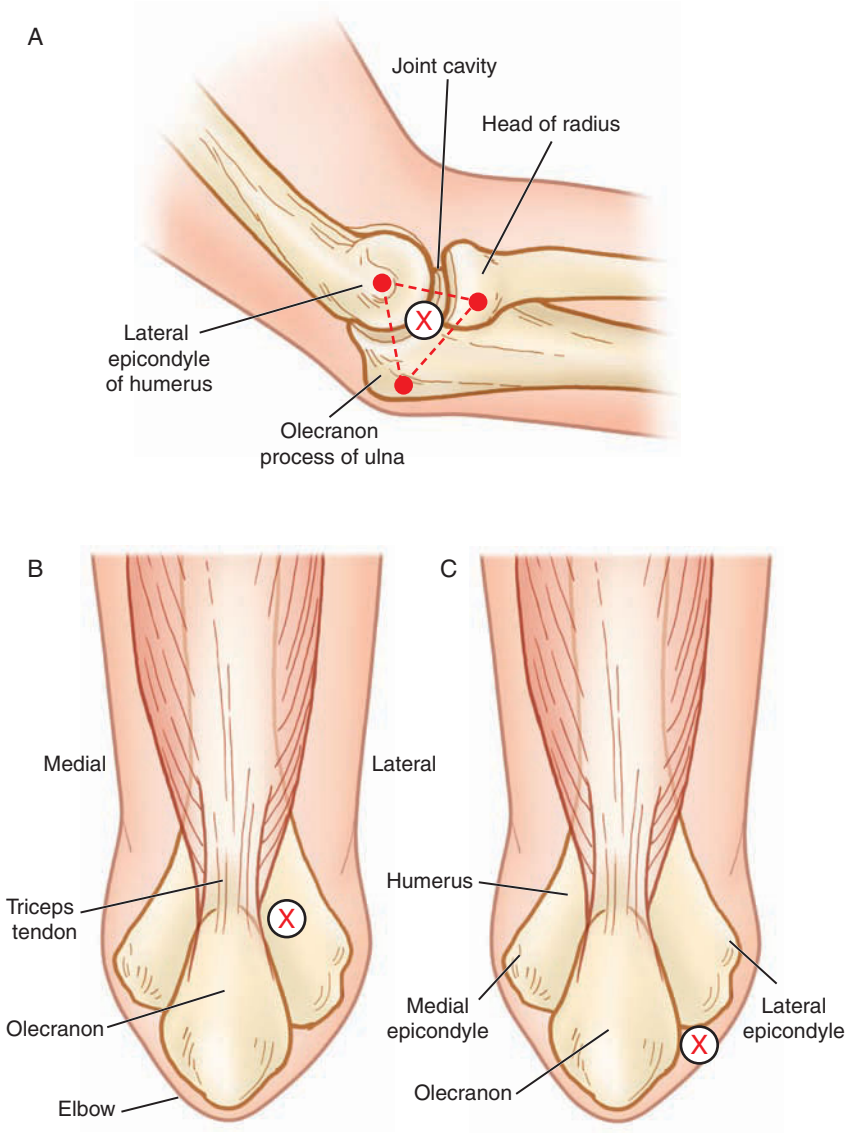

FIGURE 77-9. Elbow joint arthrocentesis. The site of needle insertion is represented by an "⊗". **A.** Lateral approach. **B.** Posterior approach. **C.** Posterolateral approach.

FIGURE 77-10. The US transducer is placed along the posterior elbow in a longitudinal orientation.

rounded bean-like elevation is felt (**Figure 77-12A**). This is the lunate. Palpate the indentations proximal and distal to the lunate. The indentation proximal to the lunate is the landmark for needle insertion.

Alternatively, identify Lister's tubercle and the extensor pollicis longus (EPL) tendon (**Figure 77-12B**). Lister's tubercle is a bony prominence in the center of the dorsal aspect of the distal radius. The EPL tendon can be found lateral (radial) to Lister's tubercle. If the EPL tendon is difficult to find, extend the hand and thumb against resistance and it will become prominent. The lunate is the bony prominence distal to Lister's tubercle. The indentation proximal to the lunate is the landmark for needle insertion.

Patient Positioning Place the patient sitting upright or supine on a stretcher. Pronate the hand with the wrist in slight (e.g., 20°-50°) flexion and ulnar deviation (**Figure 77-12A**). The palm of the physician's nondominant hand should be holding the patient's palm. Reidentify the lunate with the nondominant thumb.

Needle Insertion and Direction Insert a 22 gauge needle perpendicular to the skin in the indentation proximal to the lunate (**Figure 77-12A**). Advance the needle to a depth of 0.75 to 1.25 cm.

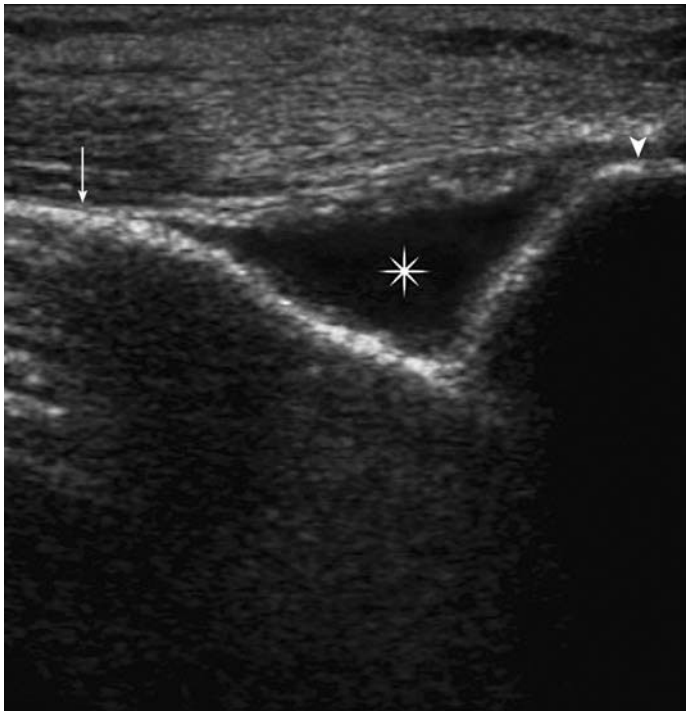

FIGURE 77-11. US image of the longitudinal view of an elbow joint. The hypoechoic joint fluid (*asterisk*) is located between the echogenic cortices of the humerus (*arrow*) and the olecranon (*arrowhead*).

Alternatively, insert the needle in the indentation just distal to Lister's tubercle and ulnar to the EPL tendon (**Figure 77-12B**).

Remarks The preferred, and easiest, method is to identify the lunate and then insert the needle in the indentation just proximal to the lunate.

Joint Injection A maximum volume of 2 mL may be instilled into this joint. A maximum dose of 20 mg of corticosteroids may be instilled into this joint.

INTERCARPAL JOINT ARTHROCENTESIS

Landmarks Identify the lunate bone (**Figure 77-12**). Palpate the middle (third) metacarpal and follow it proximally until a rounded bean-like elevation is felt (**Figure 77-12A**). This is the lunate. Palpate an indentation distal to the lunate and proximal to the base of the third metacarpal. This indentation is the landmark for insertion of the needle.

Patient Positioning Place the patient sitting upright or supine on a stretcher. Pronate the hand with the wrist in slight (e.g., 20°-50°) flexion and ulnar deviation (**Figure 77-12A**). The palm of the physician's nondominant hand should be holding the patient's palm. Reidentify the landmarks with the nondominant thumb.

Needle Insertion and Direction Insert a 22 gauge needle perpendicular to the skin in the indentation distal to the lunate. Advance the needle to a depth of 0.5 to 1.0 cm.

Remarks The joints between the carpal bones are all connected to each other (**Figure 77-13**). Fluid aspirated from one of these joints is representative of all the joints. Likewise, injection of one joint allows the pharmaceutical to be distributed to all the joints.

Joint Injection A maximum volume of 1.5 mL may be instilled into this joint. A maximum dose of 15 mg of corticosteroids may be instilled into this joint.

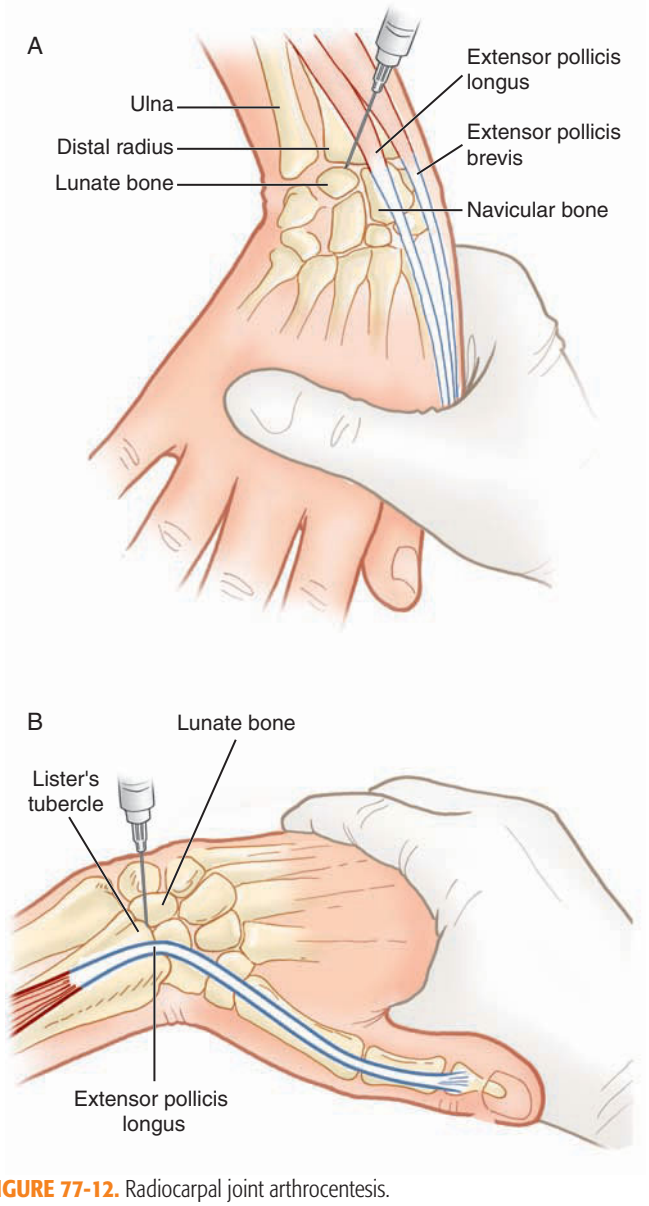

FIGURE 77-12. Radiocarpal joint arthrocentesis.

CARPOMETACARPAL JOINT OF THE THUMB ARTHROCENTESIS

Landmarks The base of the first metacarpal and the abductor pollicis longus (APL) tendon are the landmarks for this joint (**Figure 77-14**). Identify the radial aspect of the base of the first metacarpal. Have the patient rotate the affected thumb to help identify the joint. Identify the APL tendon by extending the patient's thumb against resistance.

Patient Positioning Place the patient sitting upright or supine on a stretcher. Flex the thumb into the palm with the tip of the thumb touching the fifth metacarpal head. Clench the remaining fingers into a fist (**Figure 77-14A**).

Needle Insertion and Direction Insert a 22 gauge needle into the joint space at the radial aspect of the base of the first metacarpal and just lateral (radial) to the APL tendon (**Figure 77-14A**). Direct the tip of the needle toward the base of the fourth metacarpal. Advance the needle to a depth of 0.5 to 1.0 cm.

Remarks If difficulty is encountered when inserting the needle, try an alternative thumb position (**Figure 77-14B**). Flex the first

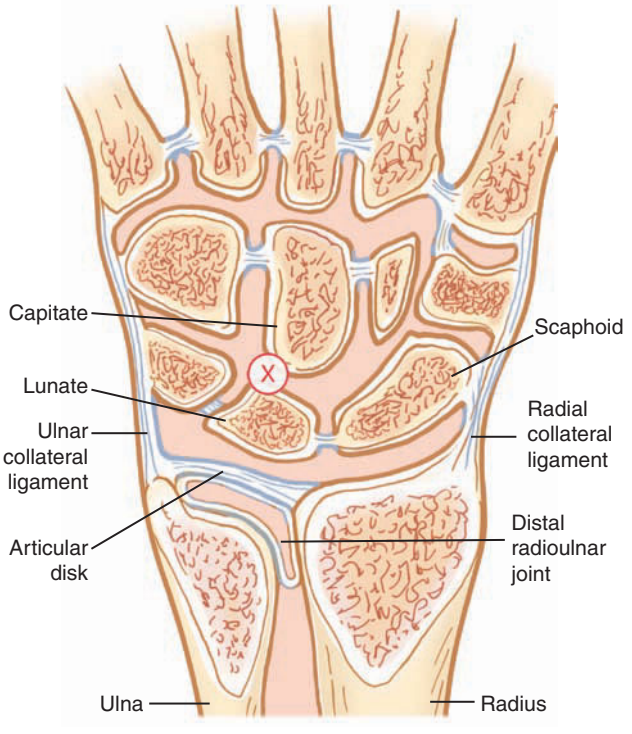

FIGURE 77-13. Intercarpal joint arthrocentesis. Coronal section through the wrist and hand demonstrating that the joints between the carpal bones are all interconnected. The site of needle insertion is represented by an "⊗".

carpometacarpal joint 45° and apply traction to the distal thumb. This in-line traction will enlarge the joint cavity and allow easier access.

Joint Injection A maximum volume of 1.5 mL may be instilled into this joint. A maximum dose of 10 mg of corticosteroids may be instilled into this joint.

METACARPOPHALANGEAL JOINT ARTHROCENTESIS

Landmarks Identify the metacarpophalangeal (MCP) joint and the extensor digitorum tendon (**Figure 77-15A**). The MCP joint can be located just proximal to the prominence at the base of the proximal phalanx of the finger. Identify the extensor tendon by having the patient extend the finger against resistance.

Patient Positioning Place the patient sitting upright or supine on a stretcher. Pronate the hand and abduct the fingers. Grasp the finger and apply distal traction.

Needle Insertion and Direction Insert a 22 gauge needle into the dorsal joint space just medial or lateral to the extensor tendon (**Figure 77-15B**). Direct the tip of the needle toward the center of the joint. Advance the needle to a depth of 0.3 to 0.5 cm.

Remarks The application of distal traction often causes a depression to appear on both sides of the extensor tendon (**Figure 77-15B**). These depressions can be used as landmarks for the site of needle insertion into the joint cavity.

Joint Injection A maximum volume of 1 mL may be instilled into this joint. A maximum dose of 5 mg of corticosteroids may be instilled into this joint.

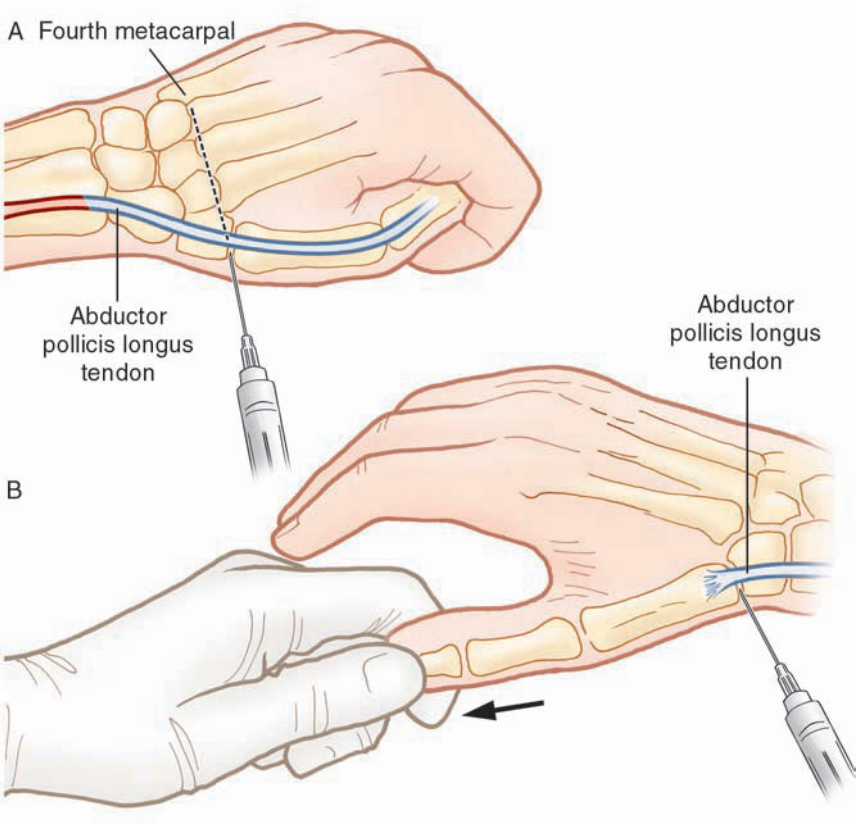

FIGURE 77-14. Carpometacarpal joint of the thumb arthrocentesis. **A.** Recommended approach. The *dotted line* represents the proper direction for needle insertion, toward the base of the fourth metacarpal. **B.** An alternative technique. The arrow represents the application of distal traction.

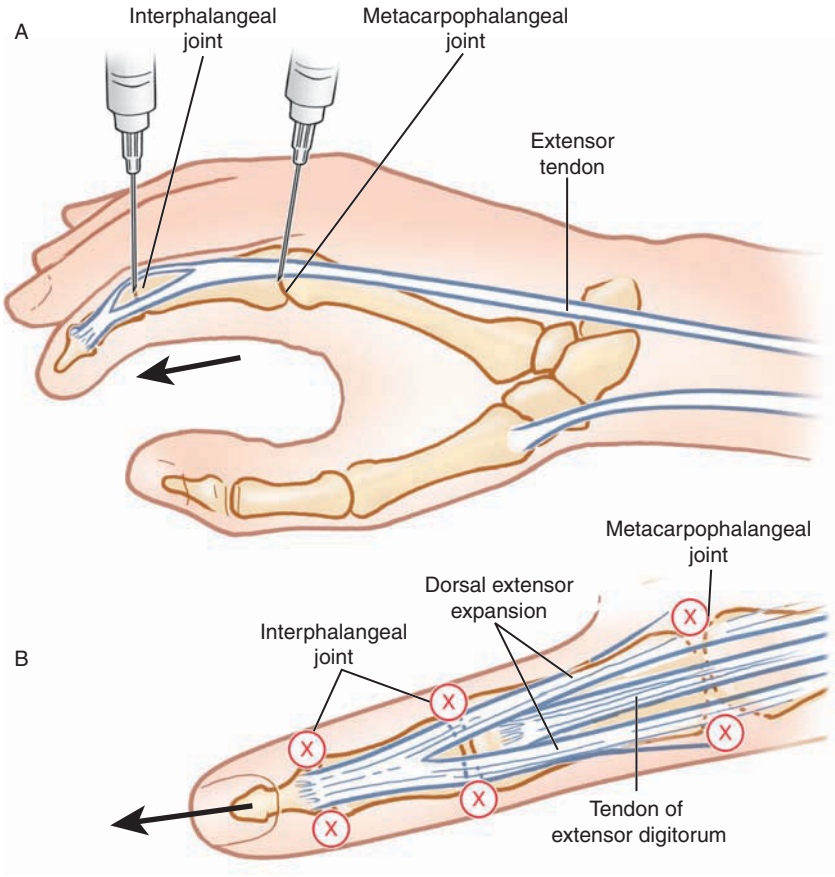

FIGURE 77-15. Arthrocentesis of the metacarpophalangeal and interphalangeal joints. **A.** Proper needle placement. **B.** Distal traction will cause dimpling of the skin in the areas noted by the "⊗". These areas of skin dimpling are the landmarks for needle insertion. The *arrow* represents the application of distal traction.

INTERPHALANGEAL JOINT OF THE FINGER ARTHROCENTESIS

Landmarks Identify the interphalangeal (IP) joint and the extensor tendon (**Figure 77-15A**). The IP joint can be located just proximal to the prominence at the base of the middle or distal phalanx of the finger. Identify the extensor tendon by having the patient extend the finger against resistance.

Patient Positioning Place the patient sitting upright or supine on a stretcher. Pronate the hand and abduct the fingers. Grasp the finger and apply distal traction.

Needle Insertion and Direction Insert a 22 gauge needle into the dorsal joint space just medial or lateral to the extensor tendon (**Figure 77-15B**). Direct the tip of the needle toward the center of the joint. Advance the needle to a depth of 0.3 to 0.5 cm.

Remarks The application of distal traction often causes a depression to appear on both sides of the extensor tendon (**Figure 77-15B**). These depressions can be used as landmarks for the site of needle insertion into the joint cavity. The joints are small and normally contain almost no synovial fluid. When inflamed or infected, the joint cavity may contain up to 2 mL of synovial fluid.

Joint Injection A maximum volume of 1 mL may be instilled into this joint. A maximum dose of 5 mg of corticosteroids may be instilled into this joint.

HIP JOINT ARTHROCENTESIS, ANTERIOR APPROACH

Landmarks Identify the anterior superior iliac spine (ASIS) and the femoral pulse (**Figure 77-16**). The landmark for insertion of the needle is 2 to 3 cm below the ASIS and 2 to 3 cm lateral to the femoral artery pulse.

Patient Positioning Place the patient supine on a stretcher with the affected leg internally rotated and the knee slightly flexed.

Needle Insertion and Direction Insert a 3.5 in., 18 gauge needle at the landmark (**Figure 77-16**). Direct the tip of the needle posteromedially. Insert the needle at a 60° angle to the skin of the thigh. Advance the needle until bone is encountered. Slightly withdraw the needle and begin aspirating the synovial fluid.

US Probe Placement Position the patient as described above.[49] Place the US transducer over the anterior hip and aligned with the long axis of the femoral neck, with the marker in a superior-medial direction and aimed toward the umbilicus (**Figure 77-17**).[44] The echogenic cortex of the femoral head is visible to the left of the image and the femoral neck to the right. The concave transition between these two areas is the anterior synovial recess.[44,49] Synovial fluid will be seen in this recess and tends to displace the joint capsule anteriorly (**Figure 77-18**).[43] Insert the needle from the inferolateral edge of the US transducer and advance it into the synovial fluid.

Remarks This approach is technically easier and recommended by many authors. A long spinal needle is usually required for this procedure. Use caution as the needle may injure the articular cartilage. This procedure should be performed by an Orthopedist, a Rheumatologist, or a Radiologist under fluoroscopic guidance if US is not available in the ED.

Joint Injection A maximum volume of 10 mL may be instilled into this joint. A maximum dose of 40 mg of corticosteroids may be instilled into this joint.

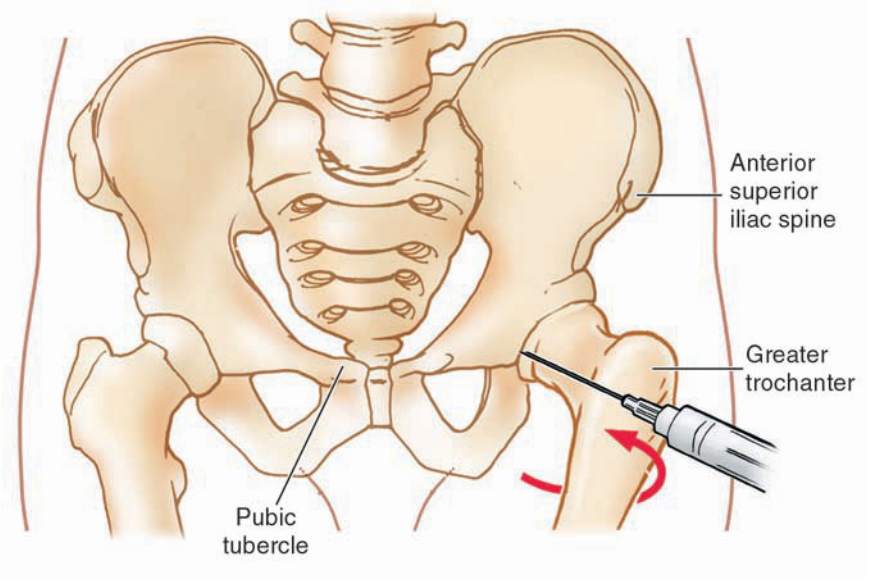

FIGURE 77-16. Anterior approach for hip joint arthrocentesis. The *curved arrow* represents internal rotation of the femur.

HIP JOINT ARTHROCENTESIS, LATERAL APPROACH

Landmarks The greater trochanter is the landmark for this technique (**Figure 77-19**). Place the patient supine with the affected leg internally rotated. Palpate the greater trochanter.

Patient Positioning Place the patient supine on a stretcher with the affected leg internally rotated (**Figure 77-19A**). Identify the greater trochanter and hold it between the thumb and index finger. A second patient position may be used for the alternative approach (**Figure 77-19B**). Place the patient lying on the unaffected side. Flex

FIGURE 77-17. The US transducer is placed anteriorly over the hip joint and aligned with the long axis of the femoral neck.

FIGURE 77-18. US image of a hip effusion. The hypoechoic effusion (*asterisk*) is located in the anterior synovial recess between the echogenic cortices of the femoral neck (*arrowhead*) and the femoral head (*arrow*).

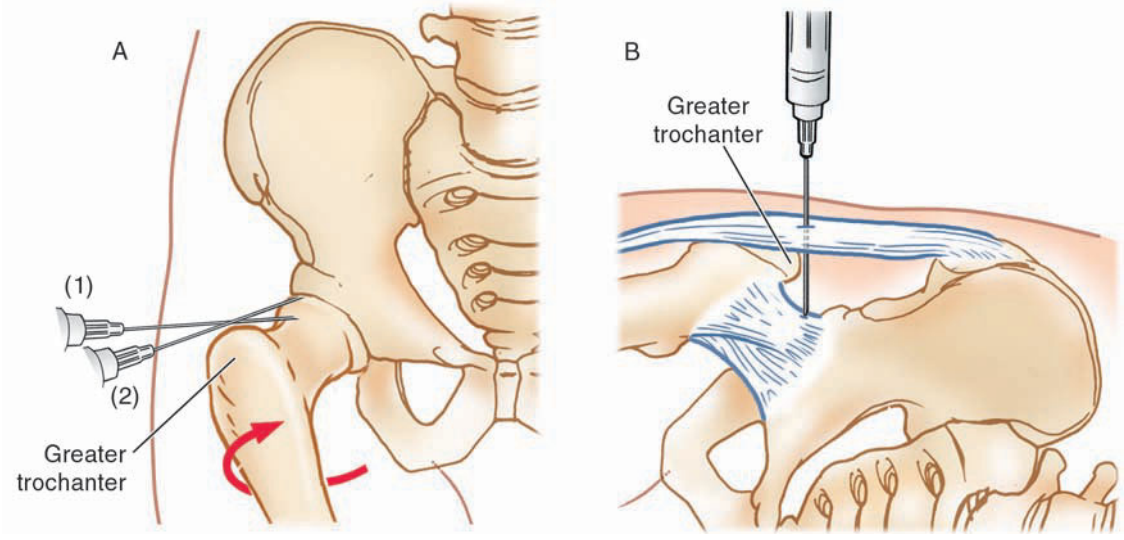

FIGURE 77-19. Lateral approach for hip joint arthrocentesis. **A.** The patient is supine with the leg internally rotated (*curved arrow*). A needle is inserted above the greater trochanter and advanced until the femoral neck is encountered (1). The needle has been withdrawn slightly, redirected cephalad, then readvanced into the joint cavity (2). **B.** An alternative approach.

the unaffected, lower leg 90°. Fully extend the upper, affected, leg with a pillow supporting the ankle.

Needle Insertion and Direction Insert a 3.5 in., 18 gauge needle just superior to the superior margin of the greater trochanter (**Figure 77-19A**). Advance the needle horizontally, parallel to the stretcher, until it contacts the femoral neck. Withdraw the needle 2 to 4 mm and redirect it slightly cephalad. Advance the needle while applying negative pressure to the syringe until synovial fluid enters the syringe. Stop advancing the needle and continue to aspirate the synovial fluid. The alternative technique requires the insertion of the needle perpendicular to the skin and 1 cm proximal to the greater trochanter (**Figure 77-19B**). Advance the needle until the femoral neck is contacted. Withdraw the needle 2 mm and begin aspirating synovial fluid.

Remarks In the morbidly obese, the greater trochanter may not be palpable. This approach is technically more difficult than the anterior approach. The advantage of this approach is that the articular cartilage will not be in the needle's path and so avoids injury. This procedure should be performed by an Orthopedist, a Rheumatologist, or a Radiologist under fluoroscopic guidance.

Joint Injection A maximum volume of 10 mL may be instilled into this joint. A maximum dose of 40 mg of corticosteroids may be instilled into this joint.

PATELLOFEMOROTIBIAL JOINT (KNEE) ARTHROCENTESIS, SUPRAPATELLAR APPROACH

Landmarks Identify the midpoint of the superolateral or superomedial border of the patella (**Figure 77-20A**). Either of these landmarks may be used as the site for needle insertion.

Patient Positioning Place the patient supine on a stretcher with the affected knee fully extended.

Needle Insertion and Direction Insert an 18 gauge needle through the midpoint of the superolateral or superomedial border of the patella (**Figure 77-20A**). Direct the tip of the needle toward the intercondylar notch of the femur. Advance the needle to a depth of 1.5 to 3.0 cm.

US Probe Placement Position the patient as described above. A small roll or towel can be used behind the knee to provide slight flexion. Place the US transducer in a longitudinal orientation superior to the patella, with the probe marker directed toward the patient's head. The cortex of the distal femur is visible as a bright echogenic line to the right of the image and the synovial fluid is visible deep to the quadriceps tendon (**Figure 77-21**). Keep the US transducer in oriented longitudinally and slowly slide it medially or laterally to move off the quadriceps tendon. Insert the needle from the superior edge of the US transducer in a longitudinal orientation and direct it toward the synovial fluid. Advance the needle into the synovial fluid.

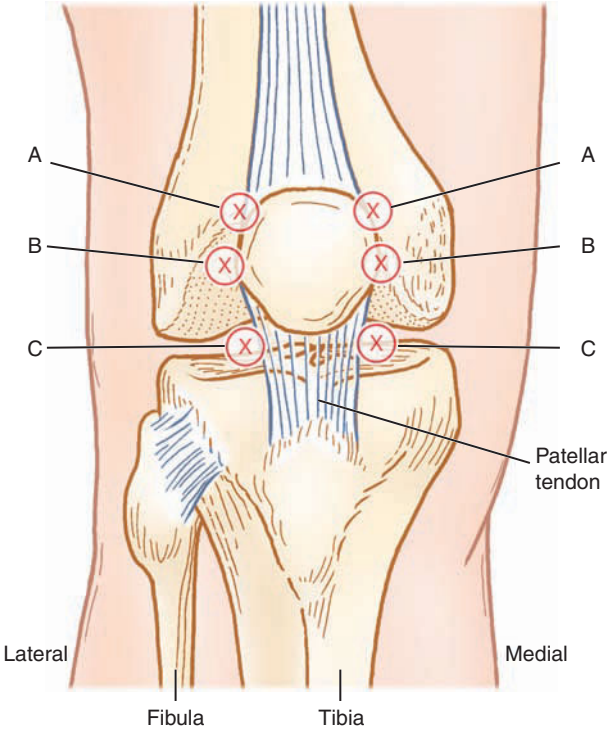

FIGURE 77-20. Knee joint arthrocentesis. The site of needle insertion is represented by an "⊗". **A.** Medial and lateral suprapatellar approach. **B.** Medial and lateral parapatellar approach. **C.** Medial and lateral infrapatellar approach.

FIGURE 77-21. US image of a knee effusion. The hypoechoic joint fluid (*asterisk*) is located above the echogenic cortex of the distal femur (*arrow*).

Remarks The needle enters the suprapatellar bursa and avoids any potential damage to the articular cartilage. The bursa is a direct continuation of the synovial cavity.[44] There are no neurovascular structures of significance to injure with this approach. If the knee effusion is minimal, synovial fluid may not be able to be aspirated from this approach. Approximately 10% of the population has a plica completely separating the suprapatellar bursa from the knee joint. If this variation exists in the patient, the bursa fluid will not represent synovial fluid.

Joint Injection A maximum volume of 10 mL may be instilled into this joint. A maximum dose of 40 mg of corticosteroids may be instilled into this joint.

PATELLOFEMOROTIBIAL JOINT (KNEE) ARTHROCENTESIS, PARAPATELLAR APPROACH

Landmarks Identify the midpoint of the lateral or medial border of the patella (**Figure 77-20B**). Either of these landmarks may be used as the site for needle insertion.

Patient Positioning Place the patient supine on a stretcher with the affected knee fully extended.

Needle Insertion and Direction Insert an 18 gauge needle just below the midpoint of the lateral or medial border of the patella (**Figure 77-20B**). Direct the needle perpendicular to the long axis of the leg and aimed toward the intercondylar notch of the femur. Advance the needle to a depth of 1 to 2 cm.

Ultrasound Probe Placement Place the US transducer oriented longitudinally, and either lateral or medial to the patella, with the marker directed toward the patients head. Identify the joint fluid. Slowly rotate the US transducer to a horizontal orientation to identify the area with the largest anechoic fluid collection.[44] Insert and advance the needle along the superior edge of the US transducer and into the joint fluid.

Remarks The easiest site for arthrocentesis is the medial parapatellar region. There are no disadvantages to using the medial parapatellar site.

Joint Injection A maximum volume of 10 mL may be instilled into this joint. A maximum dose of 40 mg of corticosteroids may be instilled into this joint.

PATELLOFEMOROTIBIAL JOINT (KNEE) ARTHROCENTESIS, INFRAPATELLAR APPROACH

Landmarks Identify the inferior border of the patella and the patellar tendon (**Figure 77-20C**). The tendon is a thick band that passes from the inferior border of the patella to the tibial tuberosity.

Patient Positioning Place the patient sitting upright on a stretcher with the affected knee bent 90° over the edge of the bed and the leg hanging freely and unsupported.

Needle Insertion and Direction Insert an 18 gauge needle 0.5 cm below the inferior border of the patella at the level of the joint line and just medial or lateral to the patellar tendon (**Figure 77-20C**). Direct the needle perpendicular to the long axis of the leg and aimed toward the intercondylar notch of the femur. Advance the needle to a depth of 1.5 to 2.0 cm.

Remarks The weight of the leg helps to open the joint cavity. The risk of injury to the articular cartilage is minimal. This approach was popular in the past but is not often used today. Do not pierce the patellar tendon with the needle.

Joint Injection A maximum volume of 10 mL may be instilled into this joint. A maximum dose of 40 mg of corticosteroids may be instilled into this joint.

TIBIOTALAR JOINT (ANKLE) ARTHROCENTESIS, ANTEROLATERAL APPROACH

Landmarks Identify the joint cavity, the lateral malleolus, and the extensor digitorum longus (EDL) tendons (**Figure 77-22**). The joint cavity is located below the distal edge of the fibula and between the bases of the malleoli. Extend the toes against resistance to identify the EDL tendons. Palpate the base of the lateral malleolus.

Patient Positioning Place the patient sitting upright or supine on a stretcher. The patient can also be placed sitting upright on a stretcher with affected knee bent 90° over the edge of the bed and the foot hanging freely and unsupported. Plantar flex the ankle.

Needle Insertion and Direction Insert a 22 gauge needle perpendicular to the fibular shaft at the level of the base of the lateral malleolus; midway between the malleolus and the lateral border of the EDL tendon (**Figure 77-22A**). Advance the needle to a depth of 0.5 to 1.0 cm.

US Probe Placement Position the patient as described above. Place the US transducer over the anterior tibiotalar joint in a longitudinal orientation, with the marker of the US transducer toward the patient's head (**Figure 77-23**).[44,46] Manipulate the US transducer with a slight rotation until the echogenic cortex of the tibia and talus bones are both visible (**Figure 77-24**). The tibia is visible to the left of the image and the talus to the right. During the rotation of the US transducer, note the location of the dorsalis pedis artery and the extensor tendons so that they may be avoided when inserting the needle.[44] The joint fluid is visible as a hypoechoic area in the V-shaped recess between the tibia and talus (**Figure 77-24**). Insert the needle at the inferior end of the transducer and advance it into the joint fluid.

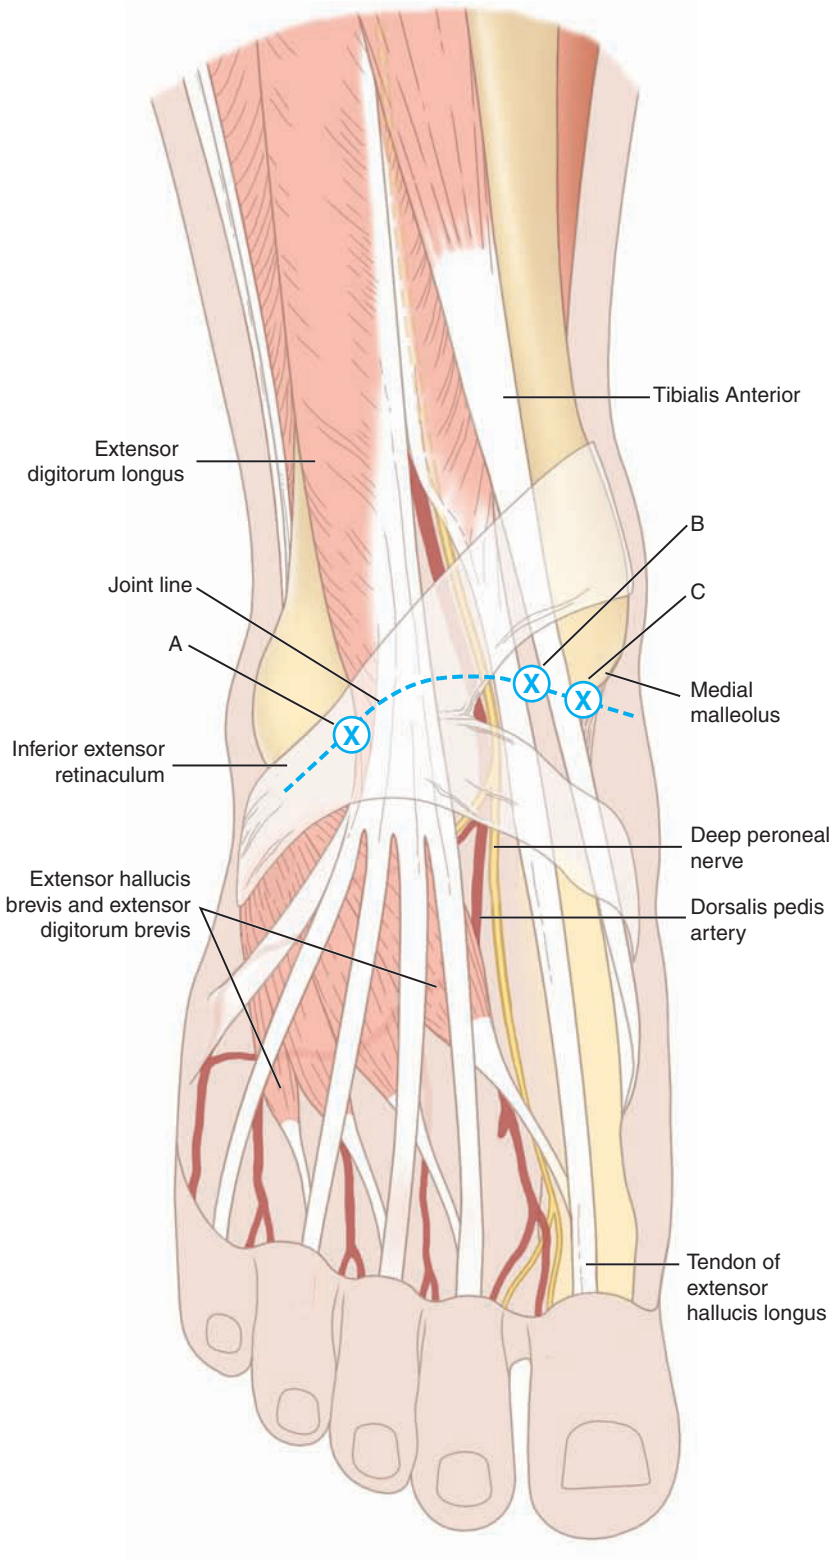

FIGURE 77-22. Arthrocentesis of the ankle joint. The site of needle insertion is represented by an "⊗". **A.** Anterolateral approach. **B.** Anteromedial approach. **C.** An alternative technique for the anteromedial approach.

Remarks This approach avoids potential injury to the dorsalis pedis vessels and the deep peroneal nerve.

Joint Injection A maximum volume of 3 mL may be instilled into this joint. A maximum dose of 20 mg of corticosteroids may be instilled into this joint.

TIBIOTALAR JOINT (ANKLE) ARTHROCENTESIS, ANTEROMEDIAL APPROACH

Landmarks Identify the joint cavity, the medial malleolus, and the tendons of the tibialis anterior (TA) and the extensor hallucis longus

FIGURE 77-23. The US transducer is placed over the anterior tibiotalar joint in a longitudinal orientation.

(EHL) muscles (**Figure 77-22**). The joint cavity is located below the distal edge of the tibia and between the bases of the malleoli. Extend the great toe against resistance to identify the EHL tendon. Plantar flex the ankle against resistance to identify the TA tendon. Palpate the base of the medial malleolus.

Patient Positioning Place the patient sitting upright or supine on a stretcher. The patient can also be placed sitting upright on a stretcher with the affected knee bent 90° over the edge of the bed and the foot hanging freely and unsupported. Plantar flex the ankle to use the EHL tendon as the landmark for the procedure. Alternatively, plantar flex the ankle and invert the subtalar joint to use the TA tendon as the landmark for the procedure.

Needle Insertion and Direction Insert a 22 gauge needle perpendicular to the tibial shaft at the level of the base of the malleolus and medial to the EHL tendon (**Figure 77-22B**). Alternatively, insert the needle medial to the TA tendon (**Figure 77-22C**).

Ultrasound Probe Placement The procedure is exactly as described above for the anterolateral approach.

Remarks If using the EHL tendon as the landmark, use caution to avoid the dorsalis pedis vessels and the deep peroneal nerve that usually lie immediately lateral to the EHL tendon.

Joint Injection A maximum volume of 3 mL may be instilled into this joint. A maximum dose of 20 mg of corticosteroids may be instilled into this joint.

FIGURE 77-24. US image of the longitudinal view of the anterior tibiotalar joint. The hypoechoic joint fluid (*asterisk*) is located in the recess between the echogenic cortices of the tibia (*arrow*) and talus (*arrowhead*).

SUBTALAR JOINT ARTHROCENTESIS

Landmarks Identify the tip of the medial malleolus. Palpate the sustentaculum tali of the calcaneus (**Figure 77-25**). It is approximately 1.5 to 2.0 cm below the tip of the medial malleolus.

Patient Positioning Place the patient supine on a stretcher with the foot held at a right angle to the leg. Externally rotate the hip until the medial malleolus is pointing upward.

Needle Insertion and Direction Insert a 22 gauge needle immediately above and slightly posterior to the sustentaculum tali (**Figure 77-25**). Advance the needle to a depth of 1.5 to 2.0 cm.

Remarks This is a difficult procedure because the joint space is very small. Fluoroscopy may be required to gain entry into the joint cavity. This procedure is seldom performed in the ED. US is not very helpful due to the small joint space and irregular body surfaces.

Joint Injection A maximum volume of 1.5 mL may be instilled into this joint. A maximum dose of 20 mg of corticosteroids may be instilled into this joint.

INTERTARSAL JOINT ARTHROCENTESIS

There are no specific landmarks for the many intertarsal joints. Radiographs are required to identify the location of a specific joint. Plain radiographs are often not helpful and fluoroscopic guidance is required. For these reasons, arthrocentesis of these joints is not routinely performed in the ED. Some authors

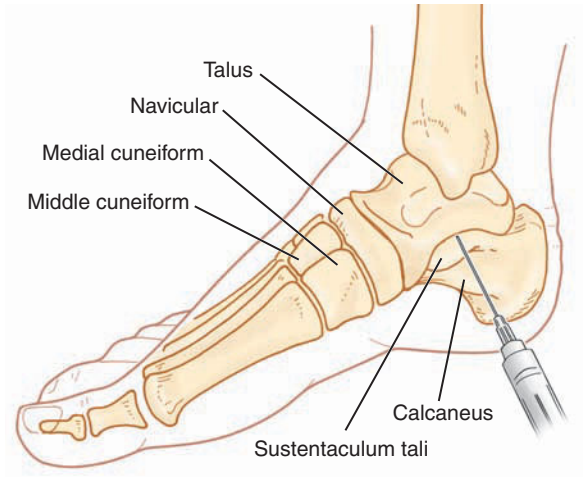

FIGURE 77-25. Subtalar joint arthrocentesis.

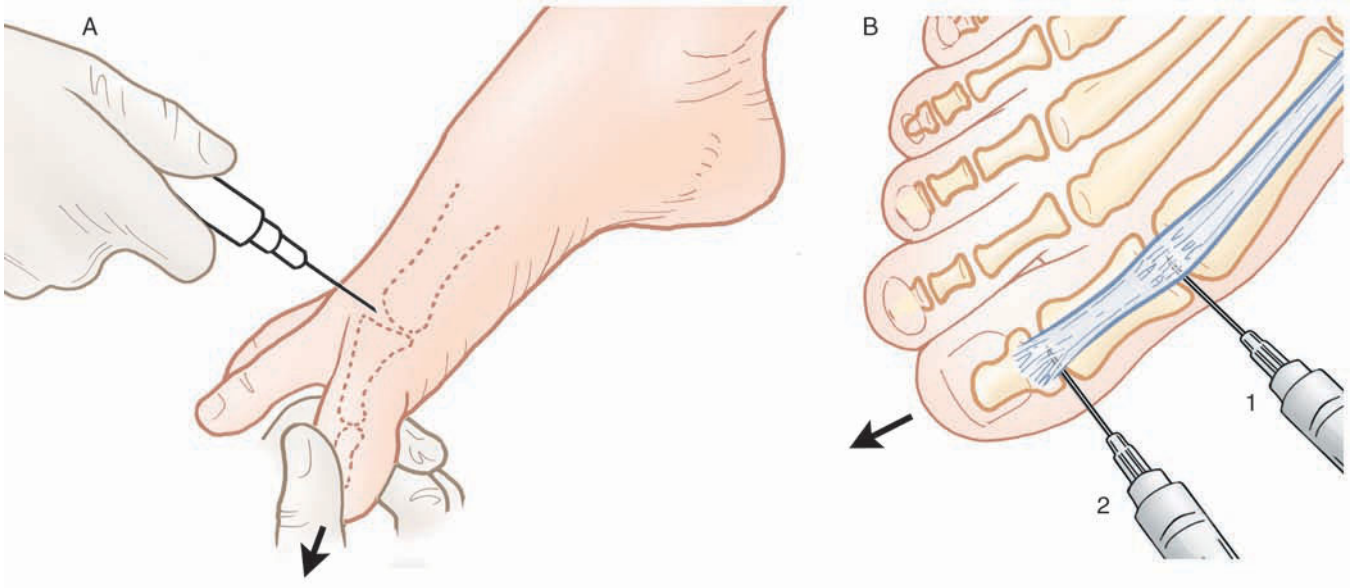

FIGURE 77-26. Arthrocentesis of the metatarsophalangeal and interphalangeal joints of the foot. **A.** The ankle is plantar flexed. The affected toe is flexed 15° to 20° at the metatarsophalangeal joint and distal traction is applied (*arrow*). **B.** The needle is inserted just inferomedial or inferolateral to the extensor tendon at the level of the metatarsophalangeal joint (1) or the interphalangeal joint (2).

recommend probing the general area of the joint with a needle until it enters the joint cavity. This is extremely painful for the patient and risks injury to the articular cartilage. Therefore, this technique cannot be recommended.

METATARSOPHALANGEAL JOINT ARTHROCENTESIS

Landmarks Identify the metatarsophalangeal (MTP) joint and the extensor tendon. The MTP joint can be located just proximal to the prominence at the base of the proximal phalanx of the toe. Identify the extensor tendon by having the patient extend the toe against resistance.

Patient Positioning Place the patient sitting upright or supine on a stretcher. Plantar flex the foot. Grasp and plantar flex the toe 15° to 20° and apply distal traction (**Figure 77-26A**).

Needle Insertion and Direction Insert a 22 gauge needle into the dorsal joint space and just medial or lateral to the extensor tendon (**Figure 77-26B**). Direct the tip of the needle toward the center of the MTP joint. Advance the needle to a depth of 0.3 to 0.5 cm.

Remarks The application of distal traction often causes a depression to appear on both sides of the extensor tendon. These depressions can be used as landmarks for the site of needle insertion into the joint cavity.

Joint Injection A maximum volume of 1.5 mL may be instilled into this joint. A maximum dose of 10 mg of corticosteroids may be instilled into this joint.

INTERPHALANGEAL JOINT OF THE TOE ARTHROCENTESIS

Landmarks Identify the IP joint and the extensor tendon. The IP joint can be located just proximal to the prominence at the base of the middle or distal phalanx of the toe. Identify the extensor tendon by having the patient extend their toes against resistance.

Patient Positioning Place the patient sitting upright or supine on a stretcher. Plantar flex the foot. Grasp and plantar flex the toe 15° to 20° and apply distal traction (**Figure 77-26A**).

Needle Insertion and Direction Insert a 23 gauge needle into the dorsal joint space and just medial or lateral to the extensor tendon (**Figure 77-26B**). The needle should be aimed toward the center of the joint. Advance the needle to a depth of 0.3 to 0.5 cm.

Remarks The application of distal traction often causes a depression to appear on both sides of the extensor tendon. These depressions can be used as landmarks for the site of needle insertion into the joint cavity. These joints are small and normally contain almost no synovial fluid. When inflamed or infected, the joint cavity may contain up to 1.5 mL of synovial fluid.

Joint Injection A maximum volume of 1 mL may be instilled into this joint. A maximum dose of 5 mg of corticosteroids may be instilled into this joint.

JOINT INJECTION TECHNIQUE

A joint may be injected with corticosteroids and/or local anesthetic solution to relieve pain and inflammation. Identify the anatomic landmarks, prepare the patient, and insert the needle as if performing an arthrocentesis. Inject the pharmaceutical(s), remove the needle, and apply a bandage.

Occasionally, synovial fluid may be required for analysis prior to the injection of pharmaceuticals. A prospective randomized study in rheumatoid arthritis patients found that aspirating all the synovial fluid prior to therapeutic steroid injection reduced the risk of relapse, led to better outcomes, and increased symptom relief.[40] Identify the anatomic landmarks, prepare the patient, and insert the needle as if performing an arthrocentesis. Aspirate the synovial fluid into the syringe. With the needle still in the joint, grasp the hub of the needle with a hemostat. Remove the original syringe containing the aspirated synovial fluid. Attach a second syringe containing the pharmaceutical(s) to be injected into the synovial cavity. Reaspirate to confirm that the needle tip remained within the synovial cavity. Inject the pharmaceutical(s). While injecting, no resistance should be felt. If resistance is encountered, the needle may have dislodged from the joint cavity. Remove the needle, reinsert it into the synovial cavity, aspirate to confirm proper positioning, and then inject the pharmaceutical(s). After injection, remove the needle and apply a bandage.

ULTRASOUND AND PEDIATRIC HIP EFFUSIONS

The evaluation of a suspected pediatric hip joint effusion requires the consideration of septic arthritis versus a toxic synovitis. Toxic synovitis is the most common cause of hip pain in children and occurs most frequently in ages 3 to 6 years old. It is a nonpyogenic, inflammatory condition of the joint synovium with an unknown etiology. It occurs most commonly in the hip joint and occasionally in the knee joint.

In contrast, septic arthritis is an acute pyogenic inflammation that occurs most commonly in children below the age of 4 years, with a peak incidence between 6 and 24 months of age. Useful studies include serum WBC, ESR, blood cultures, plain films, CT, MRI, and US. The aspiration and analysis of joint fluid being most critical.

US has been shown to be as accurate as MRI in detecting effusions. It is most easily performed using an anterior approach with the US transducer oriented in the sagittal plane and parallel to the femoral neck. An effusion is visible as a convex rather than concave joint capsule that is greater than 5 mm in thickness. Transudates are more often hypoechoic whereas exudates and hemorrhage are usually more hyperechoic.[35]

Many imaging techniques such as plain film, scintigraphy, MRI or CT are useful to help differentiate these two clinical entities. MRI and CT provide the highest quality information. However, these studies usually require sedation or even general anesthesia in young children due to the long exam times and requirement for no motion. US-guided hip joint arthrocentesis is a useful bedside imaging technique to help solve this problem. **US can only detect the presence of a joint effusion. It cannot reliably differentiate between the two entities without further joint fluid aspiration and analysis. US should not be used as a primary means to rule out a suspected septic arthritis.**[35]

AFTERCARE

There is no special care or precautions required after performing an arthrocentesis. Pain can be relieved with the use of ice, elevation, and nonsteroidal anti-inflammatory drugs. Joint injection, on the other hand, often requires some precautions. Some recommend limiting joint activity for 4 to 8 hours if an anesthetic solution is injected into a joint. An anesthetized joint, especially weight-bearing joints, may be susceptible to further injury when the joint has decreased sensation. Injection of corticosteroids into a joint cavity often requires a period of immobilization. This discussion is beyond the scope of this chapter. The readers should refer to a rheumatology or orthopedic textbook, or the medical literature, for this information.

COMPLICATIONS

Complications can occur with joint aspiration and/or injection (**Table 77-3**). Most of the complications are minor. Significant complications are rare; but they do occur.

TABLE 77-3 Complications Associated with the Aspiration and/or Injection of Joints

Allergic reactions
Bleeding
Cartilage injury
Dry tap
Infection
Joint instability
Needle-associated complications
Corticosteroid-induced complications
Vasovagal reactions

ALLERGIC REACTIONS

Allergic reactions can occur from hypersensitivity to the local anesthetic solution. Symptoms can range from mild itching and urticaria to circulatory collapse and death. Severe allergic reactions are extremely rare but may occur. Taking a thorough history can prevent many allergic reactions. The preservative in the local anesthetic solution is often the cause of the allergic reaction. Local anesthetic solutions containing no preservatives are an alternative. Some authors believe local anesthesia is not required, as the pain of anesthetic injection is equal to performing the procedure without injectable anesthesia.[4,12] If one is concerned about a potential allergic reaction associated with local anesthetic solutions, topical ice, or vapor coolant is an acceptable alternative to nothing. A solution of 1% to 2% diphenhydramine can also be used as an injectable local anesthetic agent for the skin and soft tissues. Do not inject diphenhydramine into the joint cavity as this can result in a significant inflammatory reaction and possible crystal deposition.

CARTILAGE INJURY

The articular cartilage can be damaged from improper needle insertion or needle movement within the joint cavity. The actual incidence of cartilage injury is unknown. The cartilage is avascular and injuries do not heal. Damaged cartilage can lead to focal degenerative changes and be a nidus for future infection. Injury to the articular cartilage can be prevented with a few simple steps. Select a site for the procedure and a needle path that avoids the articular cartilage. Aspirate as you slowly enter the joint cavity and stop inserting the needle when synovial fluid enters the syringe. There is no advantage to plunging the needle into the middle of the joint cavity. Avoid needle movement once the joint cavity has been entered. Finally, do not try to completely aspirate all the fluid within the joint cavity.

DRY TAP

A needle inserted into a joint does not always guarantee fluid will be aspirated.[14] A dry tap can occur due to improper needle placement, small or absent effusion, mechanical obstruction, or chronic inflammation.

A dry tap can result from improper needle placement. If the needle is not within the joint cavity, no fluid will be aspirated. Slightly withdraw the needle and reinsert it at a different angle. Alternatively, remove the needle, re-identify the anatomic landmarks, and then reinsert the needle.

One of the most common reasons for a dry tap is the lack of an effusion or a small one. It may be difficult on physical examination to determine if an effusion is present. This is especially true if the patient is obese or if a large amount of subcutaneous edema is present. Try using the non-syringe-bearing hand to "milk" fluid toward the needle while aspirating. Alternatively, if a small effusion is suspected, inject a small amount of sterile saline into the joint cavity. Allow the saline to remain for 30 to 60 seconds, then aspirate the fluid.

Synovial fluid may be loculated or inaccessible by the chosen site of needle entry if the joint has been previously injured. Choose an alternate approach or site to enter the joint cavity. This may facilitate synovial fluid aspiration.

Mechanical obstruction can result in a dry tap. Gently move the needle tip to determine if it can move freely. If it does not, it may be caught or embedded in cartilage, periosteum, or synovium. Withdraw the needle 1 to 2 mm and reaspirate. The needle may also be within the intraarticular fat pad. Slightly withdraw the needle and reaspirate. A plica may be obstructing the lumen of the needle. Rotate the needle and reaspirate. If no fluid is aspirated, slightly advance the needle and reaspirate. If still no fluid is obtained, attempt an alternate approach or reconsider if an effusion is present and if the procedure is actually required.[31]

The synovial fluid itself may be the cause of a dry tap. The presence of purulent fluid or fluid with debris may clog the needle. Remove the needle and repeat the procedure with a larger gauge needle. If the needle clogs during the aspiration, try reinjecting a small amount of the synovial fluid to dislodge the obstruction and then reaspirate. A larger gauge needle may be required to complete the procedure.

Aspiration of synovial fluid from a chronically inflamed joint may be problematic. The synovium may undergo fatty replacement known as lipoma arborescens. Long-standing inflammatory fluid may be resorbed, leaving a thick gelatinous material that is difficult to aspirate. In these cases, arthrocentesis should be referred to the experienced clinician or a consultant.

HEMORRHAGE

Significant bleeding is extremely rare. External hemorrhage can be controlled with direct pressure over the puncture site. Hemarthroses are usually small, self-limited, and only require observation. If a significant hemarthrosis or external hemorrhage occurs, treatment may be required to reverse the anticoagulant or replace clotting factors. The readers should refer to another source for management of these complications, as a detailed discussion is beyond the scope of this chapter.

Arthrocentesis can be safely performed in patients who are anticoagulated or have a bleeding disorder. The most experienced EP should perform the procedure to limit any potential complications and bleeding. Also reconsider if the procedure must be done immediately in the ED. The only true indication to perform an arthrocentesis in a coagulopathic patient in the ED is to rule-out a septic joint.

INFECTION

Infection of a sterile joint can occur when the needle penetrates unclean skin, cellulitic skin, infected subcutaneous tissues, or skin lesions. If proper aseptic technique is used, the risk of infecting a sterile joint occurs in less than 1:10,000 arthrocenteses.[4] The risk of infection is negligible when the skin is properly cleansed, aseptic technique is used, and the skin is not punctured through an obvious infection or through a skin lesion that may harbor microorganisms.

HYPODERMIC NEEDLE-ASSOCIATED COMPLICATIONS

The hypodermic needle can be the source of complications in rare circumstances. The needle may separate from the hub during the procedure and require a minor surgical procedure to recover it.[15] The needle tip may be advanced too deep and become embedded in the bony skeleton surrounding the joint. Upon withdrawing the syringe, the needle tip may break off and remain embedded in the bone or the needle may separate from the hub.

CORTICOSTEROID-INDUCED COMPLICATIONS

Corticosteroid-induced complications can be acute or chronic.[3,4,16–18] **The most severe acute complication is injection of corticosteroids into an infected joint. A septic arthritis must be ruled out prior to instillation of corticosteroids into a joint cavity.** Other local complications include steroid arthropathy, Charcot arthropathy, osteonecrosis, aseptic necrosis, tissue atrophy, tendon rupture, fat necrosis, formation of calcifications, joint instability, intraneural injection, and postinjection flare. Systemic complications include flushing, pancreatitis, posterior subcapsular cataracts, and hyperglycemia. Due to the potential for complications, many clinicians defer corticosteroid injections to the Orthopedist, Rheumatologist, or Sports Medicine consultant.

VASOVAGAL REACTIONS

The patient may experience an increase in vagal tone from apprehension, needle phobias, and/or pain. Vasovagal reactions are relatively common and may be associated with light-headedness and/or fainting. To prevent secondary injury to the patient, arthrocentesis should be performed with the patient on a stretcher or in a chair that reclines. These vasovagal reactions are self-limited and only require reassurance.

SYNOVIAL FLUID ANALYSIS

Hailed as the most valuable test in rheumatology, synovial fluid analysis provides essential diagnostic information for the appropriate management and treatment of urgent and emergent arthritic conditions.[4,30] It has been established as a fundamental component to the complete and appropriate work-up of arthritic diseases. With the possibility of potential joint destruction and chronic disability, **the role of synovial fluid analysis in the expedient diagnosis and treatment of acute joint disease cannot be overemphasized.**

Controversy exists concerning what constitutes the appropriate guidelines for a "routine" synovial fluid analysis.[4,19–21,23,24] This controversy arises from multiple issues that include the clinical scenario, physician competency with appropriate arthrocentesis techniques, the sensitivity and specificity of individual tests, the availability and proficiency of laboratories, and cost. Classification schemes have been established based upon gross, microscopic, biochemical, and microbiological analyses. The most traditional and cited classification for synovial fluid is normal, noninflammatory, inflammatory, septic, or hemorrhagic (**Table 77-4**).[4,19,20,24] Despite the controversy that exists with guidelines and classification schemes, **it is critical to differentiate between an inflammatory and noninflammatory process, with the intent of expediting the diagnosis and treatment of a possible infectious etiology**.[4]

A detailed discussion of synovial fluid analysis is beyond the scope of this book. A brief discussion of the most essential components that can be performed in the ED will be presented.

PATHOPHYSIOLOGY OF SYNOVIAL FLUID

Synovium refers to the 1 to 3 cell thick structure that lines the joint space and terminates at the articular cartilage margin.[19] This structure overlies a highly vascularized subsynovium, both of which are supported by the dense fibrous joint capsule.[19] The synovium produces synovia, an ultrafiltrate of plasma that includes hyaluronate. The synovia serves to lubricate, nourish, and clear the metabolic waste of the avascular articular cartilage.[20] Synovial fluid has been demonstrated to possess potent bactericidal activity against the most common gram-positive organisms responsible for septic arthritis.[28]

TABLE 77-4 Synovial Fluid Analysis

	Normal	Noninflammatory	Inflammatory	Septic	Hemorrhagic
Gross analysis					
Color	Clear/yellow/straw	Straw/xanthochromic	Xanthochromic/cloudy/white	White/variable	Red
Clarity	Transparent	Transparent	Translucent/opaque	Opaque	Opaque
Viscosity	Very high	High	Low	Very low/variable	
Mucin clot	Good/firm	Fair-to-good/firm	Fair-to-poor/friable	Poor/friable	
Microscopic analysis					
Total leukocyte count (WBC/mm^3)	<150	<3000	3000–50,000	>50,000	
Polymorphonuclear leukocytes (%)	<25	<25	>70	>90	
Biochemical analysis					
Glucose (mg/dL)*	Normal	Normal	70–90	>90	
Protein (mg/dL)†	1.3–1.8	3–3.5	>4.0	>4.0	
Microbiological analysis					
Gram's stain	Negative	Negative	Negative	Positive‡	Negative
Culture	Negative	Negative	Negative	Positive‡	Negative
Differential diagnosis					
		Osteoarthritis	Rheumatoid arthritis	Bacterial infections	Trauma coagulopathy
		Traumatic arthritis	Acute crystal		Anticoagulant therapy
		Early rheumatoid arthritis	Synovitis		Tumor
			Viral arthritis		Charcot's arthropathy
		Avascular necrosis	Psoriatic arthritis		Hemangioma
		Crystal synovitis§	Reiter's syndrome		A-V malformation
		Osteochondritis dissecans	Arthritis of IBD**		Sickle cell disease
			SLE		Postsurgical
		SLE	Polyarteritis		Joint prosthesis
		Polyarteritis	Scleroderma

		Amyloidosis			

WBC, white blood cells; * and † variable interpretation (refer to the text); ‡ variable results depending on organism (refer to the text); § chronic or subsiding; SLE, systemic lupus erythematosus; **IBD, inflammatory bowel disease.

The synovium has been described as a double barrier in which molecules must pass through the endothelial microvasculature as well as the synovium and its matrix.[20] This double barrier is responsible for the retention of plasma protein. In the presence of an inflammatory process, the barrier is disrupted and protein can leak through the synovium. Difficulty arises in the diagnostic interpretation of protein and smaller molecules (i.e., sodium, chloride, urea, urate, and lactate) found in synovial fluid secondary to the effects of damaged endothelial permeability and variable lymphatic drainage.[20,23,24]

GROSS ANALYSIS OF SYNOVIAL FLUID

The color of synovial fluid varies depending on the amount of protein, blood, and breakdown products of hemoglobin. Normal synovial fluid usually appears clear to a straw or yellow color. Inflammatory and purulent synovial fluid may appear xanthochromic to white. Hemorrhagic synovial fluid is red and must be distinguished from a traumatic arthrocentesis. A traumatic aspiration usually clots and is more than often nonhomogenous.[19,20] A hematocrit may be sent on a bloody aspirate to distinguish between a traumatic tap and hemorrhagic fluid. A vein was pierced by the needle (i.e., traumatic tap) if the synovial fluid hematocrit is equal to the serum hematocrit.[20]

The following synovial fluid properties observed during bedside gross analysis were found to better predict a potentially septic joint when compared to synovial fluid cell count alone.[30]

The clarity of synovial fluid refers to the amount and type of particles within the fluid. Normal synovial fluid is usually transparent and newspaper print can be easily read through a glass tube containing this fluid.[19] Inflammatory and purulent synovial fluid is translucent to opaque secondary to the presence of leukocytes. Opaque fluid can also represent crystals and other particulate matter. Infected synovial fluid cannot be differentiated from noninfected synovial fluid based on gross appearance alone.[4]

Synovial fluid viscosity is determined by the intactness and concentration of hyaluronate. Viscosity can grossly be assessed by observing a drop of fluid fall from the tip of the needle. The "string" formed will normally be 5 to 10 cm in length.[22] In inflammatory and septic synovial fluid, the hyaluronidase is depolymerized and degraded.[20] The string formed in these conditions is shorter, or not formed at all, and the fluid falls as a drop. Processes resulting in a significant effusion without inflammation may also dilute hyaluronate without degrading it and result in decreased viscosity. Clotted white blood cells may enhance viscosity in the presence of inflammation.[20] EPs must be cautious with their interpretations of viscosity because even quantitative measures often fail to distinguish between inflammatory and noninflammatory states.[4]

The mucin clot test evaluates the degree of polymerization of hyaluronate.[4,19] The mucin clot test is performed by one of two methods. The first method involves mixing the supernatant of a centrifuged specimen with a few drops of glacial acetic acid. The second method involves mixing 1 mL of synovial fluid to 4 mL of 2% acetic acid. A "good" clot consists of a dense white precipitant that indicates a high degree of polymerization and a high viscosity.[19] A "poor" clot consists of little to no precipitate and suggests an inflammatory process that has depolymerized the hyaluronate. Controversy exists concerning the subjectiveness of the clot's endpoint.[4]

MICROSCOPIC ANALYSIS OF SYNOVIAL FLUID

The total leukocyte count, more than any other test, aids in distinguishing between an inflammatory, noninflammatory, and septic process.[20] Although a significant overlap may exist, the total leukocyte count can be used to identify synovial fluid as normal, noninflammatory, inflammatory, or septic (**Table 77-4**). Using this classification scheme, a total leukocyte count of less than 3000 cells/L is considered noninflammatory. A count between 3000 and 20,000 cells/L is considered inflammatory. The range of 20,000 to 50,000 cells/L may be inflammatory or septic. A count greater than 50,000 cells/L is considered septic until proven otherwise. **The overlap between categories is considerable and clinicians must be cautious of basing a diagnosis solely on the total leukocyte count.** Depending on the acuteness of the inflammation, several arthritic conditions such as gout, pseudogout, and rheumatoid arthritis may yield a significantly elevated total leukocyte count approaching 100,000 cells/L.[21] Immunocompromised hosts and some infectious diseases, such as tuberculosis and *Neisseria gonorrhoeae*, may have lower absolute counts than expected.[4]

The differential leukocyte count may further aid in distinguishing between inflammatory, noninflammatory, and septic synovial fluid. The cell count and differential (WBC) of the joint fluid is the best diagnostic test for septic arthritis, while the serum ESR and WBC perform poorer in the identification of infection.[37] However, using the traditional cut-off value of 50,000 WBC/mm^3 lacks sensitivity enough to safely rule-out a septic arthritis.[39] Inflammatory processes generally have greater than 70% neutrophils while septic synovial fluid has greater than 90% neutrophils.[19] Again, the overlap can be significant depending on the arthritic process and its acuteness. Crystal-induced processes may present with high neutrophil counts, while immunocompromised hosts, fungal infections, and tuberculosis may present with lower neutrophil counts.[4,21] **In general, a synovial fluid containing greater than 90% neutrophils in the presence of an elevated total leukocyte count should be highly suspicious of a septic process.** High eosinophil counts may suggest parasitic infection, allergic reactions, tumor, or Lyme disease.[20,23] High monocyte counts may suggest viral infection (e.g., rubella and hepatitis B) or serum sickness.[22]

Crystal identification is an essential component of synovial fluid analysis. Crystal identification requires the use of a polarized light microscope with higher-powered lenses and oil immersion capabilities. Crystals can be identified based on their shape, size, and birefringence. Birefringence is defined as the crystals' ability to bend the light passing through it into two distinct directions, negative or positive. The light's ability to bend negatively or positively is transformed into a specific color (yellow or blue) under the polarized microscope.[19,20] Caution must be taken as artifact and tissue debris can often imitate birefringent material.

Crystal analysis requires an experienced technician and is rarely if ever performed in the ED. Monosodium urate crystals are commonly seen in gout. These crystals are needle-shaped, 2 to 25 μm in length, and have strong negative birefringence. They may clump together in sheets.[22,25] Local anesthetic solutions have the ability to dissolve monosodium urate crystals. Therefore, the joint cavity should not be penetrated with the needle when anesthetizing the skin and subcutaneous tissue.[21] Calcium pyrophosphate dihydrate crystals are seen in pseudogout. These crystals are rhomboidal or rectangular, 2 to 10 μm in length, and have weak positive birefringence.[22,25] These crystals may be more difficult to detect than monosodium urate crystals because of the weaker birefringence. Cholesterol crystals may present in multiple forms and sizes. They are typically flat rhomboidal plates, 5 to 50 μm in length, and have both negative and positive birefringence.[22] Artifact "crystals" can be produced by a variety of substances. Corticosteroids can be detected weeks after injection and have variable shapes but no regular geometric form. Maltese crosses are strong birefringent particles that are secondary to multiple compounds such as talc powder, lipids, calcium oxalate, and dust.[22]

BIOCHEMICAL ANALYSIS OF SYNOVIAL FLUID

As discussed previously under the pathophysiology section, difficulty arises with the interpretation of total protein secondary to the effects of damaged endothelial permeability and variable lymphatic drainage.[20] In theory, the damage caused by an inflammatory process should increase the permeability of proteins into the synovial fluid. Multiple studies have shown that protein samples were only able to classify synovial fluid into an inflammatory or noninflammatory process in approximately 50% of the cases.[23] Furthermore, the total protein count was unable to differentiate among various groups of arthritides, including rheumatoid arthritis and osteoarthritis.[4]

Theoretically, inflammatory and infectious processes consume glucose and thus lower the level present in synovial fluid. One study has shown that glucose levels were able to classify synovial fluid into an inflammatory or noninflammatory process in less than 50% of cases.[23] In 50% of the septic joints analyzed, the glucose level was not significantly decreased. Another study reports glucose analysis having a sensitivity of 20% and specificity of 84% in detecting inflammatory joint disease.[24] Synovial fluid glucose levels can vary from serum glucose levels when taken less than 6 hours after oral intake.[24] **These studies are just a few of many that confirm synovial fluid glucose levels are not reliable to diagnose or rule out a septic joint.**

Other biochemical markers have been studied to elicit a marker to differentiate a septic from a nonseptic joint. These include lactate, lactic dehydrogenase, and numerous immunologic and inflammatory mediators. These biochemical markers, at present, are not sensitive or specific to rule out a septic joint. They are not recommended for routine synovial fluid analysis. Bacterial polymerase chain reaction (PCR) techniques with aspirated joint fluid are currently being studied and are theoretically superior tests, able to identify difficult to culture organisms. However, many drawbacks including high false positives due to contamination limit usage until further studies are done.[38]

MICROBIOLOGICAL ANALYSIS OF SYNOVIAL FLUID

The Gram's stain is an easily performed test that yields rapid results and can lead to the expedient diagnosis and treatment of a septic joint. The Gram's stain has a sensitivity of 50% to 70% for nongonococcal infections and less than 10% for gonococcal joint infections.[24] Although the sensitivity of this test is low, the specificity of the Gram's stain approaches 100%. This makes it an essential component of routine synovial analysis. *N. gonorrhoeae* is identified as a gram-negative intracellular diplococci. *Staphylococcus aureus* and *Streptococcus* are responsible for approximately 70% of nongonococcal septic arthritis and can be identified as gram-positive cocci in clusters and gram-positive cocci in chains, respectively.[27] Recent studies have identified an increased prevalence of MRSA-associated osteoarticular pathology such as septic arthritis and subperiosteal abscesses.[36] These diagnoses should be considered in patients with and without risk factors for community-acquired MRSA infection.[36]

Bacterial identification is essential when confronted with the possibility of a septic joint. Synovial fluid cultures have a sensitivity of 75% to 95% for nongonococcal bacteria and 10% to 50% for gonococcal bacteria in the absence of previous antibiotic treatment. Difficulty arises from the low sensitivity of cultures for some organisms, culture methods, specimen preparation, and the length of time for some bacteria to grow.[24] Recent advances with the use

of polymerase chain reaction techniques have shown increased sensitivity and specificity for detecting *N. gonorrhoeae*.[19,26]

SPECIMEN COLLECTION

Minimal quantities of synovial fluid can yield valuable information. Analysis can be performed with as little as two drops of synovial fluid.[21] The total leukocyte count, differential leukocyte count, crystal analysis, and Gram's stain can be obtained from the first drop while the second drop can be sent for cultures.[21] Unfortunately, few institutions or laboratories can perform synovial fluid analysis with only two drops of fluid.

The specimen may be transported for analysis by one of two methods. First, the syringe with the synovial fluid may be capped and sent to the laboratory. The laboratory technicians will then divide the specimen for analysis. Alternatively, the synovial fluid may be placed into tubes. A new sterile needle, different from the arthrocentesis needle, should be used to place fluid in the test tubes. A needle used for steroid injection should never be used secondary to the formation of a crystal-like substance.[4] Synovial fluid for microscopic analysis should be collected in test tubes with and without preservatives. Fluid should be placed in a Culturette or culture bottle for microbiological analysis. Synovial fluid for crystal analysis should be sent in a test tube with liquid heparin (green-topped tube) because EDTA and powdered anticoagulants interfere with crystal identification.[21] A red-topped tube containing no preservatives should be used to test for chemistries, serology, and viscosity. A tube with an anticoagulant (purple-topped tube) is used for the cell count, cell differential, and cytology. Prompt examination of fluid specimens is urgent to avoid the following problems: misdiagnosing borderline inflammatory fluids because of decreased WBC counts, not identifying crystals that dissolve with time, or over interpreting findings because of new, artifactual crystals.[29]

SUMMARY

Arthrocentesis is used to diagnose and make treatment decisions regarding a joint. It is a safe, easy, and simple procedure. Arthrocentesis is relatively painless and extremely beneficial to the patient. It may be performed for diagnostic information and/or therapeutic treatment. Analysis of the synovial fluid provides unique and valuable information about a joint. It is the only method to accurately and definitively diagnose or rule out a septic arthritis. Arthrocentesis is indicated to evaluate the cause of an arthritis or a joint effusion. All patients presenting with an acute monoarthritis or an acute, nontraumatic effusion should undergo arthrocentesis when the diagnosis is not clear based upon the history and physical examination.

78 Methylene Blue Joint Injection

Joseph E. Tonna, Heather H. Bohn, and Matthew R. Lewin

INTRODUCTION

Trauma can breach the integrity of the joint capsule and result in infection, long-term arthritis, and other serious and potentially permanent morbidity. Synovial joint fluid provides nutrition to the articular cartilage. Loss of synovial fluid without prompt joint capsule closure can lead to cartilage wasting. Additionally, any breach of the joint capsule, especially through dirty skin, can introduce environmental contaminants and risk septic inoculation of the joint. The injection of joints with methylene blue dye is a simple, rapid, and definitive way to assess joint capsule integrity in cases of periarticular trauma where the clinical examination is inconclusive.

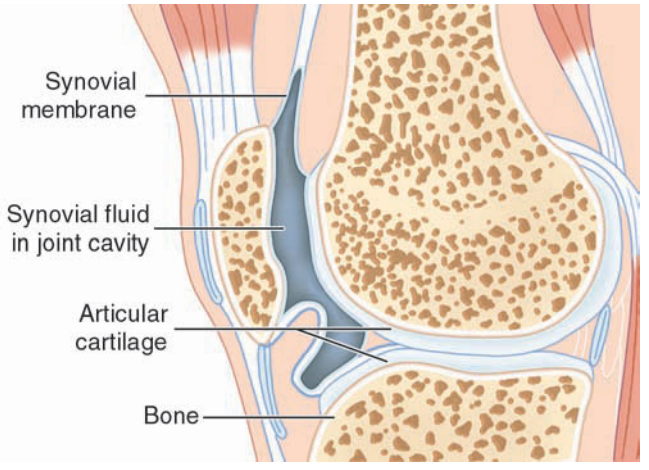

FIGURE 78-1. The anatomy of the knee joint.

ANATOMY AND PATHOPHYSIOLOGY

Synovial joints, such as those of the fingers, wrist, shoulder, and knee, consist of a fibrous capsule that overlies a thin, delicate synovial membrane (**Figure 78-1**). The synovial membrane is a highly vascular structure and the site of synovial fluid production. The synovial fluid provides nutritional support to the relatively avascular articular cartilage. Joint capsules contain varying volumes of fluid, and can be greatly expanded under conditions of inflammation or injection.

Methylene blue is a relatively safe and stable deep blue dye used in both chemistry and medicine. It has most frequently been used to treat methemoglobinemia and for marking skin and lymphatic tracts for oncologic surgery. It is readily oxidized, which has been the proposed basis for its vasoconstrictive effects.[1] Methylene blue can cause local necrosis without an immune sensitization when injected at full strength directly into tissues.[2]

The literature regarding the safety of methylene blue, even during direct intradermal injection, is supportive of its use. When used for lymph node mapping (i.e., direct intradermal and intraparenchymal injection), there is consistent evidence of local inflammatory reactions ranging from local wheal and flare (0.5% of patients) to focal erythema with induration (5% of patients).[3,4] Superficial tissue toxicity occurred in only 1.25% of patients.[4] These reactions were proportional to the concentration of methylene blue dye (ranging from a dilution of 1:1 to 1:7) and the superficiality of the injection.[4] Emergency Physicians (EPs) need to be aware of the potential complications arising from its use just as with any drug or dye introduced parenterally or intradermally. The tissue toxic effects are believed to be much less for intra-articular injections than direct intradermal injection.

INDICATIONS

The primary indication for injecting a joint with methylene blue dye is to assess the integrity of the articular joint capsule (**Figure 78-2**). This includes any of the following injuries in close proximity to a joint: skin laceration, a visible joint capsule through a wound, an open fracture, extravasation of serous or serosanguineous fluid

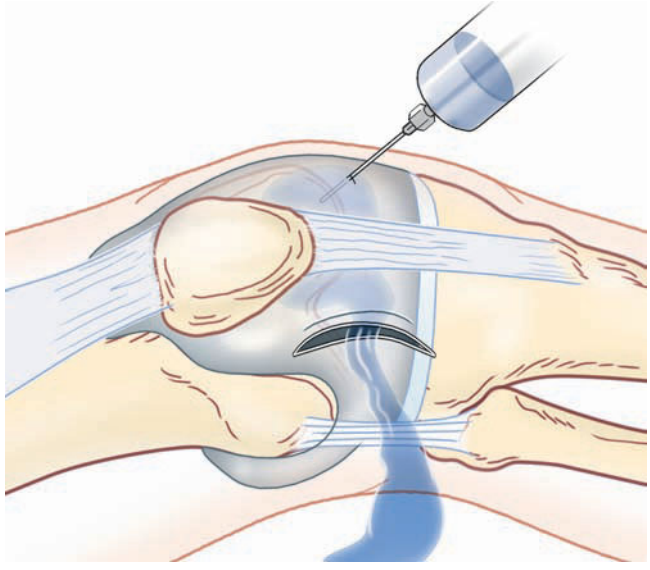

FIGURE 78-2. Methylene blue dye injection into a knee joint. The loss of capsule integrity allows the dye to flow out of the joint cavity.

from a wound, or a traumatic loading of the joint with evidence of a deformity or an acute effusion. The finger, wrist, elbow, shoulder, toe, ankle, knee, and hip (with varying success) joints can all be injected with methylene blue.

CONTRAINDICATIONS

There are few contraindications to injecting methylene blue dye into a joint. It should be avoided in patients with a known allergy to methylene blue. Patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency can develop acute reactions as they do not generate sufficient NADPH to efficiently reduce methylene blue to leukomethylene blue. These individuals are prone to methylene blue-induced hemolysis, oxidative hemolysis, and hemolytic anemia. Methylene blue can itself initiate methemoglobin formation. It should not be injected intraspinally or intrathecally.

There are a few relative contraindications to the injection of methylene blue. It should be used cautiously in a patient with a known coagulopathy, especially a factor deficiency, to prevent intra-articular hemorrhage. Consider reversing the coagulopathy before the injection. Methylene blue should not be used if there is a lack of procedural knowledge or skill by the EP. Not all synovial joints can be injected due to structural instability.

Joint injection is not contraindicated, but often unnecessary, when definitive operative treatment of the joint is indicated. This includes a visibly open joint capsule, a fracture with obvious joint involvement, intra-articular air on radiographs, and an intra-articular foreign body. In many injuries, the articular capsule will be breached but not externally open to the environment if there is no wound tracking to the skin surface. These injuries may present with an acute joint effusion or radiographic evidence of a periarticular fracture with or without intra-articular air. Despite capsular rupture, methylene blue is not helpful in such cases.

EQUIPMENT

- Sterile drapes
- Sterile gloves
- Sterile gown
- Face mask
- Eye protection
- Povidone iodine or chlorhexidine solution
- Sterile gauze
- Sterile dressing or tape
- Sterile saline
- Sterile basin
- Local anesthetic solution (lidocaine 1% or 2%, etc.)
- 25 g or 27 g needles for infiltrating local anesthetic
- 18 g or 21 g needles for joint injection
- 5 mL syringes for local anesthetic injection
- 10 mL syringes for fingers or toe injection
- 30 mL syringes for wrist or elbow injection
- 60 mL syringes for hip, knee, or shoulder injection
- 1% methylene blue dye

PATIENT PREPARATION

A complete history and physical examination should be performed prior to the injection of methylene blue dye. The affected joint should be thoroughly assessed. Inspect the skin overlying the joint for breaks, infection, old scars, prior incisions, superficial lesions, or any wounds. Palpate the joint to identify any warmth, tenderness, or effusion. Evaluate the joint for any crepitation, deformity, ligamentous instability, or limitations in motion.

As with any nonemergent procedure, consent should be obtained from the patient or their representative. Ideally, the consent should be documented in the medical record and signed by the patient. The patient should be consented for both the arthrocentesis procedure (joint injection) as well as for the use of methylene blue.

Position the patient based on the specific joint to be injected and the approach to be used. Expose the joint and surrounding areas. Identify the anatomic landmarks required for proper needle placement. The landmarks may be difficult to identify on a swollen and tender joint. Compare the "affected" joint to the "normal" joint on the opposite side of the body. Identify the joint and a landmark on the normal joint and transfer this to the affected joint. Clean any dirt and debris from the skin. Scrub the needle insertion site with povidone iodine or chlorhexidine solution and allow it to dry. Apply sterile drapes or a clear sterile dressing to maintain sterility of the injection site (**Figure 78-3**). The rate of infection resulting from intra-articular injections is very low if sterile technique is used.[5]

A comfortable, relaxed patient will facilitate arthrocentesis, as tense muscles distort the anatomy of the joint and make anatomic palpation more difficult. Oral analgesics for the precipitating injury along with adequate local anesthesia for the procedure are often sufficient. The articular cartilage has no intrinsic pain fibers, but the synovial membrane, joint capsule, and skin are richly innervated. Adequate time should be taken for the infiltration of local anesthetic solution. The subcutaneous injection of local anesthetic solution is often most practical for larger joints such as the knee, shoulder, and hip. A regional block is often easier for small and more distal joints such as the finger and ankle.

Apply anesthesia to the skin and subcutaneous tissue using 1% lidocaine, topical vapor spray, or ice. The administration of some form of local anesthesia is recommended but not required. The most common local anesthetic used is a short-acting injectable anesthetic solution of 1% lidocaine. There is disagreement if the additional needle stick to administer the anesthesia causes as much discomfort as performing the procedure without any anesthesia. This decision is specific to each EP and patient.

FIGURE 78-3. An injury at the level of the knee joint. The patient is prepared by draping the lateral joint where the needle will be inserted (**A**) or by dressing the area with a sterile clear dressing (**B**).

Alternative methods of anesthesia include ice and topical vapor coolants. A sterile drape may be placed over the prepped skin and a bag of ice water placed over the drape. Remove the ice water bag and drape after 5 minutes and perform the procedure. Ethinyl chloride topical vapor coolant may be used as an anesthetic. Spray the solution onto the area of skin in which the needle will be inserted. Apply the spray from 6 in. above the skin. Spray until the skin turns white and frosty. This usually takes 5 to 10 seconds. Immediately perform the procedure, as the anesthesia lasts only 30 to 60 seconds.

Because of the aforementioned effects of methylene blue dye, it is common, though not universal, to dilute the dye in normal saline before the injection. Draw up one to two drops of 1% methylene blue dye into an appropriately sized syringe. Fill the remainder of the syringe with sterile saline to dilute the dye. Apply an appropriately sized needle for the joint to be injected onto the syringe.

TECHNIQUES

THE BASIC TECHNIQUE

The use of musculoskeletal ultrasound is useful to assist in arthrocentesis and has been shown to have many benefits including greater fluid aspiration and greater novice physician confidence. It does not result in more pain for the patient and takes minimal additional time to perform at the bedside. The reader is referred to an ultrasound technique text for full instruction, but a few important points are included here. Bone will appear hyperechoic and easily differentiated from muscle and subcutaneous tissue. Tendons will appear fibrillar in nature, like a bundle of drinking straws. Joint fluid will appear hypoechoic and dark. The "seagull sign" is a shape that can be seen on most joint images and represents the joint space between the articular surfaces of two opposing bones. It is a V-shaped hypoechoic area surrounded by hyperechoic bone. Once the landmarks are identified, the needle can be inserted with or without ultrasound guidance.

Apply the needle to the syringe and break the resistance. This avoids any sudden and painful movements of the needle within the joint cavity. Stretch the skin over the site where the needle will be inserted. Penetrate the skin briskly with the needle and enter the joint cavity. Gently aspirate synovial fluid to confirm proper needle position within the joint cavity. If bone is encountered, slightly withdraw the needle and re-advance it in a different direction. Grasp the hub of the needle with your finger or a hemostat. Remove the syringe while leaving the needle in place. Attach the syringe filled with the diluted methylene blue onto the needle.

Inject the methylene blue slowly into the joint cavity. There should be no resistance to flow if the needle is within the joint capsule. The injection should not be painful if the needle is within the synovial capsule. Observe the skin wound for extravasation of blue dye while it is being injected into the joint cavity. Remove the needle when the procedure has been completed. Apply a bandage to the skin.

Different joints will accommodate various amounts of injected volume. The knee may allow for 30 mL or more, whereas the finger may accommodate only 1 mL. It is only necessary to inject a minimal amount of dye before extravasation is seen. If the joint capsule is ruptured, a greater amount of fluid can be injected, as it will escape through the breach. In intact joints, the capsule will expand, increasing pressure and resistance to continued injection. There is often visibly swelling of the skin around the injected joint if there is no breach.

Complete a procedure note in the medical record. A sample procedure note is described below:

After informed consent, the skin overlying the_____joint was cleaned and prepped with povidone iodine solution. The skin was anesthetized with (_____mL of_____% lidocaine, ethyl chloride vapor coolant, ice for_____minutes). Using sterile technique, an_____gauge needle was inserted on the (supero-/infero-,medial/lateral/inferior/superior) surface of the joint. It was directed (supero-/infero-,medially/laterally/inferiorly/superiorly). _____mL of fluid was obtained. It was (thin, thick, yellow, clear, straw-colored, bloody, purulent, with debris, without debris). No complications were noted.

The joint was injected with_____mL of sterile saline containing less than 0.2 mL of 1% methylene blue dye. No complications were noted.

SPECIFIC SITES

Methylene blue joint injection can be reasonably accomplished at any joint. The concern for joint capsule rupture without concomitant obvious need for operative exploration and fixation is rare

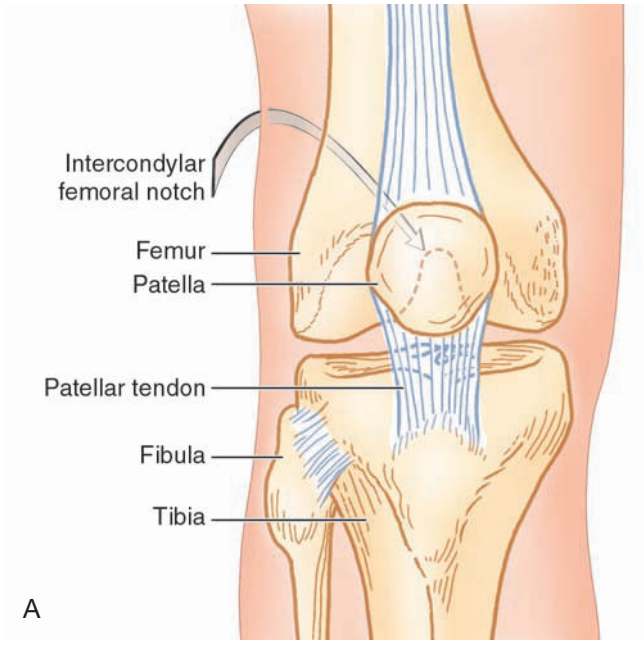

FIGURE 78-4. Methylene blue dye injection of the knee. **A.** Anatomy of the region. **B.** Palpating the boundaries of the patella. **C.** Injection of methylene blue using the medial parapatellar approach.

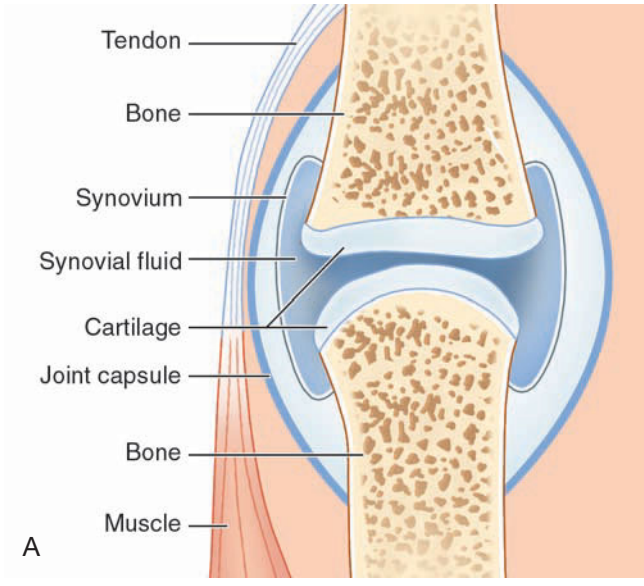
in joints other than the knee and fingers. The knee is relatively easy to inject while the fingers are more difficult. Arthrocentesis with methylene blue injection in the knee and finger is discussed below. The principles and techniques described below can be used on any synovial joint for which there is concern of a capsule breach and for which the EP feels competent to perform arthrocentesis. Please refer to Chapter 77 for the complete details of joint arthrocentesis.

PATELLOFEMOROTIBIAL JOINT (KNEE) ARTHROCENTESIS, PARAPATELLAR APPROACH



Landmarks The knee joint can be injected in a variety of locations and with the knee extended or flexed. Palpate the borders of the patella (superior, lateral, and inferior) and the patellar tendon (**Figures 78-4A & B**). Identify the midpoint of the lateral or medial border of the patella (**Figure 78-4B**). Either of these landmarks may be used as the site for needle insertion.

Patient Positioning Place the patient supine on a stretcher with the affected knee fully extended.

Needle Insertion and Direction Insert an 18 gauge needle just below the midpoint of the lateral or medial border of the patella (**Figure 78-4C**). Direct the needle perpendicular to the long axis of the leg and aimed toward the intercondylar notch of the femur. Advance the needle to a depth of 1 to 2 cm. Inject the methylene blue dye.

Ultrasound Probe Placement Start with probe placement longitudinally lateral or medial to the patella for a first view of the possible fluid collection. Then change the probe to a horizontal orientation, and rotate the probe like the hand of a clock around the patella 360° to discover the area with the largest anechoic fluid collection.

Remarks The easiest site for arthrocentesis is the medial parapatellar region. There are no disadvantages to using the medial parapatellar site. The lateral and medial parapatellar approaches are used with high relative success, most likely due to the large joint space and minimal accessory structures. Studies have demonstrated decreased success of the medial midpatellar approach (56%), relative to the lateral midpatellar (76%-93%) or the infrapatellar (71%-85% lateral and 73%-75% medial) approaches.[6,7]

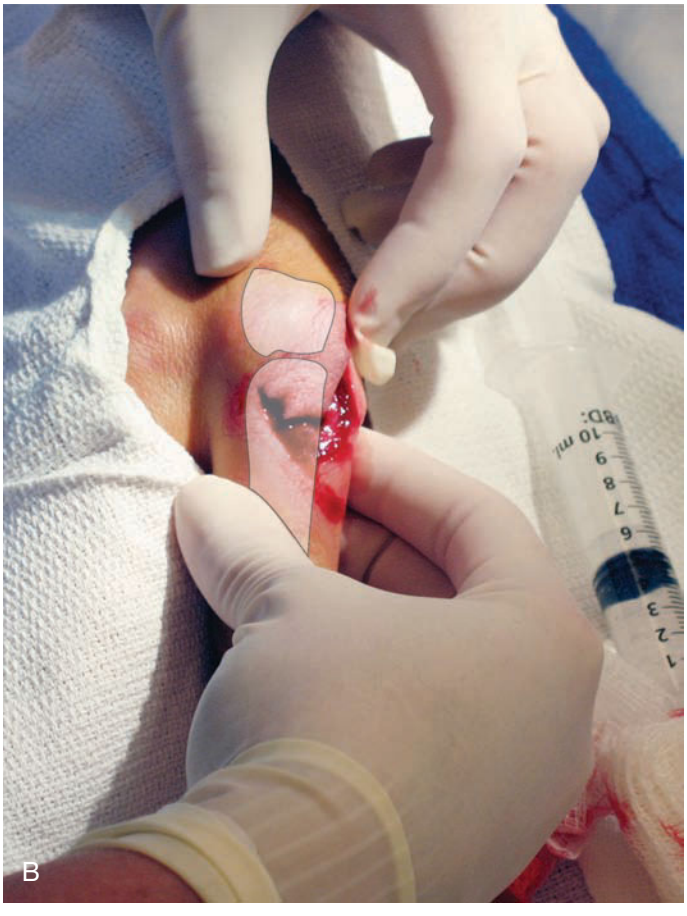


FIGURE 78-5. Methylene blue dye injection of the metacarpophalangeal (MCP) joint. **A.** Anatomy of the region. **B.** Palpation of the MCP joint. **C.** Injection of methylene blue.

METACARPOPHALANGEAL JOINT ARTHROCENTESIS

The relatively thin dermal and subcuticular layers over the phalanges often make one wonder about deep soft tissue avulsions or lacerations and the potential involvement of the joint capsule. Injection with methylene blue dye is an ideal method to assess joint capsule integrity. The success rate of arthrocentesis is much lower in the phalangeal joints than larger joints. The overlying ligaments and tendons are more prominent and the synovial capsule is smaller. A failure rate of 15% for finger arthrocentesis was found among skilled surgeons, and as high as 32% among first year residents.[8] Successful arthrocentesis was highest in the proximal interphalangeal joint compared to the distal interphalangeal joint or carpometacarpal joint of the thumb.

Landmarks Identify the metacarpophalangeal (MCP) joint and the extensor digitorum tendon (**Figures 78-5A & B**). The MCP joint can be located just proximal to the prominence at the base of the proximal phalanx of the finger. Identify the extensor tendon by having the patient extend the finger against resistance.

Patient Positioning Place the patient sitting upright or supine on a stretcher. Pronate the hand and abduct the fingers. Grasp the finger and apply distal traction.

Needle Insertion and Direction Insert a 22 gauge needle into the dorsal joint space just medial or lateral to the extensor tendon

(**Figure 78-5C**). Direct the tip of the needle toward the center of the joint. Advance the needle to a depth of 0.3 to 0.5 cm. Inject the methylene blue dye.

Remarks The application of distal traction often causes a depression to appear on both sides of the extensor tendon. These depressions can be used as landmarks for the site of needle insertion into the joint cavity.

Joint Injection A maximum volume of 1 mL may be instilled into this joint.

ASSESSMENT

The lack of methylene blue extravasation reassures the EP of an intact joint capsule. Extravasation of dye through the injury site is indicative of a ruptured joint capsule. These require exploration, high volume irrigation, and adjunctive medical treatment such as antibiotics. Although some wounds can be closed primarily in the Emergency Department after consultation with an Orthopedic or Hand Surgeon, open joints require management in the operating room.

A minimal amount of methylene blue dye needs to be injected before visible extravasation will occur. Upon injection, if no extravasation occurs, attempt to aspirate fluid. This may be difficult in small joints. Aspiration of blue fluid provides additional confirmation of intracapsular needle placement.

Given the not insignificant rate of ectopic needle placements (i.e., extrasynovial, intraligamentous, or intratendinous), a high index of clinical suspicion should be maintained for a joint capsule rupture, even in the face of a negative study. Clinical intuition and judgment should guide all decisions.

AFTERCARE

Arthrocentesis with methylene blue dye is a relatively benign procedure. The postprocedural care consists of monitoring for external bleeding and swelling. Musculoskeletal and neurovascular checks should be performed at the area and distal to the joint. Apply a bandage to the injection site. Pain should be minimal and analgesia can be achieved with oral nonnarcotic analgesics alone. In the setting of a significant traumatic injury, the patient may already be receiving opioid analgesics.

COMPLICATIONS

Complications are rare and include hemarthrosis, nerve injury, tendon injury, cartilage damage, and infection. External bleeding and nerve damage should be immediately apparent. A hemarthrosis may be insidious and appear with progressive swelling, pain with joint motion, and often without joint warmth. Tendon and cartilage damage may not be apparent for some time and present with joint stiffness or arthritis. Septic arthritis is the most concerning complication, evidenced by swelling, erythema, warmth, pain with range of motion, and systemic symptoms. Cellulitis may also complicate the procedure, appearing some time later with local warmth, erythema, and induration over the site. Please refer to Chapter 77 for a more complete discussion regarding the complications of arthrocentesis.

SUMMARY

Synovial joint injection with methylene blue dye provides the EP with a simple, rapid, and definitive method of assessing joint capsule integrity in cases of periarticular trauma. This procedure can determine between repairing a wound and sending a patient home or admitting a patient to the hospital for joint exploration and closure. Joint injection with methylene blue is technically simple with a low rate of complications.

79 Basic Principles of Fracture and Joint Reductions

Scott C. Sherman

INTRODUCTION

Orthopedic injuries are some of the most common presenting complaints facing the Emergency Physician (EP). Forces that cause injury can be large enough to result in fractures, displaced fractures, and joint dislocations. While each injury is different, some general principles can be applied to all displaced fractures and joint dislocations. For specific instructions on the techniques to reduce common fractures and dislocations, please refer to Chapters 80 through 91.

ANATOMY AND PATHOPHYSIOLOGY

The most common reason for a fracture to be displaced or a joint to be dislocated in a particular direction is the mechanism of injury. In the upper extremity, for example, a fall forward on an outstretched arm is the most common mechanism. Therefore, elbow dislocations occur most frequently in a posterior direction, distal radius fractures are most often Colles fractures, and supracondylar fractures are extension type fractures in 95% of cases.[1]

The deforming forces of muscles and ligaments also play an important role in the appearance of a fracture. Injury results in the muscles surrounding a fracture to contract or spasm. This leads to further deformity such as shortening, angulation, and rotation of the bone fragments distal and proximal to the fracture. For example, depending on the location of a humeral shaft fracture, the bone fragments will displace in different directions (**Figure 79-1**). Fractures that occur between the insertions of the pectoralis major and deltoid muscles will result in a proximal humerus that is adducted from contraction of the pectoralis major muscle and a distal humerus that is abducted from contraction of the deltoid muscle (**Figure 79-1A**). Conversely, if the fracture occurs distal to the deltoid insertion, the proximal humerus will be abducted from contraction of the deltoid muscle and the distal humerus will be adducted from contraction of the biceps and triceps muscles (**Figure 79-1B**).

INDICATIONS

The reduction of fractures and joint dislocations in the Emergency Department (ED) is more frequently indicated than it is not. Reduction is more readily achieved if it occurs soon after an injury. No fracture benefits from a prolonged period of angulation or displacement because the reduction becomes more difficult the longer the fracture has been present. No joint benefits from a prolonged dislocation as damage to articular cartilage increases with time.

Reduction should occur on an emergent basis when perfusion to the extremity is absent. A nonperfused extremity has a finite period of time before nerve and muscle death occur. For this reason, reduction should occur as soon as possible. **The earlier perfusion is restored, the better the chance of avoiding tissue necrosis.**

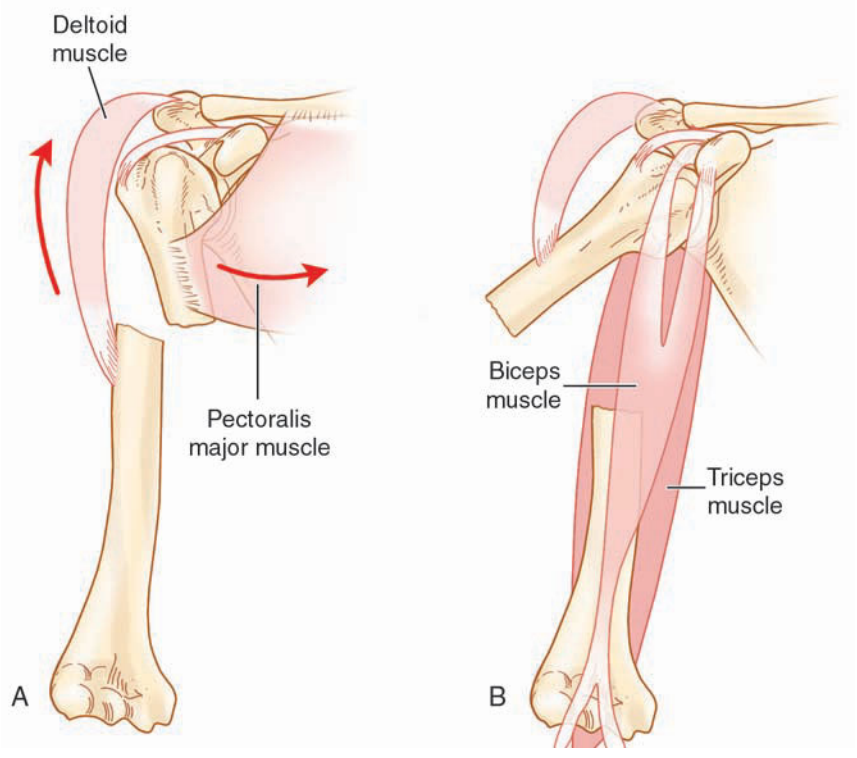

FIGURE 79-1. The direction of fracture displacement is influenced by muscle contraction following the injury. **A.** Humeral shaft fracture between the insertions of the deltoid and pectoralis major muscles. Arrows represent the direction of pull on the fracture fragments. **B.** Humeral shaft fracture distal to the deltoid muscle insertion.

Vascular injury can occur after any displaced fracture or dislocation. The EP should note the presence of an expanding hematoma, absent distal pulses, or delayed capillary refill. Some examples of orthopedic injuries more commonly associated with vascular injury include knee dislocations, posterior sternoclavicular joint dislocations, and supracondylar fractures. The importance of early reduction and repair of vascular injuries is emphasized in the case of a knee dislocation. If surgery is delayed more than 8 hours, up to 86% of patients will require an amputation.[2]

Not all displaced fractures and dislocations suspected of causing vascular injury should be reduced by the EP. When vascular injury is suspected in a patient with a posterior sternoclavicular joint dislocation, for example, reduction is best performed in the operating room with a cardiothoracic surgeon available because the distal clavicle may be tamponading a lacerated subclavian vessel.[3] In a similar manner, supracondylar fractures require immediate reduction only when the extremity is pulseless and perfusion is absent.[4]

Urgent reduction of displaced fractures and joint dislocations is also indicated to reduce the incidence of other potential complications. The incidence of compartment syndrome of the forearm is reduced by early reduction of displaced supracondylar fractures.[5] Likewise, a posterior hip dislocation should be reduced in a timely manner. The likelihood of avascular necrosis rises exponentially from a rate of 5% with less than 6 hours of being dislocated to 50% with greater than 6 hours of being dislocated.[6]

Neurologic injury results from the original injury, traction on a nerve, or compression of a nerve. Patients may experience altered sensation, decreased sensation, and/or paresthesias. **These injuries require urgent reduction to decrease potential long-term complications.**

CONTRAINDICATIONS

Despite the potential advantages of early reduction of fractures and dislocations in the ED, the EP should be aware of potential relative and absolute contraindications. Chronic or previously unrecognized dislocations are difficult to reduce in a closed manner and overly forceful attempts increase the chances of causing a fracture. An example is a surgical neck of the humerus fracture in a patient when attempting to reduce a chronic shoulder dislocation. Reduction in the ED is contraindicated when the patient requires immediate operative treatment. An open fracture in a perfused extremity should be reduced in the operating room where an appropriate surgical washout can occur.

Reduction is unnecessary when the potential for remodeling is such that the fracture angulation will correct without the need of a painful reduction or the risk of procedural sedation. For example, distal radius fractures in children have been shown to heal well even when they are 15° to 20° angulated.[7–10] Other fractures where some degree of displacement or angulation may be acceptable and frequently do not require reduction include the clavicle, humeral shaft, and neck of the fifth metacarpal.[1,11–17]

Reduction may be contraindicated in the ED for numerous other reasons. Adequate analgesia may not be possible due to the patient's medical condition or the inability to appropriately monitor the patient. These cases may require general anesthesia in the operating room. It is prudent to consult and wait for an Orthopedic Surgeon when the potential complications of a reduction attempt are high or the EP is uncomfortable performing the technique. A busy EP in a chaotic ED with single coverage may not have the time or resources to adequately sedate a patient and reduce the fracture or dislocation. This situation may require calling in an additional EP or an Orthopedic Surgeon to assist.

EQUIPMENT

- Procedural sedation equipment and supplies (Chapter 129), if applicable
- Hematoma block supplies (Chapter 125), if applicable
- Regional nerve block supplies (Chapter 126), if applicable
- Stretcher
- Weights for distraction

- Bed sheets for traction–countertraction techniques
- Splinting/casting material or commercially made splints (e.g., knee immobilizer)
- Finger traps for upper extremity reductions
- Fluoroscopy, if available, to assist with the reduction and postreduction radiographs
- Assistants depending on the reduction technique

PATIENT PREPARATION

Reduction techniques require a well-informed patient and a signed consent if possible. Explain the risks, benefits, and alternatives to the patient and/or their representative. Tell the patient what to expect. This knowledge may actually assist in the successful performance of the procedure. Anterior shoulder dislocation reduction, for example, can be performed with minimal or no sedation if the patient is able and willing to relax their musculature while the EP slowly manipulates the humeral head back into position.[18] The patient should also be consented for the anesthesia technique as this is a second procedure with potential complications much different from the reduction.

The physical preparation of a patient for the reduction of a fracture or dislocation is dependent on the type of injury and the clinical setting. In general, the patient should be resting as comfortably as possible on a gurney. The patient should be supine whenever possible. Fully expose the involved extremity. Remove any constricting pieces of clothing or jewelry both proximal and distal to the injury. If fluoroscopy is judged to be useful and it is available it should be moved into position. Frequently splint material is measured and set up prior to the start of the procedure so that it may be immediately applied to the extremity in the setting of an unstable fracture or dislocation.

TECHNIQUE

The basic principles to reduce a displaced fracture or a joint dislocation are similar. The procedure can be divided into four steps.[19] These are distraction, disengagement, reapposition, and release. The four steps can be used to reduce most, but not all, displaced fractures or joint dislocations.

The first step is distraction. It involves creating a longitudinal force to pull the fracture fragments or bones involved with a dislocated joint apart. This step should be performed gradually and sometimes requires time to be most effective in overcoming muscle spasm. Distraction is important when the fractured ends of the bone are overriding. It can be applied manually with the help of an assistant or by using weights.

To reduce a distal radius fracture, for example, one common technique to distract the injury uses finger traps to hold the hand in place while weights are wrapped around the arm (**Figure 79-2**). Saline bags placed in stockinette are equally effective and comfortable for the patient when weights are not available (**Figure 79-3**). Each liter bag of saline is equivalent to 1 kg or 2.2 pounds.

Disengagement is the second step to reduction. It allows for further disimpaction of the fracture fragments than distraction alone. Disengagement can be achieved by rotation of the distal fragment or more classically by "recreating the fracture deformity." It relieves tension on the surrounding soft tissues to allow the interlocking fracture fragments to reposition (**Figure 79-4**).

Disengagement is also important for dislocation reduction. It is most frequently achieved by rotation of the bone distal to the joint. An example is the external rotation technique to reduce an anterior shoulder dislocation.

FIGURE 79-2. Distraction for reduction of a forearm fracture.

FIGURE 79-3. Four 1 L bags of saline in stockinette is the equivalent of 8.8 pounds. This setup is useful when weights are not available to distract a fracture.

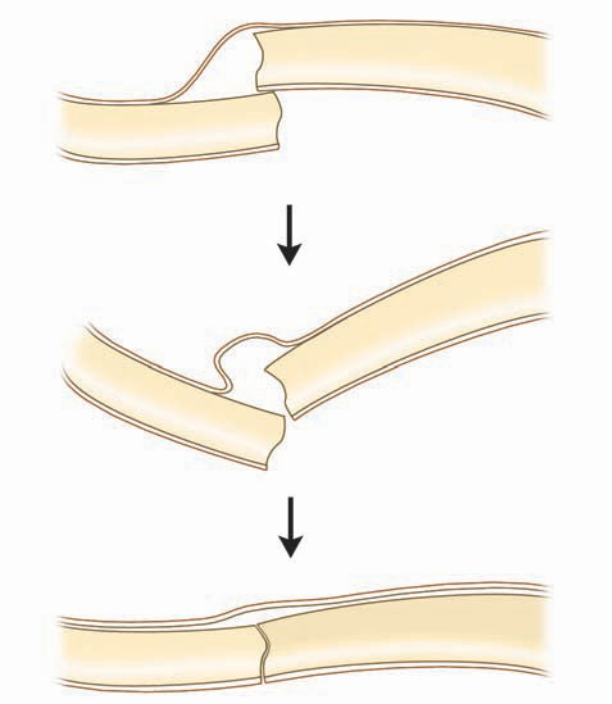

FIGURE 79-4. Disengagement. Recreating the fracture deformity allows the release of interlocking fragments by lengthening and relaxing the soft tissue hinge.

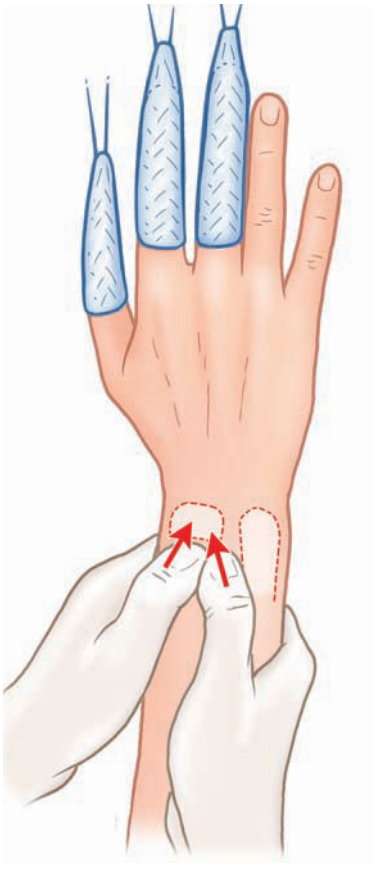

FIGURE 79-5. Reapposition of a forearm fracture.

The third step is reapposition. This is achieved by reversing the forces that caused the injury to bring the bony fragments back into alignment (**Figure 79-5**). While this step seems simple conceptually, it may not be as easy in clinical practice. One important pitfall to avoid is ignoring a rotational deformity that might create functional problems if the bone healed with a rotational deformity. This is especially important when treating fractures of the hand where a 5° rotational deformity of a proximal metacarpal fracture can translate into a distal fingertip that is 1.5 cm out of position[20] (**Figure 79-6**).

Release refers to the removal of the initial distracting force with the intent that alignment will be maintained. It is at this point that forces such as muscle contraction and gravity return and the fracture fragments are at risk for becoming malaligned again. A properly applied splint or cast can protect from loss of fracture alignment. It is advisable to have the splint measured and ready to apply before manual reduction is initiated.

ALTERNATIVE TECHNIQUES

There are frequently alternative techniques or variations of the four steps outlined above that are available to the EP depending upon the circumstance or the success of previous attempts. If the initial technique is unsuccessful, then the next maneuver is attempted and so on. The author uses the following sequence of maneuvers to reduce an anterior shoulder dislocation: scapular manipulation with downward arm traction (disengagement and distraction), then external rotation (disengagement), followed by the Milch technique (disengagement), and finally traction–countertraction (distraction).[18,21–24] The astute EP should also be aware of the limitations of the closed reduction technique. If soft tissue is interposed in an interphalangeal finger dislocation, for example, no amount of distraction or an alternative technique will reduce the dislocation without taking the patient to the operating room.

FIGURE 79-6. Rotational deformity of the fifth digit.

ASSESSMENT

The neurovascular status of the extremity must be assessed to ensure that pulses are present, the extremity is perfusing, and that nerve function has not been compromised before and after any reduction attempt. It should also be assessed after any casting or splinting to the extremity. Postreduction radiographs are taken to assess the success of the reduction, look for any fractures that may have been missed on the prereduction radiographs, and assess any complications from the reduction.

AFTERCARE

Immobilize the extremity as required for the specific fracture or dislocation. A record of the procedure should be placed in the chart including any complications and the method of reduction. The patient should undergo repeat plain radiography in most cases to document the success of the reduction. Patients with reduced fractures and dislocations should be referred to an Orthopedic Surgeon. Occasionally, a fracture that is properly reduced and immobilized will be unstable and become displaced again, frequently necessitating operative fixation.

COMPLICATIONS

When performed properly, complications of fracture and dislocation reduction are uncommon. However, even with proper techniques, complications can occur. These include converting a closed fracture to an open fracture, soft tissue trauma that produces a compartment syndrome, a reduction attempt that causes injury to the soft tissues making the fracture more unstable, producing a fracture during the dislocation reduction attempt by using excessive force, or neurovascular injury/compromise due to bony laceration, or compression of a nerve or blood vessel.

SUMMARY

Displaced fractures and joint dislocations requiring reduction are commonly seen in the ED. As the EP approaches these injuries, the initial step in assessment should be determining the neurovascular status of the extremity. When vascular compromise is present, emergent reduction is the rule with few exceptions. While all dislocations require reduction, not all displaced fractures necessitate reduction. The EP should be familiar with which displaced fractures benefit from reduction. When fracture reduction is indicated, the basic elements of the procedure are distraction, disengagement, reapposition, and release.

80 Sternoclavicular Joint Dislocation Reduction

Eric F. Reichman

INTRODUCTION

Sternoclavicular dislocations are uncommon injuries and account for less than 3% of shoulder girdle dislocations.[1] The medial clavicle may be displaced anteriorly or posteriorly. Anterior dislocations are more common by a ratio of 3:1 to 20:1.[2,3] Case reports of the less common posterior dislocations are more common in the literature due to the higher incidence of associated complications. Posterior sternoclavicular joint dislocations are often seen in younger individuals.[2,4]

Sternoclavicular dislocations are the result of direct trauma to the sternoclavicular joint or to the glenohumeral joint with the force directed toward the sternoclavicular joint. **This injury is usually associated with a tremendous force.** The most commonly reported mechanisms of injury are motor vehicle collisions and contact sports.[2,5] Anterior dislocations are often due to indirect forces transmitted through the anteromedial shoulder. As the shoulder is externally compressed and rolled backward, the lateral clavicle is pulled back and down beyond its limit of motion. The first rib acts as a fulcrum to spring the sternal end of the clavicle anteriorly from its articulation.[2,6]

Posterior dislocations may be due to direct or indirect forces.[3,4,7–13] With indirect trauma, the shoulder is externally compressed and rolled forward from a posterolaterally applied force to the shoulder. The costoclavicular ligament acts as a fulcrum that produces displacement of the sternal end of the clavicle posteriorly from its articulation.[4,9,11,13] Less commonly, a posterior dislocation may be due to a direct blow to the anteromedial clavicle.

There are reports of spontaneous and nontraumatic sternoclavicular subluxations and dislocations.[14] These are usually seen in females less than 20 years of age with sternoclavicular joint laxity. The clavicle dislocates anteriorly during abduction or flexion of the arm to the overhead position. The clavicle reduces spontaneously when the arm is returned to the side. This condition is usually associated with laxity in numerous other joints.

ANATOMY AND PATHOPHYSIOLOGY

The sternoclavicular joint is a diarthrodial joint with both surfaces covered by fibrocartilage (**Figure 80-1**). The intraarticular disk ligament divides the joint into two separate compartments, each of which is lined with synovium.[15] This joint is freely movable and functions almost like a ball-and-socket joint in that it has motion, including rotation, in almost all planes.[3,6,16] This includes 30° to 35° of upward elevation, 35° of combined forward/backward movement, and 40° to 45° of rotation about its long axis.[3,6,16] Less than half of the medial clavicle articulates with the upper angle of the sternum. This gives the sternoclavicular joint the distinction of having the least amount of bony stability of any of the major joints.[3] Given this amount of joint incongruity, it is surprising that sternoclavicular joint dislocations are uncommon. However, its stability comes from strong surrounding ligaments (**Figure 80-1**). These ligaments include the intraarticular disk ligament, the extraarticular costoclavicular ligament (rhomboid ligament), the anterior and posterior sternoclavicular ligaments, and the interclavicular ligament.[15]

The region that lies directly posterior to the sternoclavicular joint contains numerous vital structures (Figure 80-2). Within the confines of the thoracic inlet are the trachea, esophagus, lungs, and great vessels. This proximity, and the small size of the thoracic inlet, accounts for the injuries that may occur to these structures with posterior sternoclavicular joint dislocations.

The medial clavicular epiphysis is the last epiphysis of the long bones to appear. It usually ossifies by the age of 18 to 20 and occasionally not until the age of 25.[3,17] It is also the last to fuse.[3,17] This epiphysis is difficult to see on plain radiographs. Many injuries in patients under 25 years of age that are initially felt to be sternoclavicular joint dislocations are actually Salter I or II epiphyseal injuries.[3,10,18–23]

The diagnosis of a traumatic sternoclavicular joint dislocation may be difficult and delayed. This is particularly true in the patient with multiple injuries.[7,24,25] Symptoms include severe pain that increases with movement of the ipsilateral arm. Physical signs include edema and ecchymosis over the region of the sternoclavicular joint. The

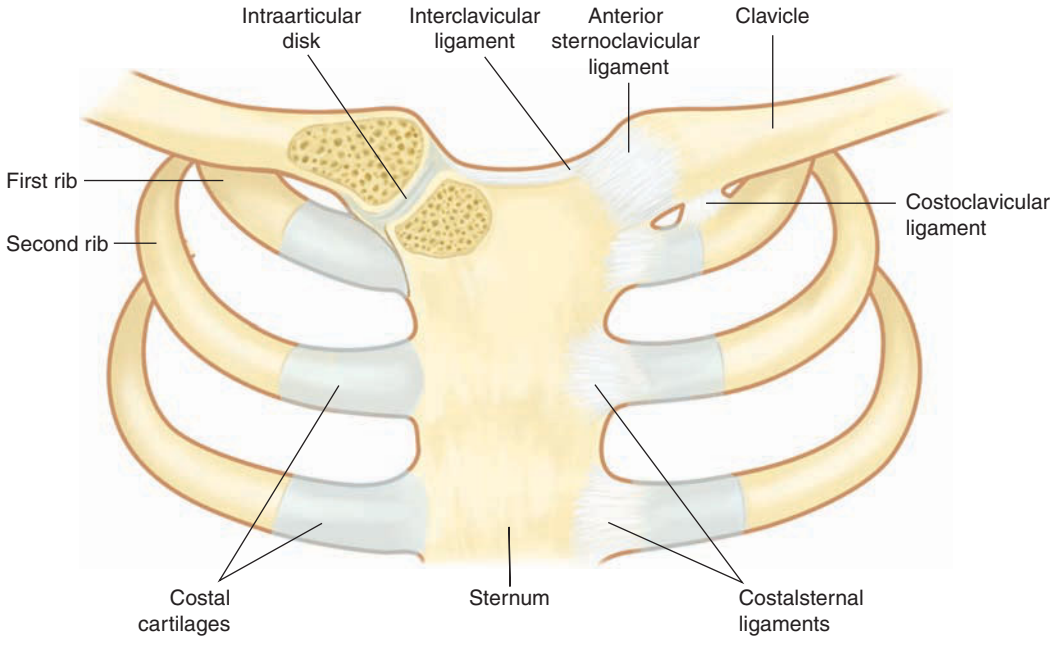

FIGURE 80-1. Anatomy of the sternoclavicular joint and surrounding structures.

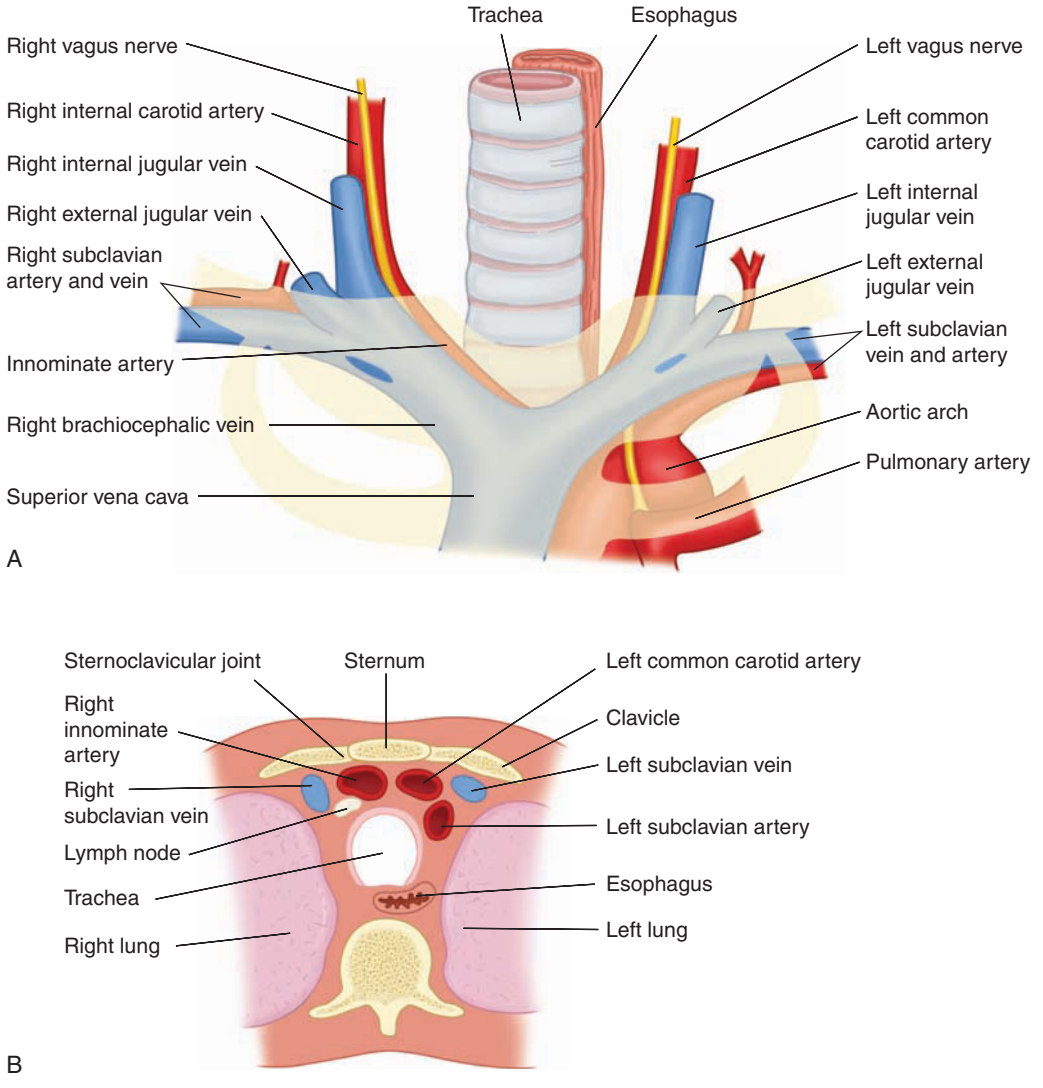

FIGURE 80-2. Anatomic relationships of structures to the sternoclavicular joint. **A.** Anteroposterior view. **B.** Cross section through the level of the sternoclavicular joint.

patient usually holds the injured arm adducted across the trunk. Their head may be tilted toward the affected side to relieve the pain caused by traction of the sternocleidomastoid muscle on the medial clavicle. With anterior dislocations, the medial end of the clavicle may be palpated anterior to the sternum. It may also be fixed or mobile. A visible depression may be noted or a hollow palpated at the location of the sternoclavicular joint with posterior sternoclavicular joint dislocations. However, accompanying edema may obscure these physical findings. The shoulder may be held forward. When the patient is supine, the affected shoulder does not lie flat against the bed.

Additional signs and symptoms associated with a posterior sternoclavicular joint dislocation may also be due to injury or compression of mediastinal structures.[3,4,7,9,11–13,18,25–32] **It is extremely important to perform a careful and complete physical examination, as associated injuries are common.** Compression of the trachea or esophagus may result in cyanosis, dyspnea, or dysphagia. Circulation to the ipsilateral arm may be reduced if the subclavian artery is compressed. Venous congestion of the upper extremity or neck can result from compression of the subclavian or jugular veins. The patient may present in shock due to compression or injury to the retrosternal great vessels. Paresthesias of the upper extremity are due to a brachial plexus injury. Voice changes are due to compression of the recurrent laryngeal nerve. Tracheal or lung injuries can result in pneumothoraces.

The clinician cannot always rely on the clinical findings of observation and palpation to distinguish between anterior and posterior sternoclavicular joint dislocations.[3] Documentation with appropriate radiologic studies is recommended prior to the decision to treat. Routine radiographs of the sternoclavicular joint are often difficult to interpret due to overlapping structures. Several different radiographic projections have been reported to improve the ability to demonstrate asymmetry of the joints.[3,8,9,33] Computed tomography (CT) is the preferred imaging modality to study the sternoclavicular joint. It should always be performed if the diagnosis is uncertain.[9,10] The use of ultrasound to aid in the diagnosis has also been reported.[12,34]

With posterior sternoclavicular joint dislocations, the Emergency Physician should also consider appropriate studies to rule out associated injuries to neighboring structures. This could include a chest radiograph, which may reveal mediastinal widening, a pneumomediastinum, or a pneumothorax. CT will reveal the relationship of the clavicle to the great vessels, esophagus, and trachea. It may also demonstrate compression of these structures, a mediastinal hematoma, or mediastinal emphysema. Angiography, venography, and Doppler studies may be considered to investigate potential vascular injury. Esophagoscopy and/or an esophagram may be employed to evaluate the esophagus. Bronchoscopy is indicated if a tracheal or bronchial injury is suspected.

INDICATIONS

It is generally held that closed reduction should be attempted on all acute traumatic anterior and posterior sternoclavicular joint dislocations.[3,10,27] Anterior sternoclavicular joint dislocations have been reduced via closed techniques up to 10 days postinjury.[9] Successful closed reduction of posterior sternoclavicular joint dislocations has been reported up to 5 days postinjury.[12,27] Posterior sternoclavicular joint dislocations are uncommon injuries. Early consultation with an Orthopedic Surgeon is recommended. Careful evaluation of the patient's airway, breathing, and circulation should be performed prior to the reduction. It is recommended that the reduction be performed where staff and facilities are immediately available to intervene should any thoracic emergency develop.[25] **The dislocation should be reduced emergently if neurologic or vascular compromise exists in the affected extremity.**

Many of these injuries are in fact Salter–Harris I or II epiphyseal injuries in patients less than 25 years of age.[3,10,18–23] Closed reduction should still be attempted after consultation with an Orthopedic Surgeon.

CONTRAINDICATIONS

Reduction may be postponed to attend to more serious injuries unless a posterior sternoclavicular joint dislocation is present and is compromising adjacent structures. Open reduction of posterior sternoclavicular joint dislocations may be preferred if surgery is planned for associated injuries.

Attempted reduction of chronic traumatic anterior dislocations or spontaneous anterior dislocations is not indicated.[41] These patients usually have minimal discomfort, normal range of motion, and can return to normal activity.[3,14] Patients do well without treatment other than nonsteroidal anti-inflammatory drugs, the application of heat, and rest.[2,14,35] The results of operative treatment of such injuries have not been impressive.[3,14]

There is controversy regarding the necessity of reducing chronic posterior sternoclavicular joint dislocations. Some feel that all should be reduced due to the potential compression of adjacent structures or erosion into them.[3,28,36,37] However, there have been reports of patients who have chronic dislocations without sequelae.[6] Treatment decisions for such injuries should be made in consultation with an Orthopedic Surgeon. Reduction would require general anesthesia and operative intervention.[35]

EQUIPMENT

- Sandbags or folded towels
- Povidone iodine or chlorhexidine solution
- Sterile towel clamps
- Sterile gloves
- Local anesthetic solution
- 18 gauge needles
- 25 gauge needles
- 10 mL syringe

PATIENT PREPARATION

Explain the risks, benefits, potential complications, and aftercare of the procedure to the patient and/or their representative. Obtain a signed consent to perform the reduction.

Place the patient supine with the affected side near the edge of the gurney. Place sandbags or towels between the patient's scapulae. They should be thick enough to raise the patient 5 cm off the gurney.[4]

A form of anesthesia and analgesia is required to reduce a sternoclavicular joint dislocation. Closed reduction of anterior sternoclavicular joint dislocations may be performed with local anesthetic solution infiltrated about the medial clavicle and sternoclavicular joint. Consider the administration of supplementary intravenous sedation or procedural sedation. Posterior sternoclavicular joint dislocations have also been reduced using local anesthesia. However, procedural sedation or general anesthesia is recommended. Infiltrate local anesthetic solution about the medial clavicle and sternoclavicular joint if procedural sedation will be performed.

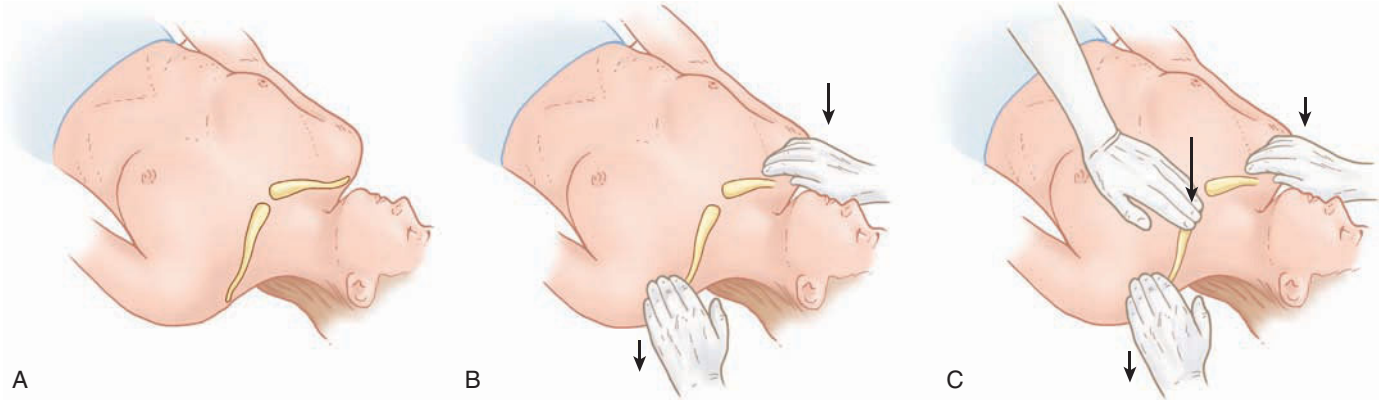

FIGURE 80-3. Reduction of an anterior sternoclavicular joint dislocation. **A.** Patient positioning. **B.** An assistant applies anterior pressure to both shoulders. **C.** The medial clavicle is pushed posteriorly.

TECHNIQUES

ANTERIOR STERNOCLAVICULAR JOINT DISLOCATION REDUCTION

Position the patient as mentioned above. The patient's arms should be at their sides (**Figure 80-3A**). Apply analgesia and sedation. Instruct an assistant to apply downward pressure to the anterior surface of both shoulders (**Figure 80-3B**). Pushing the shoulders posteriorly pulls the clavicles laterally and distracts the dislocated medial clavicle. Push the medial clavicle posteriorly and into anatomic position (**Figure 80-3C**). Relocation of the clavicle usually occurs promptly. Carefully sit the patient upright while the assistant maintains the shoulders in a posterior position. Apply a figure-of-eight splint (**Figure 90-3C**).

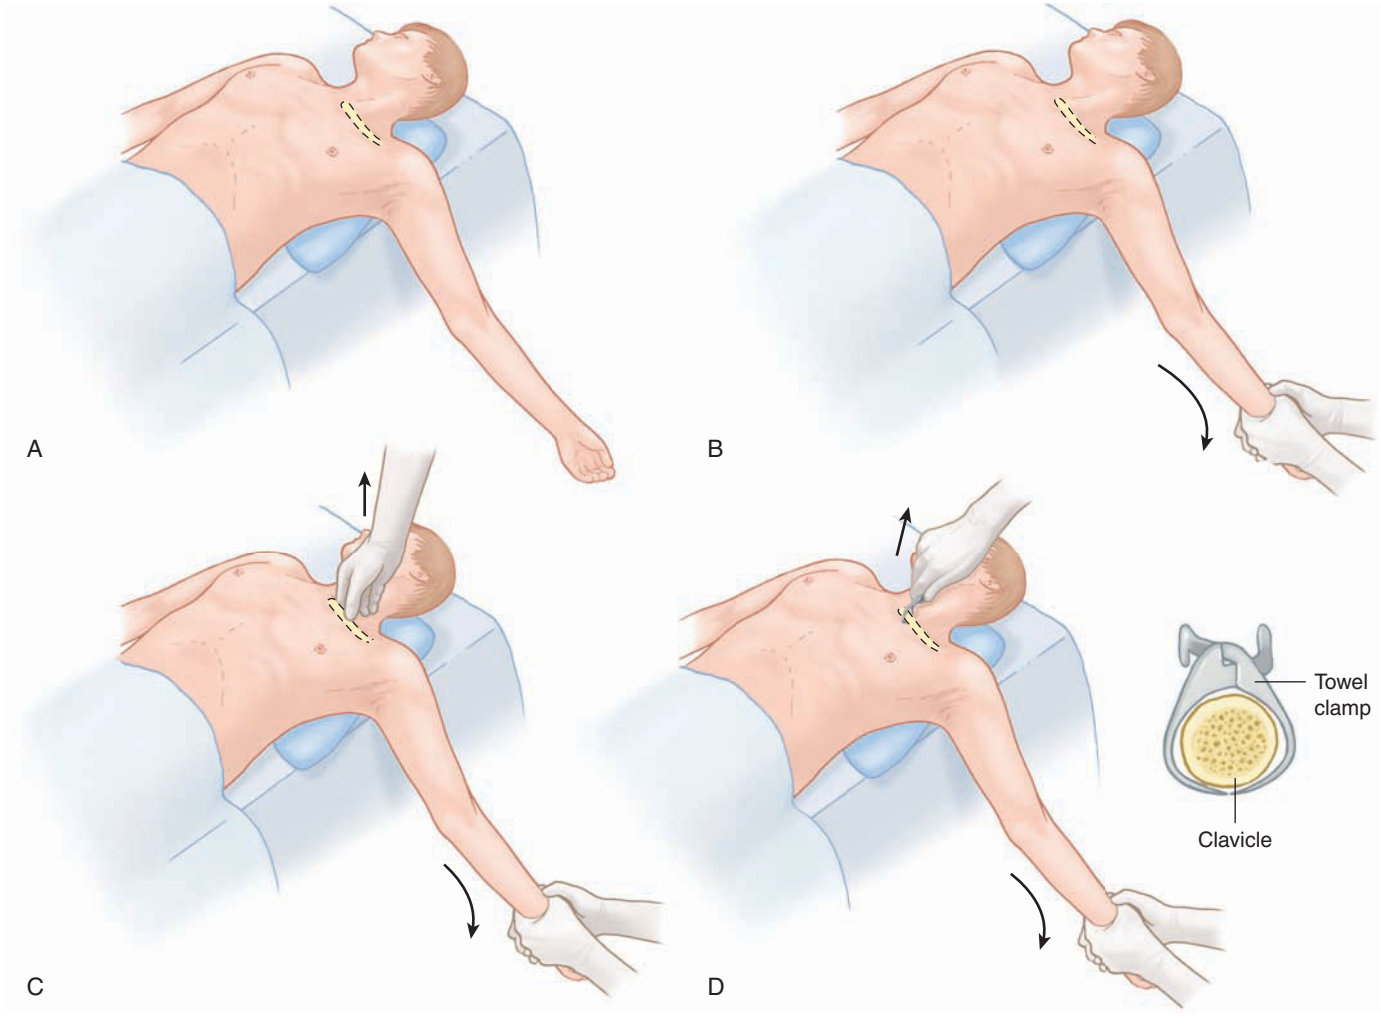

FIGURE 80-4. Reduction of a posterior sternoclavicular joint dislocation. **A.** Patient positioning. **B.** An assistant applies distal in-line traction. **C.** The medial clavicle is grasped and elevated while maintaining distal traction on the extremity. **D.** An alternative technique. A towel clamp is placed around the medial clavicle. The clamp is used to elevate the medial clavicle while maintaining distal traction on the extremity.

POSTERIOR STERNOCLAVICULAR JOINT DISLOCATION REDUCTION

Position the patient as mentioned previously. Apply analgesia and sedation. Abduct the affected extremity 90° and extend it 20° in line with the clavicle (**Figure 80-4A**). Spontaneous reduction may occur at this point. If not, instruct an assistant to apply distal inline traction to the extremity (**Figure 80-4B**). This may be aided by wrapping a sheet about the patient's upper torso to provide countertraction. The clavicle may reduce under traction. Keep the patient's arm abducted, extended, and under traction if the sternoclavicular joint does not reduce. Manually manipulate the clavicle into position. Grasp the medial clavicle and pull it upward into anatomic position (**Figure 80-4C**).

It may be difficult at times to achieve a secure grasp on the medial clavicle. In such cases, clean the skin surrounding the medial clavicle of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry. Grasp through the skin and around (not through) the shaft of the medial clavicle with a towel clamp (**Figure 80-4D**). The thick cortical bone often prevents purchase of the towel clamp into the clavicle. Ensure that the towel clamp follows the contours of the clavicle when applying it. Grasping too deep can result in injury to the subclavian artery and/or vein. Elevate the medial clavicle into anatomic position while the assistant is maintaining traction on the abducted and extended extremity (**Figure 80-4D**).

ALTERNATIVE TECHNIQUES

An alternative technique may be applied to reduce a posterior sternoclavicular joint dislocation.[4] It uses the first rib as a lever and has been reported to be successful when the previous technique has failed. Position the patient with their arms adducted (**Figure 80-5A**). Apply analgesia and sedation. Instruct an assistant to apply distal in-line traction to the adducted arm (**Figure 80-5B**). This will lever the medial clavicle over the first rib and above the superior sternum (**Figure 80-5B**, inset). Apply downward pressure to the anterior shoulder, forcing it into retraction (**Figure 80-5C**). This will lever the medial clavicle anteriorly and laterally into anatomic position (**Figure 80-5C**, inset). Reduction may occur at this point. If not, elevate the medial clavicle either by manual grasp or using a towel clamp, as described previously. It is postulated that this technique requires less force than the prior technique. A variation of this technique involves applying lateral traction to the upper humerus using a sheet looped around the upper arm.[38]

Other methods of closed reduction for a posterior sternoclavicular joint dislocation have been described but are not often performed. Successful reduction has been described using 4.5 kg

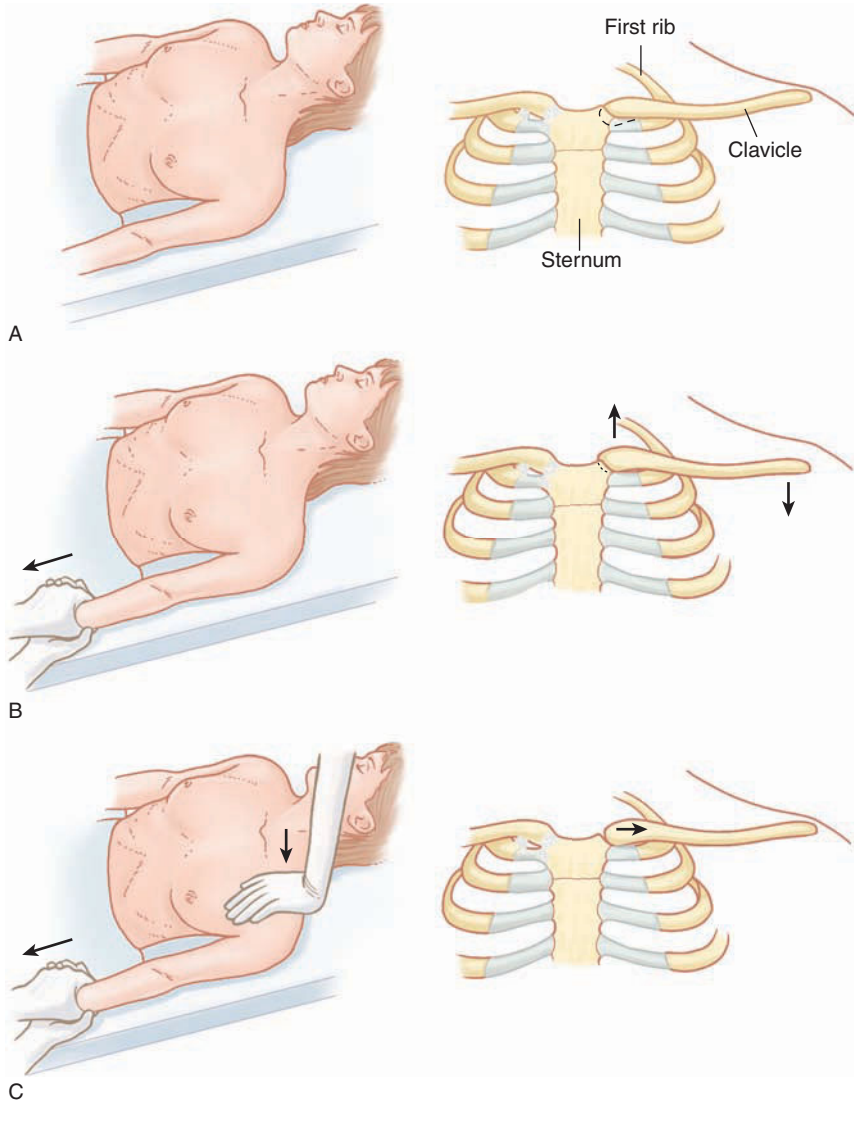

FIGURE 80-5. An alternative technique for reducing a posterior sternoclavicular joint dislocation. (Modified from the study of Buckerfield and Castle.[4]) **A.** Patient positioning. **B.** An assistant applies distal in-line traction (*large arrow*). The medial clavicle will be elevated above the sternum (*small arrows*). **C.** A posteriorly directed force is applied to the shoulder to draw the medial clavicle anteriorly and laterally into its normal anatomic position.

(10 pounds) of lateral skin traction on the abducted arm for 30 minutes.[39] Reduction has also been achieved by simple forced retraction of the lateral clavicle.[8] Reduction has been reported in a sedated patient who was placed for 8 hours on rolled towels between the scapulae.[13]

ASSESSMENT

Assess all patients, both initially and following any reduction attempts, for neurologic and vascular integrity of the upper extremity. Obtain postreduction radiographs to confirm proper bony positioning. The procedure may be repeated if the radiographs show incomplete reduction. **Positioning is not critical if the reduction was performed for neurologic or vascular compromise. The primary consideration is the relief of the compromised nerve and/or artery.** The Orthopedic Surgeon can later reduce the defect that remains.

AFTERCARE

The general principles of orthopedic care should be applied. These include rest, ice, nonsteroidal anti-inflammatory drugs, and supplemental narcotic analgesics.

ANTERIOR STERNOCLAVICULAR JOINT DISLOCATIONS

The sternoclavicular joint is often unstable following reduction. These injuries require splinting to maintain the normal anatomic relationships and allow ligamentous healing. This is best accomplished with a figure-of-eight splint (**Figure 90-3C**). Unfortunately, patients do not often tolerate this splint. Alternatives include a sling, sling and swath, or a sling and Velpeau dressing (**Figures 90-3A & B**). Apply one of the above splints if the medial clavicle will not remain reduced. Orthopedic follow-up should be scheduled within 5 to 7 days of the reduction.

POSTERIOR STERNOCLAVICULAR JOINT DISLOCATIONS

The sternoclavicular joint is usually stable following reduction. The splinting and follow-up are the same as with an anterior sternoclavicular joint dislocation.

COMPLICATIONS

ANTERIOR STERNOCLAVICULAR JOINT DISLOCATIONS

Complications of the reduction are relatively minor. The sternoclavicular joint is usually unstable postreduction and often dislocates spontaneously. This should be explained to the patient prior to attempted reduction. A "cosmetic bump" can remain if reduction is not maintained. Occasionally, these patients will continue to have persistent pain.[3]

POSTERIOR STERNOCLAVICULAR JOINT DISLOCATIONS

Most complications result from the original injury and are due to compression or injury of neighboring structures. The incidence of associated injuries is reported to be 25%.[25] Death secondary to these complications has been reported.[31,40]

Complications of the reduction include pain, incomplete reduction, subclavian vessel injury, and brachial plexus injury. A higher incidence of injury to the subclavian vessels may be seen if a towel clamp is used in the reduction. The reduction of a posterior dislocation can result in an anterior subluxation or dislocation.[42] This conversion of a posterior to anterior dislocation during reduction should not be reduced as it may resolve spontaneously or require open management.

SUMMARY

Sternoclavicular joint dislocations are uncommon injuries. They are usually due to high-impact forces from motor vehicle collisions or contact sports. Anterior sternoclavicular joint dislocations are easily reduced but often do not maintain reduction. However, patients tend to do well with persistent dislocations. Posterior sternoclavicular joint dislocations are even less common. The Emergency Physician should be aware of the high incidence of associated injuries. These dislocations tend to be stable after reduction.

81 Shoulder Joint Dislocation Reduction

Eric F. Reichman

INTRODUCTION

The shoulder joint is the most commonly dislocated of all joints.[1–4] Shoulder dislocations were depicted in Egyptian murals as early as 3000 BC.[1] Despite 5000 years of medical advancements, shoulder dislocations continue to be a major cause of Emergency Department (ED) visits. They account for more than 50% of all joint complications treated by Emergency Physicians (EPs).[2]

The human shoulder is remarkable for its degree of motion. The anatomic features that contribute to this mobility also contribute to its instability.[3] The shallow glenohumeral joint allows the shoulder to be dislocated anteriorly, posteriorly, or inferiorly. The anterior shoulder dislocation is the most common and accounts for 95% of all shoulder dislocations.[1–4] The overall incidence of shoulder dislocations is 17 per 100,000. There is a bimodal age distribution.[1,4] It occurs in males from 20 to 30 years of age most commonly related to athletics and trauma. The other large group is women from 60 to 80 years of age, primarily due to falls.

ANATOMY AND PATHOPHYSIOLOGY

The shoulder (glenohumeral) joint is a multiaxial ball-and-socket type of synovial joint that permits a wide range of motion. Unfortunately, the range of motion is at the expense of stability.[5] The shoulder has greater than 180° of motion in both the sagittal and coronal planes as well as 180° of rotary movement.[6] The spheroidal head of the humerus articulates with the shallow glenoid fossa of the scapula. The glenoid fossa accommodates roughly one-third of the humeral head. The bony landmarks surrounding the shoulder joint are the coracoid and acromion processes of the scapula. A loose, thin fibrous capsule encloses the glenohumeral joint. The muscular component of the shoulder is a fusion of four separate muscles (supraspinatus, infraspinatus, teres minor, and subscapularis) that together form the rotator cuff. These muscles have a tendency to be torn and injured in shoulder dislocations, especially posterior and inferior dislocations.[7] The shoulder receives its blood supply from branches of the axillary artery (the anterior and posterior circumflex humeral arteries).

Innervation of the shoulder is from branches of the suprascapular, axillary, and lateral pectoral nerves. The axillary nerve lies at

the level of the humeral neck. When it is dislocated anteriorly, the humeral head is displaced into the quadrangular space where it may compress and damage the axillary nerve. This can result in a neurapraxia, paralysis of the deltoid muscle, and/or a sensory loss to the skin over the shoulder.

Shoulder dislocations can occur anteriorly, posteriorly, or inferiorly depending on the mechanism of injury. Anterior shoulder dislocations are by far the most common and account for 95% of all dislocations. An anterior dislocation usually results from direct or indirect forces causing abduction, extension, and external rotation of the limb. Anterior dislocations are classified based on the location of the humeral head into subcoracoid, subglenoid, subclavicular, and intrathoracic. Subcoracoid dislocations account for 75% of all anterior shoulder dislocations. The dislocated humeral head can shift between the first three positions but generally remains in one anatomic location.[2] In younger patients, the injury is usually linked to athletics, such as spiking a volleyball or blocking a basketball shot. Older patients may sustain anterior shoulder dislocations from falling on an outstretched arm or from a direct blow on the posterior shoulder.[4] The patient will present in obvious distress, holding the affected arm in slight abduction and internal rotation. Typically, the elbow is flexed and supported by the unaffected arm. The shoulder will have the typical "squared off" appearance, with loss of the normal deltoid contour. The humeral head may be palpable anteriorly.[1]

Posterior shoulder dislocations account for 4% of all shoulder dislocations.[1–4] They have a tendency to be missed, even by experienced EPs. Delayed diagnoses have been made up to a year after the initial injury.[8] The mechanism of injury is usually indirect, with a combination of internal rotation, adduction, and flexion. The most common precipitating mechanism is a seizure. Other etiologies include high voltage electrical injury, direct trauma, and falls.[3] Direct trauma, such as a head-on motor vehicle collision in which the patient braces their hands against the dashboard, can result in bilateral posterior shoulder dislocations in rare instances. Posterior shoulder dislocations are classified based on the location of the humeral head into subacromial, subglenoid, or subspinous. Subacromial dislocations account for 98% of posterior shoulder dislocations.[2,8] The patient usually presents with the arm held in adduction and internal rotation.[9] The shoulder will appear flat anteriorly. The coracoid process of the scapula will be visually prominent and palpable.[1]

Inferior shoulder dislocations are the least common type.[1–4] They represent less than 0.5% of all shoulder dislocations. The inferior shoulder dislocation is also known as luxatio erecta, because the dislocated extremity is extended upward. Inferior shoulder dislocations are usually sustained from indirect forces with the arm hyperabducted, causing the rotator cuff to tear and the arm to rotate 180° externally.[7] Alternatively, a direct axial force applied to the arm above the head, as in a fall or Olympic-style weight lifting, will drive the humeral head inferiorly.[10] The patient will present with the affected arm shortened and fixed above their head, with the hand rotated as if asking a question.[7] The humeral head may be palpable along the lateral chest wall. Inferior shoulder dislocations are often associated with fractures.[1] The fractures can involve the acromion process, coracoid process, clavicle, greater tuberosity, humeral head, and/or glenoid rim.[1,2,6,11] Complete disruption of the rotator cuff often occurs with inferior shoulder dislocations.[1,2,6,11] Dislocations can cause capsular and rotator cuff tears, compression or tears of the axillary artery and its branches, and injury to the subclavian vein. Because of their anatomic proximity, damage to the brachial plexus, suprascapular nerve, and the axillary nerve occur at a rate of 21% to 36% due to traction and compression of these nerves.[8] Prompt reduction of the dislocation may alleviate compression injuries and enable a more thorough examination and evaluation of all components of the shoulder.

Radiographs are required to classify the type of dislocation and diagnose fractures. Associated fractures are detected in up to 24% of anterior shoulder dislocations.[3] They include fractures of the greater tuberosity, humeral head, coracoid process, acromion process, clavicle, and glenoid. Recent evidence suggests that clinically obvious dislocations without a high-energy mechanism can be reduced without prior radiographs.[61–66] There is no consensus at present to eliminate prereduction radiographs versus the current recommendation that all patients have at least two-view prereduction plain radiographs of the affected joint.[12] Postreduction films should be obtained both to document the reduction of the joint and any injury induced by the reduction technique as well as to document bony abnormalities (Hill–Sachs lesions, Bankart lesion) or previously hidden fractures that were not visible on the initial radiographs. There is some evidence that postreduction radiographs may be unnecessary, but further study is required before this can be made the standard of care.[13,14,64–68]

The anteroposterior (AP) view will clearly demonstrate anterior dislocations, inferior dislocations, and almost all humeral fractures. In evaluating radiographs of anterior shoulder dislocations, look for an impaction fracture defect in the posterolateral portion of the humeral head, called a Hill–Sachs deformity. These are found in up to 50% of all anterior shoulder dislocations.[2] A Bankart lesion is an avulsed fragment of the glenoid labrum with contiguous bone.[6] Both lesions tend to get worse the longer the humeral head remains dislocated.

In patients with posterior shoulder dislocations, however, the AP view often shows a "normal" picture, which accounts for the high incidence of missed dislocations. One study showed that up to 50% of posterior shoulder dislocations were missed using only the AP view, whereas lateral views increased the diagnostic accuracy to 100%.[15] There are four features that suggest a posterior dislocation on AP films. First is the loss of the normal elliptical pattern produced by overlap of the humeral head and the posterior glenoid rim. Second, the distance between the anterior glenoid rim and the articular surface of the humeral head will be increased. This is known as the "rim sign." The third is internal rotation of the greater tuberosity to make the humerus take on a "light bulb" or "ice cream cone" appearance.[2,4] Finally, an isolated fracture of the lesser tuberosity on the AP view is suggestive of a posterior shoulder dislocation until proven otherwise.[2] If there is any question, a lateral view (either the Y view or an axillary view) will help delineate the posterior position of the humeral head behind the glenoid fossa.[1]

INDICATIONS

Shoulder dislocations, whether first-time or recurrent, are typically very painful and distressing for the patient. **All attempts should be made to reduce the joint as quickly as possible once the diagnosis is made.** In general, uncomplicated joint dislocations should be reduced within 20 to 30 minutes to alleviate further injury to surrounding neurologic and vascular structures. **A patient with a neurologic deficit or a compromised distal pulse in the setting of a shoulder dislocation should undergo immediate reduction.**

CONTRAINDICATIONS

There are no absolute contraindications to reducing a dislocated shoulder. The patient's airway, breathing, and circulation should be assessed and managed prior to reducing the dislocated shoulder. Any life- or limb-threatening injuries should be managed before the shoulder reduction is attempted.

An Orthopedic Surgeon should be consulted prior to the reduction of a shoulder dislocation in patients with posterior and inferior

dislocations. They are relatively rare, there is a high incidence of complications requiring operative management, dislocations associated with fractures may make the reduction difficult, and other indications for surgical management may exist.[69] The indications for surgical intervention in anterior shoulder dislocations include complete rotator cuff tears, fracture of the greater tuberosity with displacement of more than 1 cm, or fractures of the glenoid rim that are displaced more than 5 mm.[2] Posterior shoulder dislocations with major displacement of a fractured lesser tuberosity or an impression defect greater than 20% of the articular surface necessitate surgical intervention or open reduction.[2,3] Open dislocations require operative management but may be reduced in the ED if there is a delay in getting the patient to the Operating Room. Surgical reduction is indicated in patients with evidence of hemorrhagic shock from a suspected axillary artery injury sustained during a shoulder dislocation.

An Orthopedic Surgeon should be consulted before reducing a dislocated shoulder that presents greater than 7 to 10 days after the acute injury. There is a higher risk of vascular injury when an "old" dislocation is mistaken for an acute injury and subsequently reduced. The axillary artery, which is bound down by the pectoralis major muscle and anterior pericapsular scarring, becomes brittle and may not withstand the traction required to reduce an "old" dislocation. This is especially true in the elderly. A 1941 study reported a 50% hemorrhage-related mortality in patients who had shoulder reductions performed several weeks after initial injury.[11]

Shoulder dislocations in children present unique problems. Pediatric patients whose ossification centers have not yet fused tend to have Salter-Harris type fractures of the epiphyseal plate. **An Orthopedic Surgeon should be consulted prior to the reduction of a pediatric shoulder dislocation unless neurologic or vascular compromise is present in the affected extremity.** Otherwise, the same techniques for reduction can be applied to both adult and pediatric patients.

EQUIPMENT

General Supplies

- Equipment and supplies for procedural sedation (Chapter 129)
- Assistants
- Sheets
- 10 to 15 pounds of weights
- Sling and swath or shoulder immobilizer
- Splinting material (plaster, fiberglass, and prepackaged casting material)

Intraarticular Analgesia

- Povidone iodine or chlorhexidine solution
- 20 mL syringe
- 25 gauge, 2.5 in. needle
- Local anesthetic solution (Carbocaine, lidocaine, and bupivacaine)

Miscellaneous

- Equipment and supplies for nitrous oxide anesthesia (Chapter 128)
- Equipment and supplies for regional anesthesia (Chapter 126)

PATIENT PREPARATION

The risks, benefits, potential complications, and aftercare of the procedure should be explained to the patient and/or their representative. Obtain an informed consent for the reduction procedure. An informed consent should be obtained for procedural sedation and/or an intraarticular injection if they are performed in addition to the reduction procedure.

Place the patient in a position of maximal comfort, usually sitting upright or at a 45° angle, with the affected extremity supported and its motion limited. Placing the patient supine or prone is difficult, painful, and often requires analgesia before being attempted. The patient presenting in spinal immobilization should remain supine. If the spine cannot be cleared, shoulder reduction can be performed without changing the patient's position. Intravenous access should be obtained if indicated. Pain should be addressed quickly and aggressively.

ANALGESIA

There are several methods to control pain for patient comfort before and during the joint reduction procedure. Intravenous or intramuscular narcotics should not be withheld pending prolonged radiographic studies. Commonly administered medications include morphine, meperidine, hydromorphone, and fentanyl.

An alternative to intramuscular or intravenous narcotics is the intraarticular instillation of local anesthetic solution.[16,70–73] This was formally introduced in 1991 as an effective method of analgesia for anterior shoulder dislocations. It is often used in addition to procedural sedation. It can also be used as the only method of analgesia when procedural sedation is contraindicated. Clean the anterolateral shoulder of any dirt and debris. Apply povidone iodine or chlorhexidine solution to the shoulder area and allow it to dry. Identify the hollow 2 cm inferior to the lateral border of the acromion process (**Figure 81-1**). Using sterile technique, insert a 25 gauge needle perpendicular to the skin and into the hollow to a depth of 2 cm (**Figure 81-1**). Inject 10 to 20 mL of a 50:50 mixture of sterile saline and local anesthetic solution. This technique is

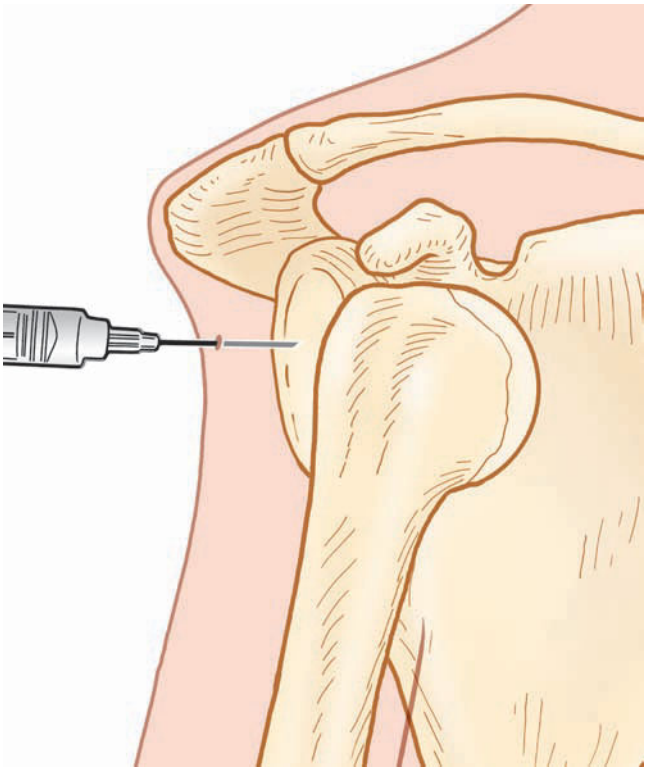

FIGURE 81-1. Local anesthesia for a shoulder dislocation. The needle is introduced in the hollow under the lateral surface of the acromion process.

effective in controlling muscle spasm and pain. The book editor and chapter author believes this should be performed on every dislocated shoulder before attempts at reduction.

Alternative methods for providing analgesia include the use of nitrous oxide, procedural sedation, and regional nerve blocks. Nitrous oxide has numerous advantages including a short onset, it wears off quickly, self-administration by the patient as needed, and a decreased ED length of stay.[74] Unfortunately, the use of nitrous oxide produces a quite variable analgesic response. Please refer to Chapter 128 for a discussion regarding the use of nitrous oxide anesthesia. Procedural sedation is commonly used us aid in the reduction of a dislocated shoulder. Please refer to Chapter 129 for a discussion regarding the use of procedural sedation. Ultrasound-guided brachial plexus blocks provide excellent analgesia but require equipment and training on the part of the EP.[75–79] Please refer to Chapter 126 regarding the details of this technique.

Several sources suggest that patients with an anterior shoulder dislocation without a significant trauma history may actually accept some degree of discomfort as a tradeoff for the prompt resolution of pain by reduction without anesthesia.[17–19] Patient comfort should not be sacrificed for expediency. Anterior shoulder dislocations may require procedural sedation prior to reduction, depending on the patient's level of discomfort and the reduction method chosen. Posterior and inferior shoulder dislocations definitely require procedural sedation prior to reduction.

ANTERIOR SHOULDER DISLOCATION REDUCTION TECHNIQUES

The methods for treating a closed shoulder dislocation depend on overcoming muscular spasm to relocate the humeral head into the glenoid fossa. Reduction techniques are classified into traction techniques, leverage techniques, scapular manipulation, and combinations of the three previous techniques. A study evaluating the various reduction techniques found similar success rates of 70% to 90% regardless of the technique.[20] However, postreduction complication rates are variable.[20] The major considerations in deciding which technique to use are physician experience, familiarity with the technique, availability of time, and the presence or absence of an assistant.[20]

HENNEPIN TECHNIQUE

The Hennepin technique, popularized at Hennepin County Medical Center, is often the preferred method to reduce anterior shoulder dislocations (**Figure 81-2**). This technique can

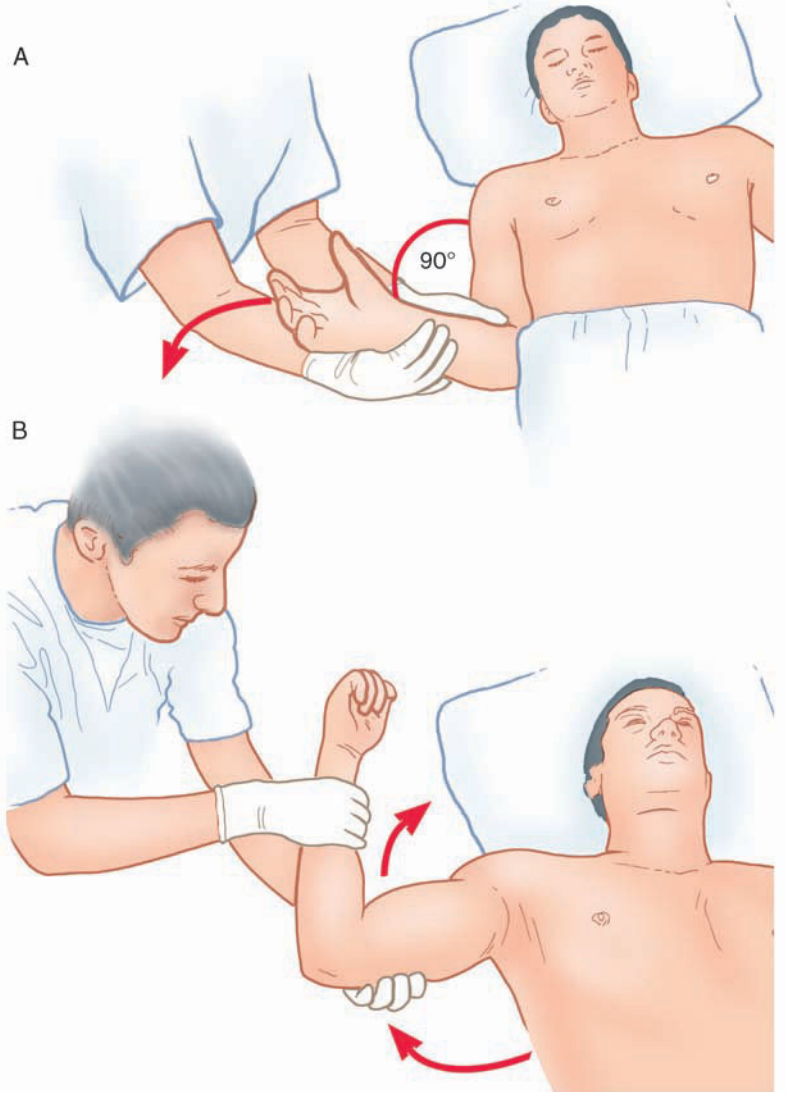

FIGURE 81-2. The Hennepin technique to reduce an anterior shoulder dislocation. **A.** Patient positioning and external rotation of the humerus. **B.** Abduction of the arm with the elbow flexed 90°.

be accomplished with no anesthesia or with the intraarticular instillation of local anesthetic solution. Procedural sedation is not required but may be used if the patient has severe pain and muscle spasms.

Place the patient seated, supine, or reclined 45° on a gurney (**Figure 81-2A**). Place the affected arm in adduction. Flex the elbow 90°. Support the patient's flexed elbow against their torso with the nondominant hand. Grasp the patient's forearm with the dominant hand. Slowly rotate the arm externally. **If pain becomes severe, typically as a result of rotator cuff spasm, stop the motion and wait until the spasm subsides. Do not release the arm or return it to its original position.** Continue to rotate the arm externally until the humeral head reduces or the arm reaches the coronal plane (90° of external rotation). This can take up to 10 minutes to accomplish. If the humeral head is still dislocated, slowly abduct the arm until the humeral head reduces or full abduction is obtained[2] (**Figure 81-2B**). Full abduction occurs when the patient's hand crosses over their head and is able to touch the contralateral ear. Adduct the arm until it is against the patient's torso. Another technique should be attempted if the humeral head is still dislocated.

The advantages of this technique include little to no patient manipulation or positioning, the relative ease of reduction, minimal equipment, the requirement of only a single operator, and the ability to perform the reduction without analgesia. The success rate when performed by EPs is approximately 80%, with 36% of patients not requiring analgesia.[3] The major disadvantage is that patients are often too apprehensive and experiencing too much discomfort to relax their arms sufficiently to allow for reduction to occur. This problem can be eliminated by the intraarticular instillation of local anesthetic solution. Occasionally, patients will require procedural sedation.

EXTERNAL ROTATION TECHNIQUE

This is a modified version of the Hennepin technique.[21–24,98] The technique is identical to the Hennepin technique except that the procedure is terminated when the arm reaches 90° of external rotation. The step of abduction is not performed. The advantages and disadvantages are as listed for the Hennepin technique.

STIMSON TECHNIQUE

The Stimson technique is a safe first-line technique that uses gravity and weights to overcome muscle spasm and reduce the dislocated shoulder[25–28] (**Figure 81-3**). Instill intraarticular local anesthetic solution into the shoulder joint prior to attempting the reduction. Procedural sedation is usually not necessary. **The patient must be under constant observation to monitor their pulse oximetry and respiratory status if procedural sedation is used because of the patient's prone positioning.**

Place the patient prone with the dislocated arm hanging over the side of the gurney (**Figure 81-3**). Flex the shoulder 90°. A pillow or folded sheets may be placed beneath the affected shoulder for patient comfort. Tie a sheet around the patient's hips and the gurney to prevent them from falling off the bed (**Figure 81-3**). Apply 3 to 5 pounds of weight to the wrist or forearm. The weights can be attached by a commercially available device, hung off a padded wrist restraint, or hung off gauze wrapped circumferentially around the wrist. Raise the gurney so that the weights are suspended off the ground (**Figure 81-3**). Every few minutes, add an additional 3 to 5 pounds of weights until a total of 10 to 15 pounds is achieved. The weights will provide traction in a position of forward flexion and are usually sufficient for reduction to take place within 15 to 30 minutes.[4] If the reduction is unsuccessful after 30 minutes, grasp the patient's forearm and twist it to gently rotate the humerus externally and then internally while the patient is prone and the arm is maintained under traction. This maneuver will often reduce the dislocation if the weights alone are unsuccessful.

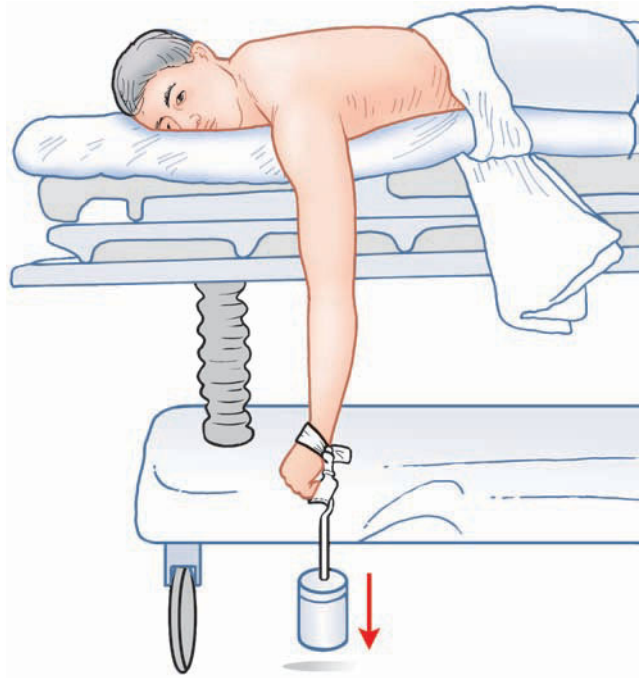

FIGURE 81-3. The Stimson technique to reduce an anterior shoulder dislocation. Weights are progressively added to the wrist to distract the humerus.

An alternative method is to have the patient grip a bucket approximately half full of water. This will provide the necessary traction weight to reduce the joint. The disadvantage of the bucket technique is that the patient will have to grip the bucket for a considerable length of time without releasing it.

The advantage of the Stimson technique is that it is safe and does not require the presence of an assistant. A 96% success rate has been reported with this technique.[3] The disadvantage of the procedure is that the patient must be placed in a prone position that may be painful, uncomfortable, or impossible because of other injuries. There is a small risk of the patient slipping off the elevated gurney. A strap or sheet tied around the patient and the gurney is recommended in order to prevent this. Procedural sedation is not recommended due to the prolonged prone positioning required, which may interfere with the patient's respiration. Additionally, procedural sedation for 15 to 30 minutes is relatively contraindicated and difficult to maintain without potential complications.

SCAPULAR MANIPULATION TECHNIQUE

Scapular manipulation accomplishes reduction by repositioning the glenoid fossa rather than manipulating the humeral head[4,29–33] (**Figure 81-4**). This is a popular technique due to its low complication rate and high patient satisfaction. This technique can be accomplished with no anesthesia or with the intraarticular instillation of local anesthetic solution. Procedural sedation is usually not required.

Place the patient prone with the dislocated extremity hanging over the side of the gurney (**Figures 81-4A & B**). Flex the shoulder 90°. A pillow or folded sheets may be placed below the affected shoulder for patient comfort. Place 5 to 15 pounds of weights suspended from the patient's wrist or in their hand. If weights are not available, an assistant may apply downward traction on the

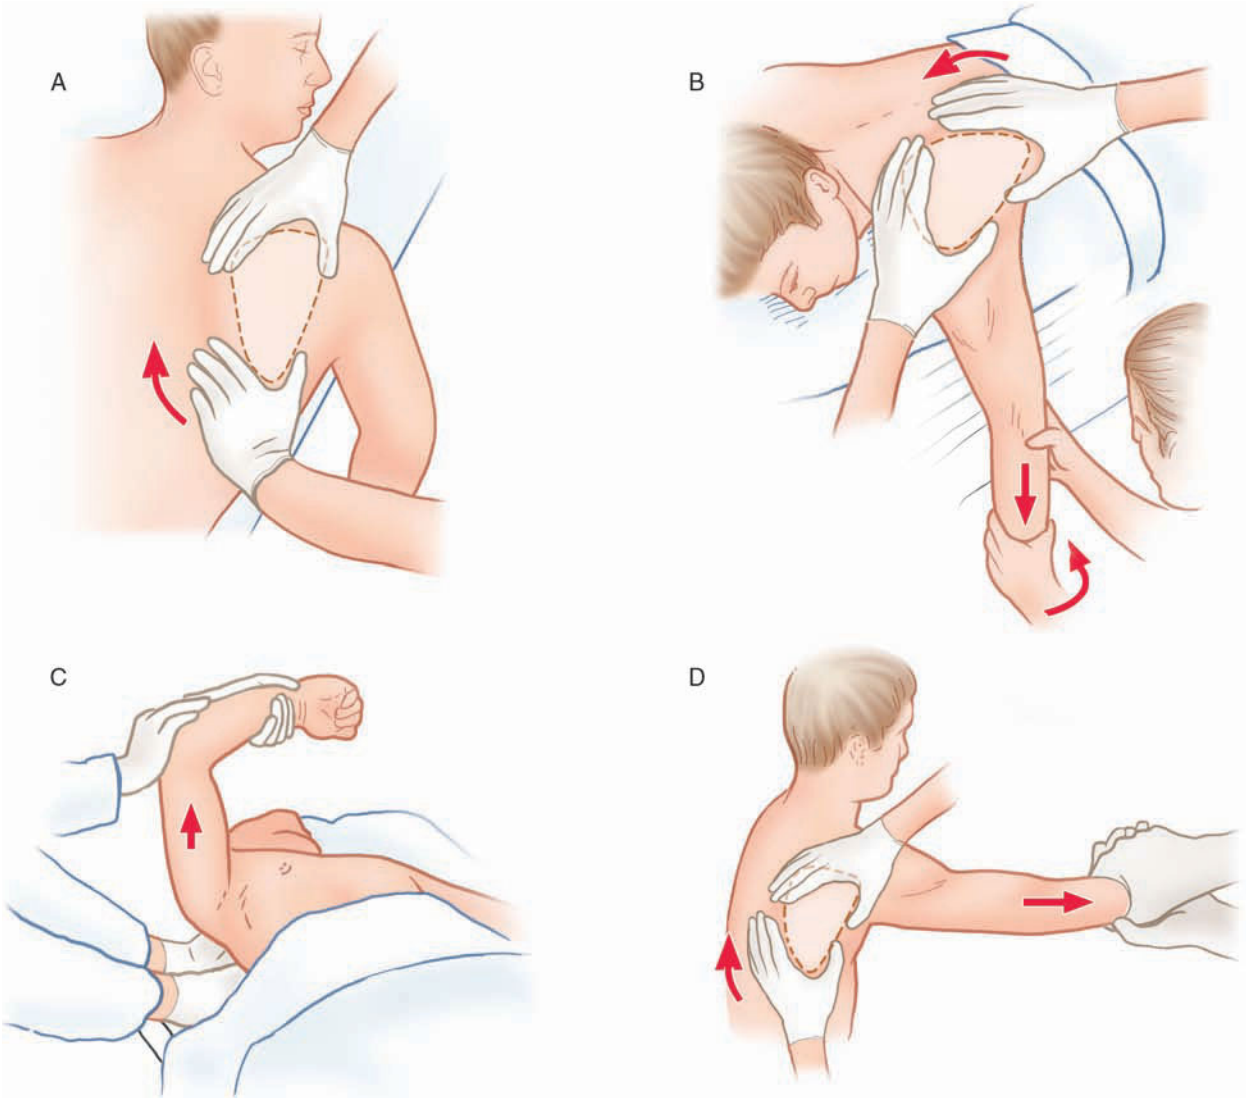

FIGURE 81-4. The scapular manipulation technique to reduce an anterior shoulder dislocation. **A.** Proper hand positioning. The upper hand stabilizes the base of the scapula while the lower hand applies medial and upward pressure on the tip of the scapula (*curved arrow*). **B.** Reduction with the patient prone. Traction is applied by an assistant (*straight arrow*). Occasionally, external rotation is also required (*curved arrow*). **C.** Reduction with the patient supine. Traction is applied on the humerus to elevate the shoulder off the bed (*arrow*). **D.** Reduction with the patient sitting. Traction is applied on the humerus (*arrow*).

extremity (**Figure 81-4B**). The weights or the assistant will provide in-line traction to the arm.

Identify the scapula and its borders. The scapular tip will "wing" laterally. Stabilize the superior portion of the scapula with one hand (**Figure 81-4A**). Place the thumb of the stabilization hand along the superolateral border of the scapula. Apply constant and firm medial and upward pressure to the inferior tip of the scapula using the other hand or thumb (**Figure 81-4B**). The thumb of the stabilizing hand can also be used to apply medially directed pressure to the tip of the scapula. Push the tip of the scapula as far medially as possible. The shoulder should reduce within 1 to 3 minutes. A small degree of dorsal displacement of the scapular tip has also been recommended.[3,33] If the reduction is unsuccessful, slight external rotation of the humerus (by an assistant) while the scapula is being manipulated and the arm is under traction may facilitate reduction (**Figure 81-4B**). This maneuver releases the superior glenohumeral ligament and presents a favorable profile of the humeral head to the glenoid fossa.[31,33]

The scapular manipulation technique may be performed with the patient supine (**Figure 81-4C**). This is particularly helpful when other injuries or conditions preclude using the prone position. Flex the affected shoulder 90°. Instruct an assistant to grasp the forearm and apply upward traction to elevate the shoulder off the bed. Apply your hands to stabilize and manipulate the scapula as described in the previous paragraph.

This technique may also be performed with the patient sitting (**Figure 81-4D**). This is particularly helpful when other injuries or conditions preclude using the prone or the supine position. Flex the affected shoulder 90°. Instruct an assistant to grasp the forearm and apply horizontal traction. Apply your hands to stabilize and manipulate the scapula as described in the previous paragraphs. This method is technically a more difficult version of the scapular manipulation technique because the patient's torso is not stabilized and moves during the traction and scapular manipulation.[3,31,33]

The reduction of an anterior shoulder dislocation by the scapular manipulation technique is usually quite subtle and may be missed by both the patient and the physician. In a few rare cases, the act of lying prone will be sufficient to relocate the shoulder. Success rates of over 90% have been reported with this technique.[3,30–33] The procedure is well tolerated.[3,29–33] In addition, there is a very low incidence

of complications with this procedure and it can be performed without analgesia and monitoring.[97] Disadvantages include the prone position and the need for an assistant to apply traction on the arm.

TRACTION-COUNTERTRACTION TECHNIQUE

The traction-countertraction technique is commonly performed in the ED, mostly out of tradition (**Figure 81-5**). It may be used as a first-line technique or a backup for patients who have failed the Stimson technique.[2] This technique requires anesthesia and analgesia. Instill local anesthetic solution intra-articularly. This may be sufficient, but most patients will require procedural sedation. This technique can cause significant patient discomfort.

Place the patient supine. Pass a sheet around the chest and axilla of the affected arm (**Figure 81-5A**). Abduct the affected arm 45°. Instruct an assistant to grasp the loose ends of the sheet firmly. Grasp the patient's wrist and apply slow and steady traction. Instruct the assistant to apply countertraction. The assistant and EP should be exerting equal and opposite forces. **If pain becomes severe, typically as a result of rotator cuff spasm, stop the motion and wait until the spasm subsides. Do not release the arm or return it to its original position.** After the spasm subsides, continue applying traction and countertraction until the shoulder reduces.

Direct traction on the extended arm may result in rapid EP fatigue. This is especially true if the EP is creating most of the force of traction through contraction of their biceps (**Figure 81-5A**). A less strenuous alternative is available and preferred (**Figure 81-5B**). Position the patient as above. Flex the elbow of the affected arm 90°. Place a looped sheet over the proximal forearm and the EP's hips. Do not loop the sheet around your back, as this can cause low back strain. This method allows the EP to lean back slowly and use their body weight to supply the traction force. The EP's arms should be extended with the hands grasping the patient's distal forearm. When leaning back to apply traction, the EP's hands should maintain the patient's forearm upright with the elbow flexed 90° (**Figure 81-5B**).

Traction may have to be applied for several minutes. The application of gentle and limited external rotation to the affected arm while under traction may speed up the reduction. Alternatively, a second assistant can apply lateral pressure (lateral traction) on the humeral head with their hands. A variation of this technique involves a second assistant with a looped sheet placed high in the patient's axilla (**Figure 81-5C**). This second assistant is used to create lateral traction at the proximal humerus that is perpendicular (90°) to the traction-countertraction axis.[2] As lateral traction is applied, the EP continues in-line traction and can simultaneously adduct the patient's arm to maneuver the humeral head back into position (**Figure 81-5C**). The second assistant may also be used with the technique demonstrated in **Figure 81-5A or B**.

Successful reduction is noted by a lengthening of the arm, a noticeable "clunk," and/or a brief fasciculation of the deltoid muscle. Disadvantages of the traction-countertraction technique include the need for more than one person, the significant degree of force required, the prolonged time and endurance required of the EP and assistant, and the need for procedural sedation. **This technique should not be used to reduce shoulder dislocations associated with significant fractures. The force required for this technique can displace fracture fragments,** necessitating an open reduction or operative management of the displaced fragments.

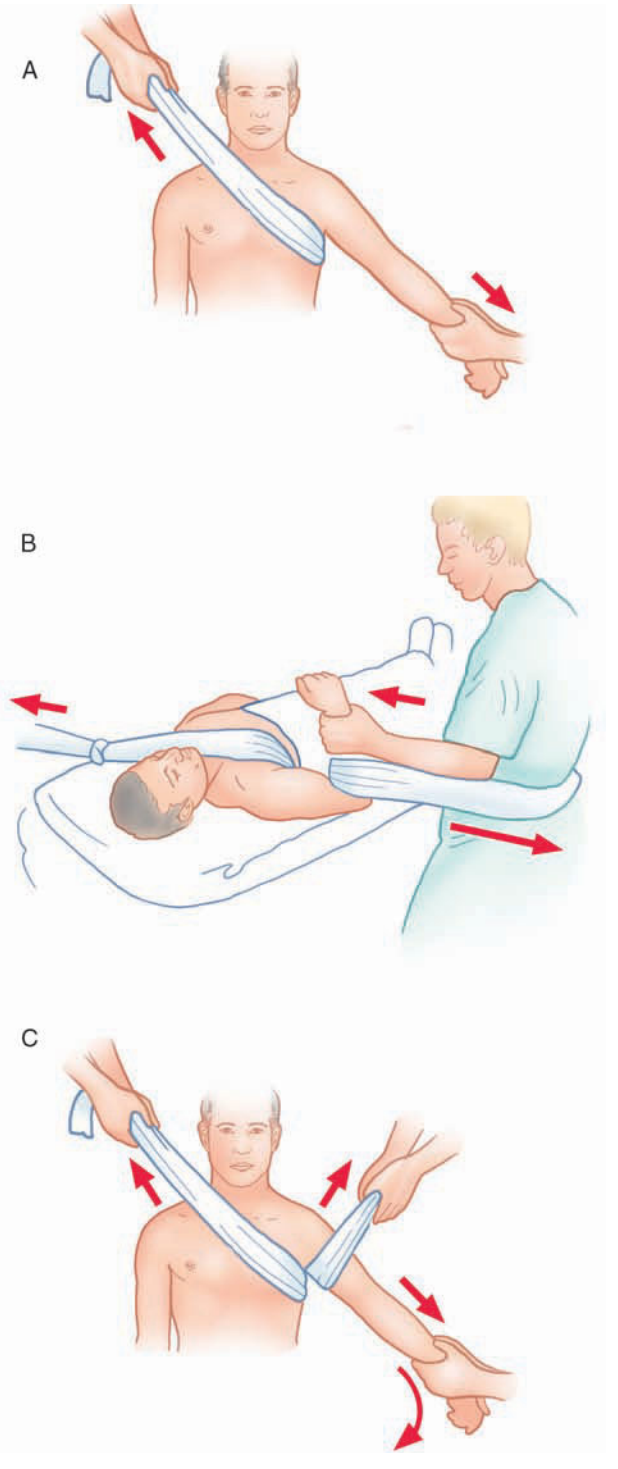

FIGURE 81-5. The traction-countertraction technique to reduce an anterior or posterior shoulder dislocation. **A.** In-line traction is applied to the affected extremity after it is abducted 45°. An assistant provides equal and opposite countertraction with a sheet. **B.** An alternative method. A sheet is looped around the flexed forearm and the EP's hips. The EP leans back (*arrow*) to allow their body to do the work of reduction while their hand maintains the patient's elbow in 90° of flexion. **C.** An additional assistant is applying traction 90° to the traction-countertraction axis with a sheet in the axilla. Simultaneous adduction (*curved arrow*) and in-line traction by the EP may aid in the reduction.

SNOWBIRD TECHNIQUE

The Snowbird technique was named after a ski area in Utah where this technique originated.[34] It was developed in order to reduce the large number of ski-related glenohumeral dislocations quickly while also conserving time and resources. This is an effective alternative reduction technique as compared with the more traditional methods. While this technique can be accomplished with no anesthesia, the intraarticular instillation of local anesthetic solution is highly

FIGURE 81-6. The Snowbird technique to reduce an anterior shoulder dislocation. Downward traction is applied to the humerus (*arrow*) while the humeral head is manipulated back into the glenoid fossa.

recommended. Procedural sedation is usually not required for this reduction technique.

Place the patient in a sitting position on a chair with a back (**Figure 81-6**). Completely adduct the affected arm. Flex the elbow to greater than 90°. Support the affected arm with the other arm or a pillow. Make a 3 foot long loop of 4 in wide cast stockinette. Place the stockinette around the proximal forearm. Instruct the patient to sit as straight as possible. Instruct an assistant to maintain the patient in an upright position by standing adjacent to the unaffected shoulder and clasping their hands around the chest, in the axilla, of the affected shoulder. The EP then places one foot in the stockinette loop and applies firm downward traction with the foot while the patient tries to keep the shoulder relaxed and the affected elbow flexed. Instruct the assistant to provide countertraction to keep the patient from moving. The shoulder may reduce. If not, with continued downward traction on the stockinette, the EP will have both hands free to apply gentle rotation and pressure on the humeral head until the shoulder is reduced.[34]

The Snowbird physicians had a 97% success rate and were able to reduce 93% of anterior shoulder dislocations without any form of analgesia.[34] The advantages of this technique include the relative ease of setup, the rapid nature of the technique, limited use of analgesia, and limited patient positioning. Potential disadvantages include the use of an assistant and the fact that this technique was used and developed on a limited patient population of young healthy skiers.

MILCH TECHNIQUE

Milch, in describing this technique, wrote that a fully abducted arm is in a natural and neutral position in which there is little tension on the muscles of the shoulder girdle.[35–37] Accordingly, the technique that Milch developed relies on gentle manipulation through abduction, external rotation, and traction on the arm.[19,35–40] The patient's affected arm moves in a gradual arc, assisted by the EP, to reduce the dislocation without extensive or forceful manipulation (**Figure 81-7**). While this technique can be accomplished with no anesthesia,[95] the intraarticular instillation of local anesthetic solution is highly recommended. Procedural sedation is not usually required for this reduction technique.

Place the patient supine. Position one hand with the thumb under the dislocated humeral head (**Figure 81-7A**). Slowly abduct the affected arm 180° to an overhead position (**Figure 81-7B**). This can be accomplished by having the patient lift the affected arm. Many patients are unable to do this due to pain, muscle spasm, or apprehension. Gently grip the elbow or wrist and slowly abduct the arm to 180° (**Figure 81-7B**). Once the arm is fully abducted, grasp the patient's distal arm or proximal forearm with one hand. Apply gentle longitudinal traction with slight external rotation to the arm (**Figure 81-7C**). The humeral head may reduce. If not, while maintaining traction with external rotation, apply upward pressure under the humeral head with the other hand to guide it into the glenoid fossa (**Figure 81-7C**).

Successful reduction is attained in 70% to 90% of the cases with no requirement for assistance, other equipment, or medications.[19,35–40] Advantages of the Milch technique include its gentleness, high success rate, limited complications, and good patient tolerance. Disadvantages include positioning the arm in full abduction with or without analgesia, as many patients cannot attain the optimal position due to severe pain, muscle spasm, and/or apprehension. This technique can be modified slightly so that the patient can perform a self-reduction under the instruction of the EP.[96]

ALTERNATIVE ANTERIOR SHOULDER DISLOCATION REDUCTION TECHNIQUES

Numerous alternative and less commonly used techniques are available to reduce an anterior shoulder dislocation. Some of these are modifications of existing methods. Others are original techniques that had too many associated complications and were modified with time and experience. Some are well known and effective techniques that have been used for many years. There is very little research regarding many of these techniques. Some of these techniques may prove to be useful in the reduction of an anterior shoulder reduction. **None of these techniques are advocated as first-line treatments for the reduction of shoulder dislocations. Their inclusion here is for the sake of completeness; it does not necessarily constitute an endorsement for their use.** Only a select few of these techniques are discussed.

HIPPOCRATIC TECHNIQUE

The Hippocratic technique is the original traction-countertraction technique[41] (**Figure 81-8**). It is one of the oldest documented techniques to reduce a shoulder dislocation.[2,11,26,41] This technique has the advantage that it can be performed by one person in any setting. While effective, the Hippocratic technique is not recommended due to the great force required to achieve reduction. Common complications of the technique include fractures, brachial plexus injury, vascular injury, and poor patient tolerability.[2,6,11]

Place the patient supine (**Figure 81-8**). Grasp the wrist of the affected arm and abduct the arm 20° to 30°. Place one foot into the axilla of the affected arm. Firmly grasp the patient's wrist and apply traction to the arm while extending the foot in the axilla to provide countertraction.

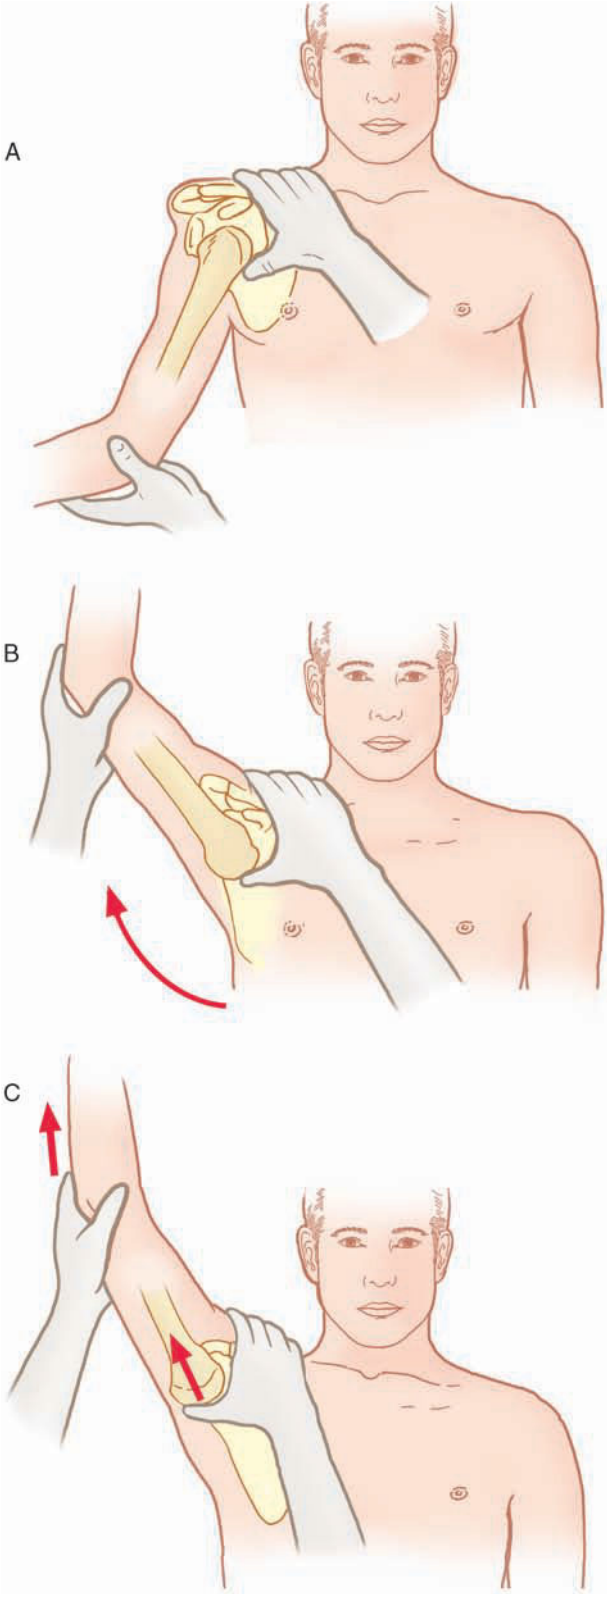

FIGURE 81-7. The Milch technique to reduce an anterior shoulder dislocation. **A.** The distal humerus is grasped with one hand while the thumb of the other hand is placed under the dislocated humeral head. **B.** The arm is abducted to 180°. **C.** In-line traction is applied to the humerus while the thumb pushes the humeral head into the glenoid fossa.

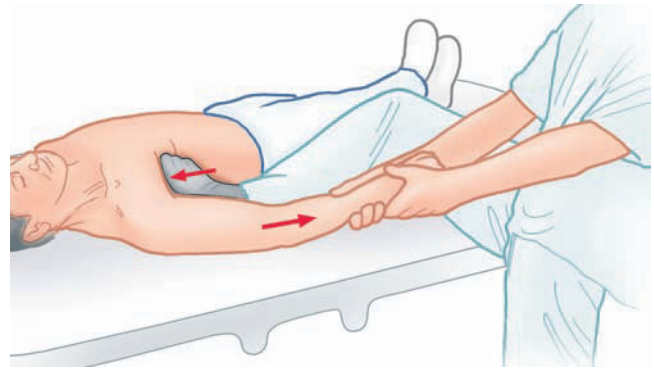

FIGURE 81-8. The Hippocratic technique to reduce an anterior shoulder dislocation. Traction is applied to the arm while countertraction is applied using a foot in the axilla.

KOCHER TECHNIQUE

The Kocher technique was first recorded on an Egyptian mural dated 1200 BC.[42] It is another traditional method that has come into disfavor. This maneuver relies upon leverage and humeral manipulation to reduce the shoulder (**Figure 81-9**). The humeral head is levered on the anterior glenoid while the humeral shaft is levered against the anterior thoracic wall until reduction is achieved.[11,42,43] A substantial amount of force must be applied while adducting and externally rotating the arm in order to reduce the joint.

Place the patient sitting at a 45° incline or supine. Abduct the affected arm 45° and flex the elbow 90° (**Figure 81-9A**). Grasp the patient's distal humerus with the dominant hand and the patient's wrist with the nondominant hand (**Figure 81-9A**). Apply in-line traction to the distal humerus. Rotate the arm externally to its maximum extent while maintaining in-line traction (**Figure 81-9B**). Move the patient's elbow across their chest and to the midline while maintaining in-line traction and external rotation (**Figure 81-9C**) while the elbow is held tightly against the patient's chest. Finally, internally rotate the arm while in-line traction is maintained and until the patient's hand touches their opposite shoulder (**Figure 81-9D**).

The main advantage of this method is that it is a one person technique that has withstood the test of time. However, studies have shown that the forces generated are sufficient to cause fractures of the humeral neck, spiral humeral fractures, vascular trauma, and brachial plexus injury.[11]

ESKIMO TECHNIQUE

The Eskimo technique uses the patient's body weight and gravity as a traction mechanism to reduce an anterior shoulder dislocation.[44] It can be performed in the field, where access to a healthcare facility may be limited. Disadvantages of this technique include the strength and stamina required to lift the patient, EP injury due to heavy lifting, poor patient tolerability, and increased stress on the brachial plexus and axillary vessels.

Place the patient on the floor and lying on the unaffected side (**Figure 81-10**). Instruct the patient to place the affected arm tightly adducted with the elbow flexed 45° (**Figure 81-10A**). Grasp the injured arm and slowly lift the patient 6 to 12 in. off the ground (**Figure 81-10A**) so that the patient's body weight produces enough traction to reduce the joint. Poulsen initially described this technique and reported a 74% success rate.[44]

Alternatively, the patient can be positioned on the unaffected side with the affected arm abducted 90° (**Figure 81-10B**). One or two

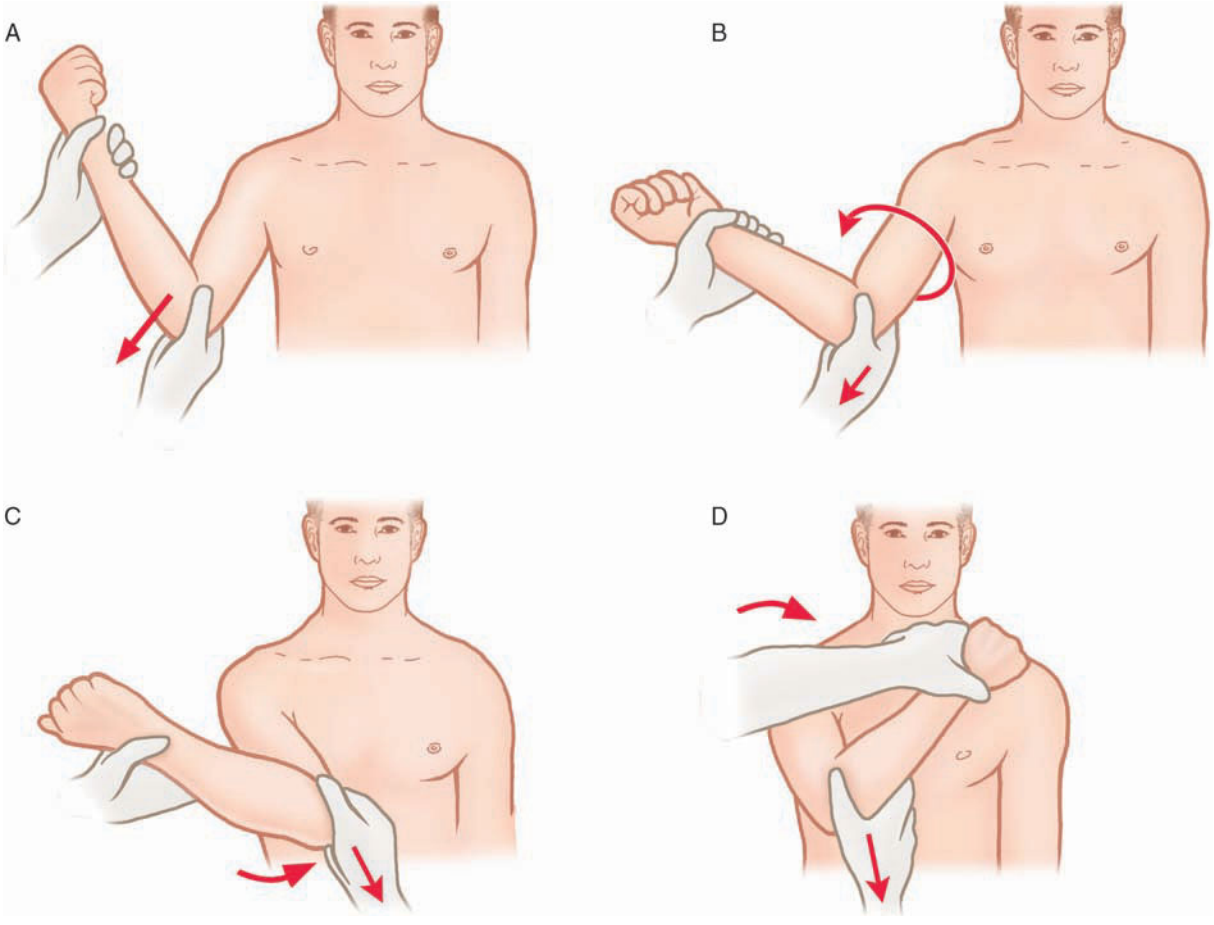

FIGURE 81-9. The Kocher technique to reduce an anterior shoulder dislocation. **A.** The arm is abducted 45° with the elbow flexed 90°. In-line traction is applied to the humerus (*arrow*). **B.** The arm is rotated externally (*curved arrow*) while traction is maintained (*straight arrow*). **C.** The elbow is brought across the chest to the midline while the arm is still rotated externally and traction on the arm is maintained (*straight arrow*). **D.** Traction is maintained while the arm is rotated internally until the patient's hand touches their opposite shoulder.

people can then grasp the patient's wrist and forearm and lift the patient 6 to 12 in. off the ground (**Figure 81-10B**).

CHAIR TECHNIQUE

The chair technique is a simple method to reduce an anterior shoulder dislocation.[45–47,80] It is a variation of the traction-countertraction technique. Place the patient sitting sideways or backwards in a chair with the affected arm draped over the back rest (**Figure 81-11**). Supinate the patient's wrist and apply downward traction while the patient attempts to stand and provide countertraction (**Figure 81-11**).

This technique has a 72% success rate.[3] The advantages include the simplicity of the technique and the fact that analgesia is not required. Unfortunately, a large amount of force is required to reduce the shoulder. These forces can cause injury to the brachial plexus and axillary vessels as the axilla is impinged on the back of the chair.

WRESTLING TECHNIQUE

Zahiri et al. recently described a new technique based on optimal anatomic positioning with limited complications.[48] Place the patient supine with the elbow of the affected shoulder flexed 120°. Grasp the dislocated arm just above the humeral condyles and apply distal traction to the arm. Grasp the distal forearm overhanded with the opposite hand and move the hand from the condyles through the acute angle of the arm, grasping the wrist of the hand holding the forearm. The wrestling hold is now established (**Figure 81-12**). With the hold in place, the patient's forearm will be used as a fulcrum. Abduct the patient's shoulder 45° while maintaining constant traction. Externally rotate the arm in a slow, smooth motion. While maintaining traction and external rotation, move the patient's arm over their chest wall and rotate it internally.[1] The shoulder should then reduce.

This technique has the advantages of requiring no equipment, no analgesia, and no assistants. It may be used in the field where a healthcare facility is not readily available. The main disadvantage is the amount of force applied to the shoulder and surrounding structures. The twisting of the forearm as a lever can displace fracture fragments or cause fractures. This technique also requires the EP to have a significant amount of upper body strength and arms long enough to accomplish the wrestling hold, especially if the patient has large arms. The series of movements is difficult to accomplish while always maintaining distal traction.

PNEUMATIC STRETCHER TECHNIQUE

This technique was developed to reduce a shoulder dislocation when assistants were not available or if the physician did not have the physical strength required to use other techniques.[49] It is a modification of the traction-countertraction technique.

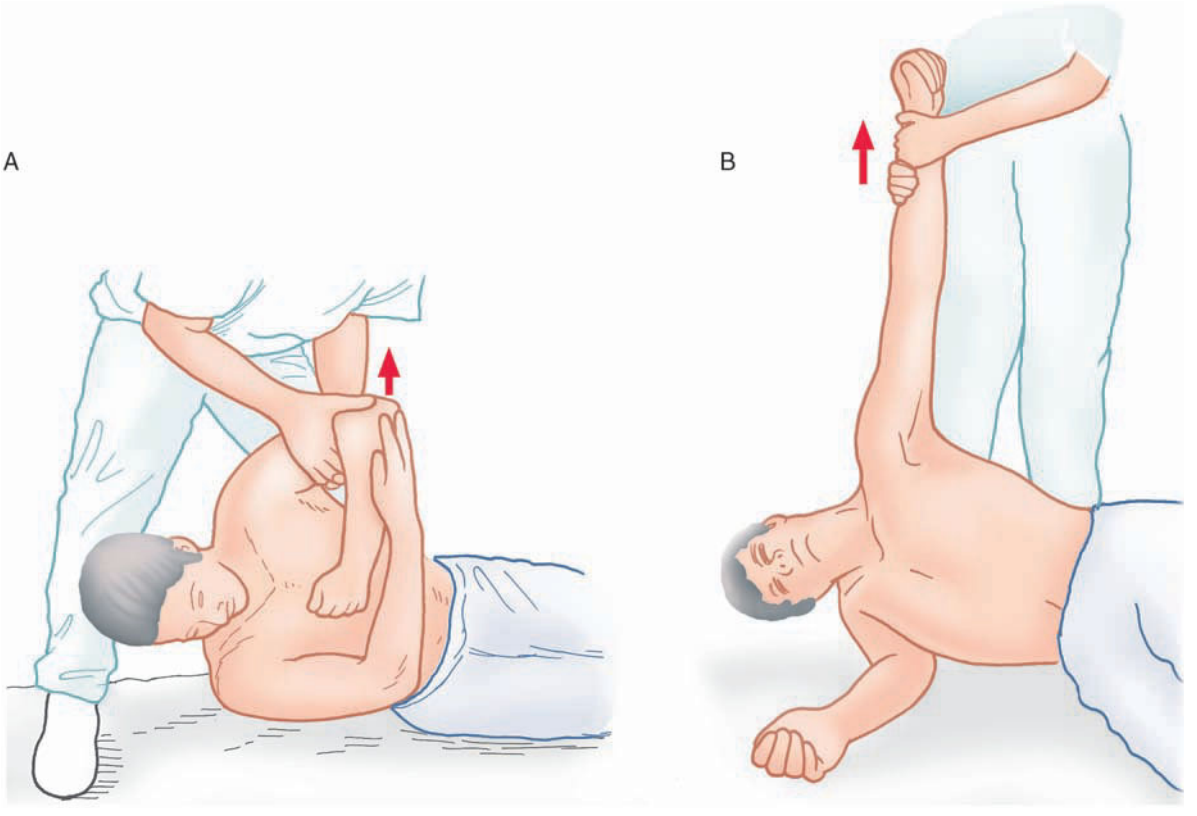

FIGURE 81-10. The Eskimo technique to reduce an anterior shoulder dislocation. The patient is lying on the floor on the unaffected side. **A.** The patient is lifted off the ground by grasping the adducted arm. **B.** The patient is lifted off the ground by grasping the distal forearm of the affected arm.

This technique should never be used to reduce a shoulder dislocation. It will cause stretching and possible rupture of the brachial plexus, ligaments of the shoulder region, muscles and tendons crossing the shoulder, nerves of the upper extremity, vascular structures of the upper extremity, and injury to other joints. Tremendous forces are applied to the extremity with this technique.

Place the patient prone with the affected arm hanging off the gurney (**Figure 81-13**). Wrap a sheet around the patient's waist and hips and the gurney to hold the patient in position. Tie the ends of the sheet into a knot or have them held by an assistant. Wrap the patient's wrist with gauze and tie it to the base or wheel of the gurney. Begin elevating the bed until the dislocation is reduced.

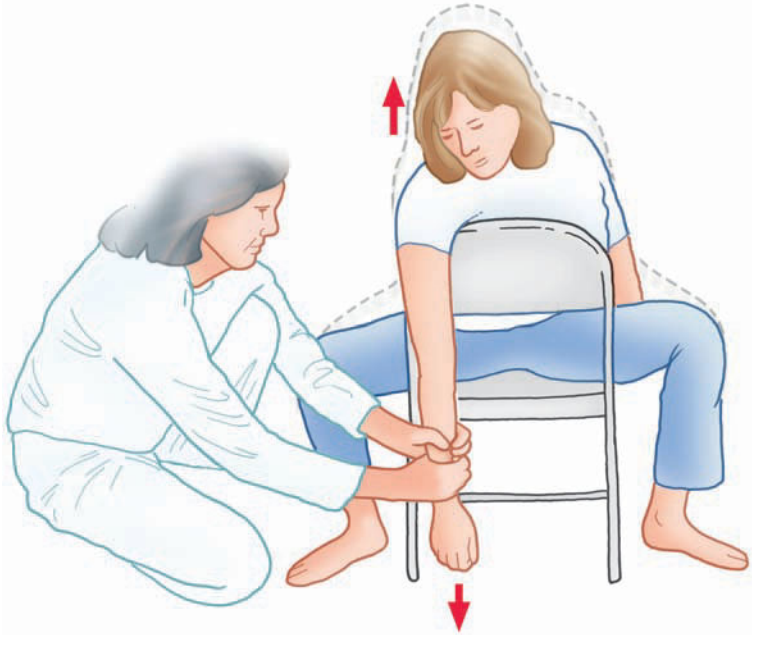

FIGURE 81-11. The chair technique to reduce an anterior shoulder dislocation. Traction is applied to the arm as the patient attempts to stand and provide countertraction.

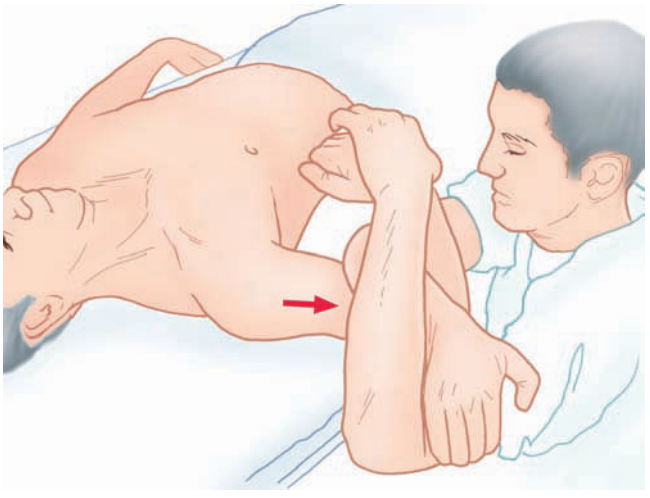

FIGURE 81-12. The wrestling technique to reduce an anterior shoulder dislocation. After the hold is established, traction and external rotation are applied to the arm.

SPASO TECHNIQUE

The Spaso technique is a one person technique that is simple to perform.[81–85] It uses minimal force and can be performed without procedural sedation. This technique is similar to the Stimson technique with the main difference being the patient's position.[82] Successful rates of reduction can be seen in up to 87% of patients.[83–85]

Place the patient supine. Grasp the wrist of the affected arm with the dominant hand and the patient's proximal forearm with the nondominant hand (**Figure 81-14**). Slowly flex the patient's shoulder until the arm is upright and the shoulder flexed 90° (**Figure 81-14**). Apply upward traction to the arm while gently externally rotating the arm. Slowly increase the upward traction until the shoulder reduces. If reduction does not occur, use the nondominant hand to apply externally directed pressure to the humeral head to push it into the glenoid fossa while maintaining the arm in traction and external rotation with the dominant hand. An assistant may be required to push on the humeral head while the EP uses both hands to apply upward traction.

FIGURE 81-14. The Spaso technique to reduce an anterior shoulder dislocation. Upward traction is applied (*arrow*) as the arm is externally rotated (*curved arrow*).

OZA MANAUVER

Direct manipulation of the humeral head with simultaneous arm traction may allow for a simple reduction of the humeral head.[86] This technique is a modification of the traction-countertraction technique. Very little information exists in the literature regarding the effectiveness of this maneuver.

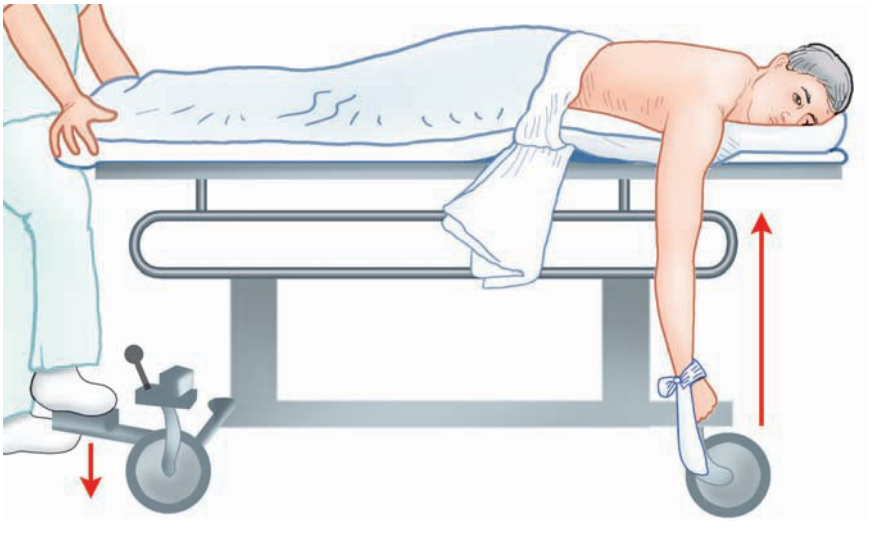

FIGURE 81-13. The pneumatic stretcher technique to reduce an anterior shoulder dislocation. The gurney is raised to provide countertraction to the traction applied to the wrist that is tied to the base of the gurney.

FIGURE 81-15. The Oza maneuver to reduce an anterior shoulder dislocation. Traction is applied to the arm as the humeral head is pushed outward.

Place the patient supine with the affected arm and their body against the edge of the gurney (**Figure 81-15**). Instruct an assistant to grasp the patient's wrist and slowly abduct the arm until it is at 45° to 90°. Stand between the patients abducted wrist and their body, with your back against the patient's body. Place both thumbs against the dislocated humeral head. Wrap the fingers of both hands around the proximal humerus and interlace your fingers. Instruct the assistant to apply traction to the arm while simultaneously using your thumbs to lift and push the humeral head up and over the anterior glenoid lip and back into the glenoid fossa. Alternatively, the EP can stand outside the patient's abducted arm, wrap their fingers around the proximal humerus, and pull the humeral head back into the glenoid fossa.

BEST OF BOTH (BOB) MANEUVER

The BOB maneuver is a combination of distally applied traction and scapular manipulation.[87] This maneuver is quick to perform and does not use procedural sedation. It requires the patient to sit upright with their legs dangling off the gurney. Thus, this maneuver is not appropriate to use with procedural sedation, intubated patients, multiply injured patients, those who cannot sit upright, or anyone with altered mentation. The BOB maneuver can be performed with no analgesia or the instillation of local anesthetic solution intra-articularly.

Lower the gurney as much as possible. Elevate the head of the gurney 90°. Place the patient sitting upright on the side of the gurney with their unaffected arm against the upright head of the gurney. The patient's feet may touch the floor or dangle. Instruct the patient to "scoot over" until their unaffected shoulder and hip are tight against the head of the gurney. Kneel on the gurney facing the patient (**Figure 81-16**). Flex the elbow of the affected arm 90°. Place one hand on the patient's proximal forearm adjacent to the antecubital fossa. Grasp the patient's wrist with your other hand. Lean down with your body weight, pulling the patient's humerus downward (**Figure 81-16**). Instruct an assistant to simultaneously stand behind the patient and perform the scapular manipulation technique. The combination of traction of the humerus and scapular manipulation will allow the humeral head to relocate in the glenoid fossa.

LEGG REDUCTION MANEUVER

This maneuver is a simple technique to reduce an anteriorly dislocated shoulder.[88] It was developed and used to treat athletes in the field. Many patients may not tolerate the pain associated with this maneuver. It is not appropriate to use with procedural sedation, intubated patients, multiply injured patients, those who cannot sit upright in a chair, or anyone with altered mentation. The maneuver can be performed with no analgesia or the instillation of local anesthetic solution intra-articularly.

Place the patient sitting upright in a chair. Instruct an assistant to provide slight downward pressure on the unaffected shoulder (**Figure 81-17A**). Instruct the assistant to maintain downward pressure on the shoulder throughout the maneuver. Place one hand on the affected shoulder and apply downward pressure while abducting the patient's arm with your other hand (**Figure 81-17A**). Externally rotate the arm and flex the elbow 90° until the patient's palm faces

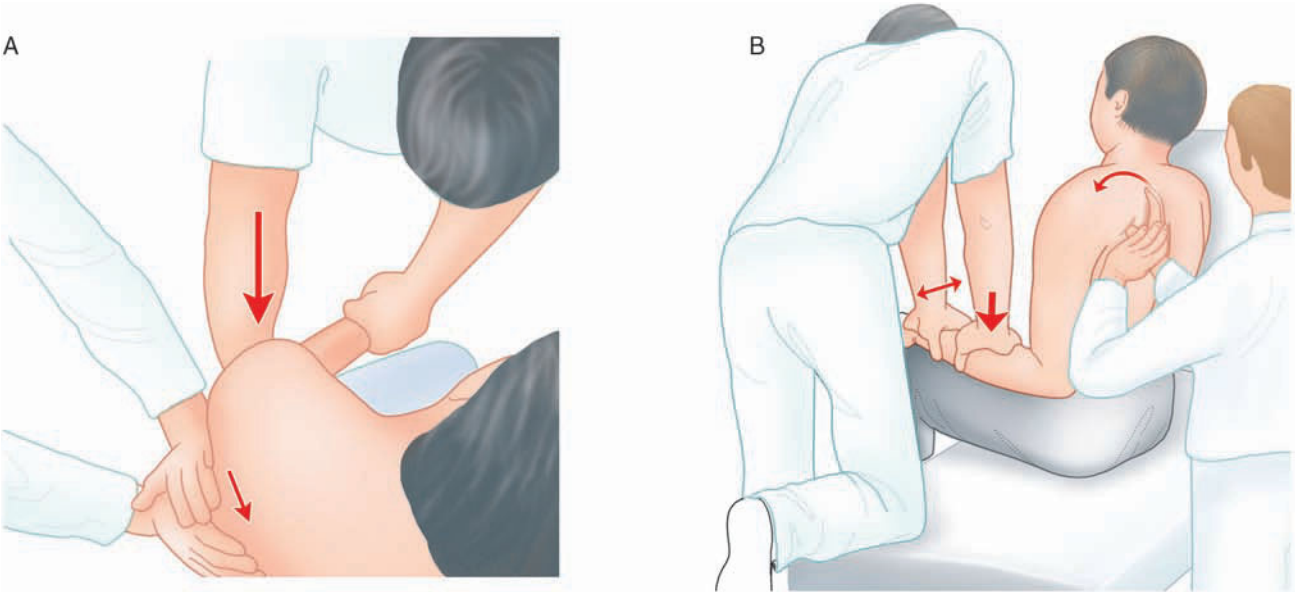

FIGURE 81-16. The best of both (BOB) maneuver to reduce an anterior shoulder dislocation. Traction is applied to the humerus as the tip of the scapula is pushed medially. **A.** Superior view. **B.** Lateral view.

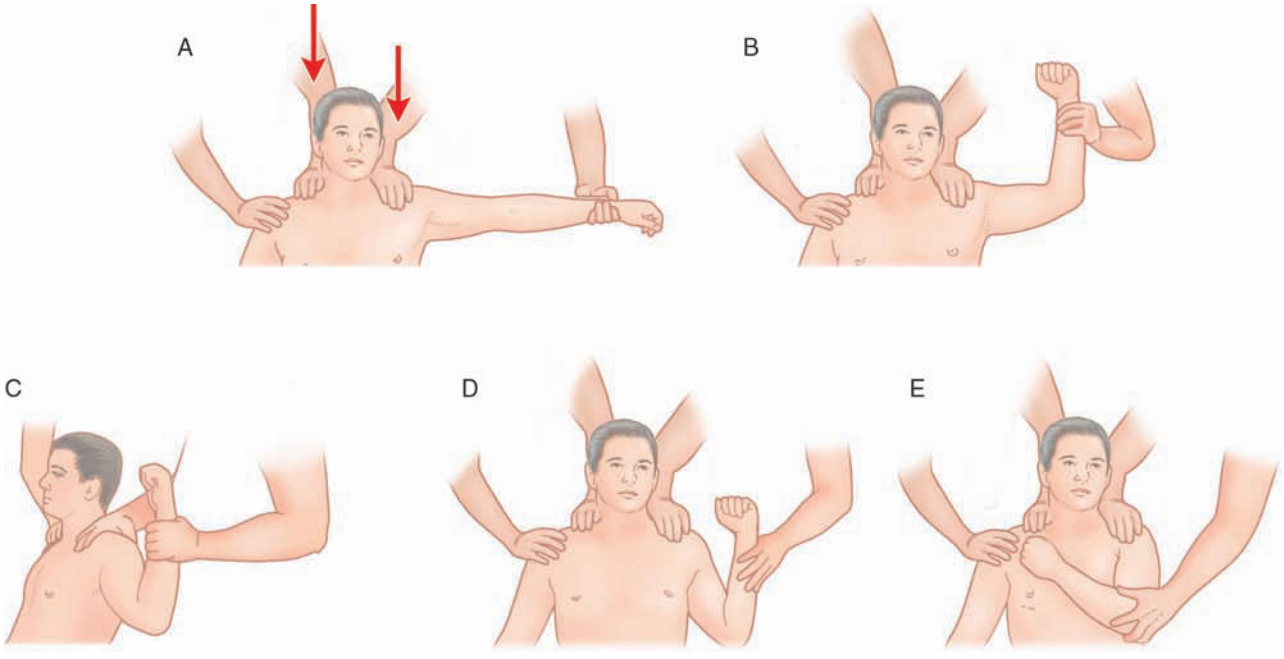

FIGURE 81-17. The Legg reduction maneuver to reduce an anterior shoulder dislocation. **A.** Initial positioning. **B.** The arm is externally rotated and the elbow flexed 90°. **C.** The arm is moved posteriorly. **D.** The arm is adducted while fully flexing the elbow. **E.** Internal rotation of the arm.

outward (**Figure 81-17B**). Pull the elbow and forearm posteriorly until it crosses a plane across the occiput (**Figure 81-17C**). Adduct the arm while simultaneously flexing the elbow from 90° to full flexion (**Figure 81-17D**). Once fully adducted, internally rotate the arm until the hand touches the unaffected shoulder and the humerus relocates (**Figure 81-17E**).

CUNNINGHAM TECHNIQUE

Dr. Cunningham developed a technique to simply, quickly, and painlessly reduce an anterior shoulder dislocation without the use of drugs.[89,90] This small case series is based on the principle of relaxing the biceps brachii muscle with massage while the rhomboids retrovert the scapula to allow the humeral head to relocate.

Place the patient sitting upright in a chair or on a gurney (**Figure 81-18**). Stand next to the affected arm and face the patient. Fully adduct the humerus and flex the elbow 90°. Insert one hand between the patient's forearm and their body. Grasp the patient's proximal forearm so that their hand and wrist is resting on your upper forearm (**Figure 81-18**). Instruct the patient to shrug their shoulders superiorly and posteriorly to square-off the angle of their shoulder. Apply steady and downward pressure to the patient's forearm. With your other hand simultaneously massage the patient's trapezius, deltoid, and biceps muscles sequentially. While maintaining the downward traction, repeat the massage process while concentrating on the biceps until the shoulder reduces.

BOSS-HOLZACH-MATTER TECHNIQUE

This technique allows the patient to self-reduce an anterior shoulder dislocation.[91–93] The patient can control the application of force so that their pain can be minimized during the reduction. It is a hybrid of the traction-countertraction and scapular manipulation techniques. The EP instructs the patient through the technique. This technique is only successful in 60% of anterior shoulder dislocations, significantly lower than many other commonly used reduction techniques.

Place the patient supine on a gurney. Elevate the head of the gurney to 90°. Bind the patient's wrists together with an elastic or gauze bandage. Instruct the patient to flex their knee on the affected side. Instruct the patient to place their bound wrists in front of the flexed knee (**Figure 81-19**). Lower the head of the gurney completely. Instruct the patient to slowly lean back while simultaneously hyperextending their neck and shrugging their shoulders anteriorly to antevert the glenoid fossa. The humeral

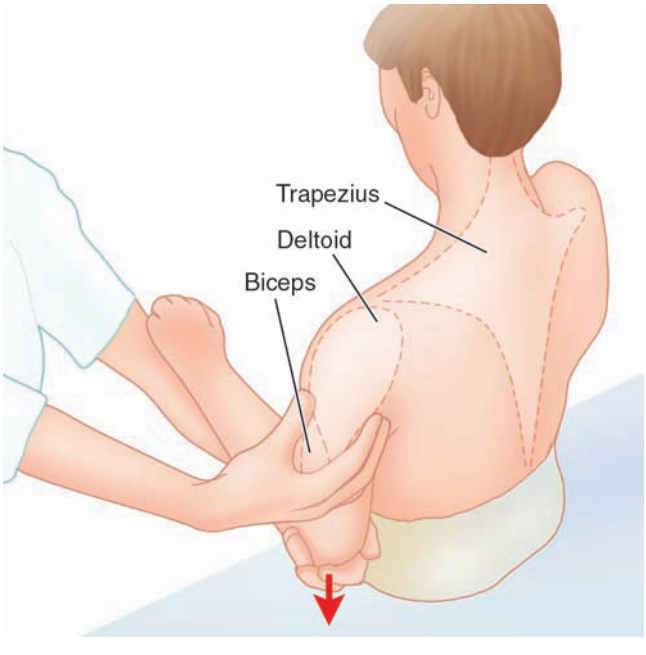

FIGURE 81-18. The Cunningham technique to reduce an anterior shoulder dislocation. Traction is applied to the humerus while the trapezius, deltoid, and biceps muscles are massaged sequentially.

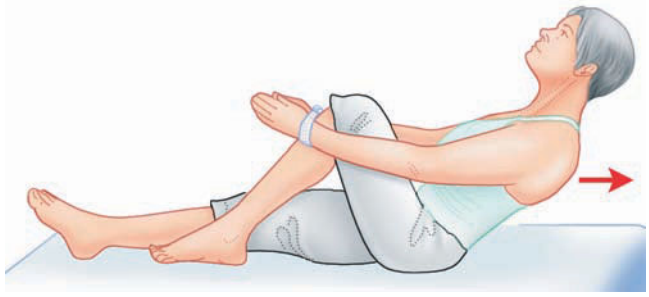

FIGURE 81-19. The Boss-Holzach-Matter technique to reduce an anterior shoulder dislocation. The patient leans back to provide countertraction while the wrists are secured over the knee to provide distal traction.

head will reduce as the glenoid fossa moves toward the humeral head while traction is applied to the humerus.

FARES METHOD

This technique can reduce an anteriorly dislocated shoulder in an average of 2 to 3 minutes with the use of procedural sedation.[94] The FARES method has a 78% success rate and only requires one person to perform the reduction.

Place the patient supine with the affected arm at their side. Fully extend the elbow and place the forearm in the neutral position with the patient's thumb pointing upward. Grasp the distal forearm and hand. Apply longitudinal traction on the arm (**Figure 81-20A**). Oscillate the forearm continuously with brief (two to three cycles per second) and short range (5 cm above and below the horizontal plane) vertical movements of the arm (**Figure 81-20A**). Slowly abduct the arm while maintaining longitudinal traction and vertical oscillatory movements (**Figure 81-20B**). Externally rotate the arm until the palm is facing upward when the arm is approximately 90° abducted. Continue to slowly abduct the arm while maintaining longitudinal traction and vertical oscillatory movements until the shoulder reduces (**Figure 81-20C**). The shoulder usually reduces at approximately 120° of abduction. Once reduced, gently internally rotate the arm and adduct it until the humerus is against the chest and the forearm is resting across the chest.

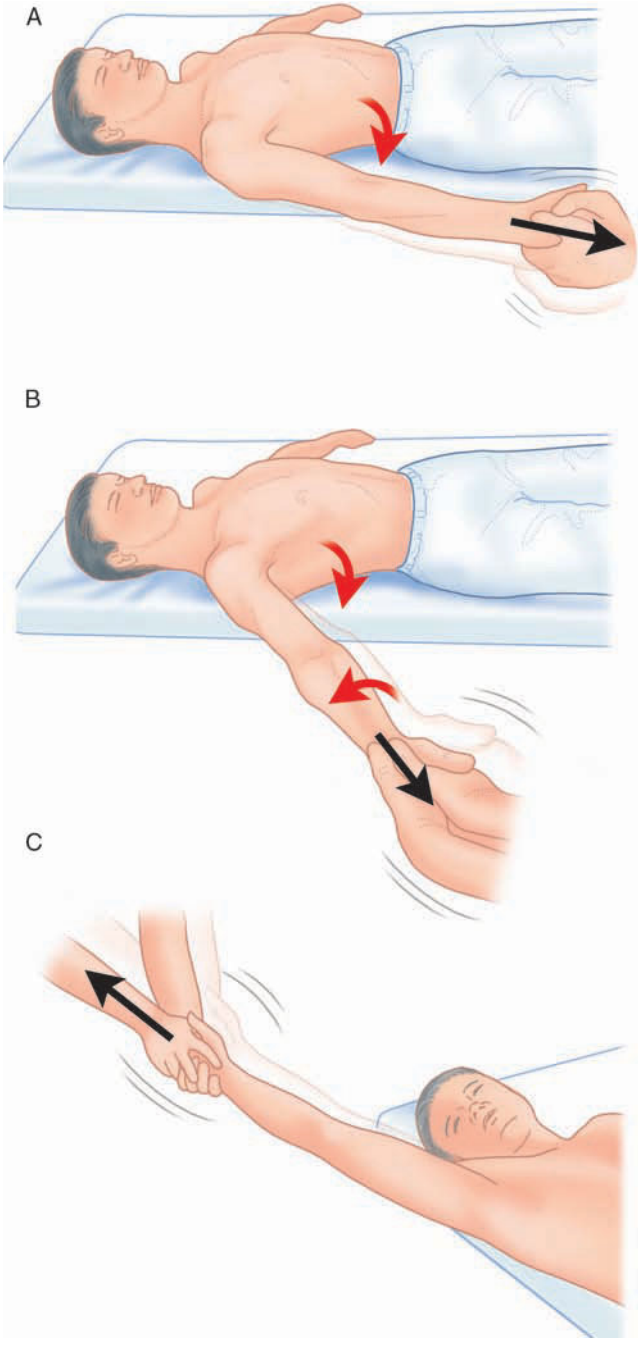

FIGURE 81-20. The FARES method to reduce an anterior shoulder dislocation. **A.** Longitudinal traction is applied to the abducted arm as vertical oscillatory movements are made with the forearm. **B.** The arm is further abducted and externally rotated as longitudinal traction and vertical oscillatory movements are continued. **C.** The arm is further abducted as longitudinal traction and vertical oscillatory movements are continued until the shoulder reduces.

POSTERIOR SHOULDER DISLOCATION REDUCTION TECHNIQUE

An Orthopedic Surgeon should be consulted before attempting to reduce the shoulder due to the rarity of posterior shoulder dislocations, the difficulty of reduction, the high incidence of associated injuries, and the need to operate to repair the associated injuries.[2,4,8,11,99,101] **The only exception is when the affected extremity has signs of neurologic or vascular compromise and the Orthopedic Surgeon is not immediately available to reduce the shoulder.** The patient will require intraarticular instillation of local anesthetic solution and procedural sedation for the performance of this technique.

TRACTION-COUNTERTRACTION

Place the patient supine. Perform procedural sedation. Pass a sheet around the axilla and torso of the affected arm in the same manner as in the traction-countertraction technique (**Figure 81-5A**). Grasp the distal forearm. Apply axial traction in-line with the humerus. Instruct an assistant to apply countertraction on the sheet looped around the patient's torso. The traction and countertraction should be equal in force and in opposite directions. While maintaining traction, gently internally rotate and adduct the arm. The shoulder may reduce. If not, instruct a second assistant to apply simultaneous lateral pressure on the humeral head.[3] While continuing to exert pressure on the humeral head, in trying to work it over the glenoid rim, the arm may need to be gently rotated externally. If this fails to reduce the shoulder, apply lateral traction, with a second assistant using a sheet looped around the proximal humerus, and repeat the

process (**Figure 81-5C**). If the shoulder will still not reduce, this is an indication for general anesthesia and an open or closed reduction in the Operating Room.[4,9] The shoulder joint is usually unstable and may not remain articulated once it is reduced.

An alternative to grasping the forearm is to apply a padded wrist restraint. Tie the loose ends of the restraint straps to create a loop around the EPs hips. A second alternative is to loop a sheet around the patient's flexed forearm and the EPs hips as in the traction-countertraction technique (**Figure 81-5B**). These two alternatives are preferred, as they allow the EPs body to reduce the shoulder rather than depending on biceps strength.

INFERIOR SHOULDER DISLOCATION REDUCTION TECHNIQUE

Like posterior shoulder dislocations, **inferior shoulder dislocations require an Orthopedic Surgeon to be consulted before attempting closed reduction unless neurologic or vascular compromise is present in the affected extremity.** Consultation is required because of the rarity of inferior shoulder dislocations, the difficulty of reduction, the high incidence of associated injuries, and the need to operate to repair the associated injuries.[2–4,10,50–52,100,101] The patient will require intraarticular instillation of local anesthetic solution and procedural sedation for the performance of these techniques.[4] An inferior shoulder dislocation is usually reduced using the traction-countertraction technique.[10,100–102]

TRACTION-COUNTERTRACTION

Place the patient supine. Loop a sheet over the clavicle of the affected shoulder with the loose ends of the sheet at the opposite hip (**Figure 81-21**). Stand above the patient's head and grasp the distal forearm. Apply axial traction to the arm. Instruct an assistant to apply equal countertraction on the sheet. While maintaining axial traction on the humerus, gently adduct the arm in a full arc from the patient's head to their side (**Figure 81-21**). The shoulder should reduce. The shoulder joint is usually unstable and may not remain articulated once reduced. In rare instances, buttonholing of the joint capsule will prevent closed reduction and require an open reduction.[2]

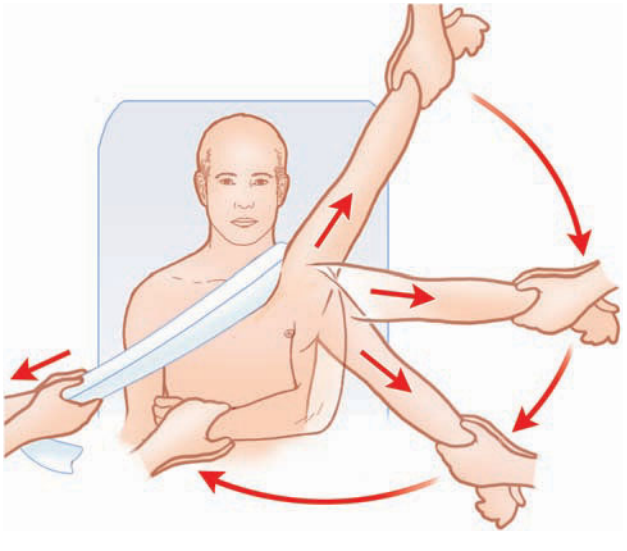

FIGURE 81-21. Reduction of an inferior shoulder dislocation. Axial traction (*straight arrows*) is applied and maintained on the dislocated extremity while it is simultaneously hyperadducted (*curved arrows*).

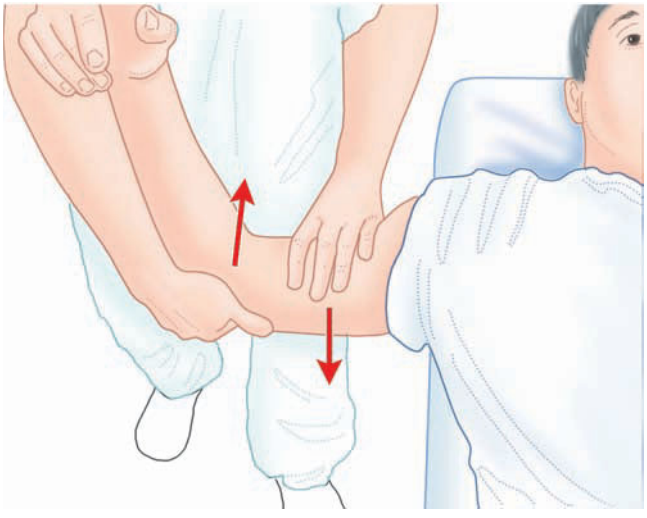

FIGURE 81-22. The two-step maneuver to reduce an inferior shoulder dislocation. Step one involves pushing the lateral aspect of the distal humerus while pulling on the medial condyle to convert the inferior dislocation into an anterior dislocation. Step two is the external rotation technique (**Figure 81-2A**).

TWO-STEP MANEUVER

This maneuver consists of two steps.[103] The first step converts an inferior shoulder dislocation into an anterior shoulder dislocation. Step two is the reduction of the anterior shoulder dislocation using the external rotation technique described previously in this chapter. The two-step maneuver has several advantages over using the traction-countertraction technique. This includes requiring a single person, using one reduction attempt, possibly using less sedation, and not requiring a trip to the Operating Room for the reduction.

Place the patient supine. Stand adjacent to the affected shoulder and facing the patient's feet. Place one hand on the distal aspect of the lateral humerus and the other hand on the medial epicondyle (**Figure 81-22**). Use the hand on the lateral aspect of the distal humerus to push inward while simultaneously pulling the elbow outward (**Figure 81-22**). This will convert the inferior dislocation into an anterior dislocation. Apply the external rotation technique to reduce the anterior dislocation.

ASSESSMENT

The postprocedural care of the dislocated shoulder is as important as the initial reduction. Successful shoulder reduction is usually sensed by the operator as a shift or "clunk" in the shoulder joint. Sometimes this can be a very subtle sign. Generally, the normal contour of the shoulder is restored and patients often report marked improvement in their pain. A simple test to evaluate the success of the reduced joint, especially in anterior and posterior dislocations, is to have the patient touch their nose or contralateral shoulder with the hand of the affected limb.[3] The ability to do so usually signifies a relocated shoulder joint. **The patient should have a thorough examination to evaluate the extremity for vascular and/or neurologic compromise. Any compromise requires immediate consultation with an Orthopedic Surgeon.**

It is important to immobilize the shoulder to prevent further external rotation or abduction of the reduced shoulder by the patient. Place the affected extremity in a shoulder immobilizer (**Figure 81-23A**) or a conventional sling with a swath (**Figure 81-23B**).[1,2,11,20,53,54] The shoulder should be immobilized in

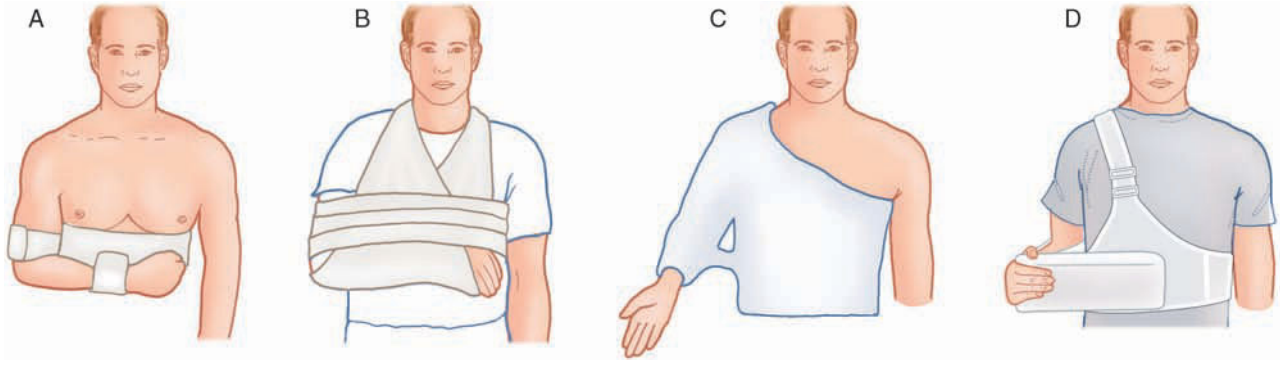

FIGURE 81-23. Methods of shoulder immobilization after reduction of a dislocation. **A.** Shoulder immobilizer. **B.** Velpeau dressing. **C.** Spica cast. **D.** Immobilization in external rotation.

external rotation in a spica cast if a successful reduction is unstable[3] (**Figure 81-23C**). Recent studies have shown that splinting the shoulder with the arm adducted and in 10° to 20° of external rotation may prevent recurrent dislocations.[106–109] Patients should remain in this position for 3 weeks.[106] A splint to hold the shoulder in external rotation can be made with splinting material or a commercially available product may be purchased (**Figure 81-23D**).[106–109]

Postreduction films are indicated after immobilization to confirm the reduction of the joint, to rule out missed fractures on the original radiographs, to rule out a fracture from the reduction procedure, and to evaluate for displacement of fracture fragments. There is some evidence that postreduction radiographs may be unnecessary, but further study is warranted before this can be routinely recommended.[13,14]

Bedside ultrasound (US) can be used to verify the shoulder is reduced.[104,105] A high frequency (7-13 MHz) US probe is preferred, but a lower frequency probe can also be used if available. Place the US probe transversely on the patient's back just inferior to the lateral aspect of the scapular spine to obtain a posterior US.[104] It may be more practical to obtain anterior or lateral US image in the supine patient.[105] The advantages of bedside US over plain radiographs include time saving, lack of radiation, not waiting for procedural sedation to wear off before transporting the patient to the radiology suite, US can be performed with the patient in any position, and it does not require patient cooperation.

AFTERCARE

Following procedural sedation, the patient will need to be observed before being discharged home in the care of friends or family. It is necessary to have the patient awake, alert, oriented, and to have the pain adequately controlled before discharge. The patient should be discharged with adequate pain control and follow-up care by an Orthopedic Surgeon. Generally, oral nonsteroidal anti-inflammatory drugs are sufficient to control pain. Oral narcotics may be given as needed for 2 to 3 days to aid with pain during the acute inflammatory response period. Orthopedic follow-up should be arranged within 24 hours for anterior shoulder dislocations complicated by fractures or soft tissue injuries beyond ligamentous strain. Orthopedic follow-up within 5 to 7 days is generally sufficient for uncomplicated anterior shoulder reductions.

The duration of immobilization depends on the patient's age.[2,11,20] The only large-scale prospective study of first-time anterior shoulder dislocations followed patients over a 10 year period. It found that the duration of immobilization had no effect on the incidence of recurrence. Age was the only prognostic factor for recurrence. Patients under 20 years of age should be immobilized for 3 weeks and then begin active range-of-motion exercises. Patients aged 20 to 40 years should be immobilized for 1 to 2 weeks and begin active range-of-motion exercises 5 days postreduction. Patients older than 60 years of age should have minimal immobilization—less than 1 week—and begin active range-of-motion exercises within 72 hours postreduction to limit subsequent shoulder stiffness.[2,11] Patients should be instructed to avoid external rotation and abduction activities, such as combing their hair, to avoid a recurrent dislocation.[1]

Range-of-motion exercises should include dangling-arm rotation.[2,11] While supporting the torso with the other arm, the patient makes a small circular motion with the injured arm against the force of gravity. For anterior dislocations, strengthening the subscapularis muscle by doing internal rotation against a resistance band with the elbow flexed 90° is advocated.[2]

COMPLICATIONS

Complications of shoulder dislocations can occur as a result of the initial injury, the reduction technique, or a combination of both. Complications are discussed with respect to both the initial injury and the reduction. They include fractures, displacement of fracture fragments, rotator cuff tears, vascular injury, neurologic injury, recurrence of dislocation, hemarthroses, and the inability to reduce the shoulder.

FRACTURES

Most fractures are caused during the dislocation and rarely during the reduction procedure if the proper techniques are used.[2,4,8,11,50] Prereduction radiographs will identify most fractures. Postreduction radiographs are required to identify fractures initially missed or new ones associated with the reduction. Fractures of the humerus and coracoid process are rare and almost always associated with traumatic anterior shoulder dislocations.[1,2,8] These fractures make closed reduction very difficult and should generally be treated under general anesthesia by an Orthopedic Surgeon or by open reduction.

More common bony injuries include the Hill–Sachs deformity and the Bankart lesion, both caused during and from the dislocation. The Hill–Sachs lesion occurs in up to 50% of shoulder dislocations.[1,2] More significant fractures can occur during reduction in rare situations in which the humeral head is dislocated anteriorly with impaction on the glenoid rim.[1,2,8,11] The Bankart lesion is more commonly seen in recurrent dislocations and is associated with rupture of the joint capsule, but it spares the rotator cuff.[1,2,8,11]

DISPLACEMENT OF FRACTURE FRAGMENTS

Prereduction radiographs should be obtained on all traumatic shoulder dislocations. They will identify most fractures and any associated displacement. Many of the reduction techniques use significant force and may displace a fracture fragment. Postreduction radiographs are required to evaluate for displacement of fracture fragments. The displacement of fracture fragments may make reduction difficult or impossible, in some cases necessitating operative reduction under general anesthesia.

ROTATOR CUFF TEARS

Rotator cuff injury is most commonly seen in inferior dislocations and in patients greater than 60 years of age.[11,51,52] Overall, 38% of shoulder dislocations will have associated rotator cuff tears at the time of injury. This injury is not typically seen as a complication of the reduction technique.[3,11] Rotator cuff tears generally do not impede reduction, as they are often missed during the initial evaluation. One study showed that 86% of shoulder dislocations had rotator cuff tears diagnosed by arthroscopy an average of 7 months after the dislocation.[1,4] Rotator cuff injuries complicate restoration of normal shoulder function and may require surgical correction.

VASCULAR INJURY

Vascular injuries are seen in the arteries and veins of the shoulder region in association with shoulder dislocations.[1,8,11,50,55,56] **An evaluation for the signs of an axillary artery injury should be sought before and after any reduction attempt.** The most common vessel injured, during both dislocation and forceful reduction, is the axillary artery.[110–112] Such an injury is usually seen in older patients who have brittle vessels that have lost some elasticity. Inferior dislocations have the highest association with vascular injuries.[11] The second and third parts of the axillary artery are deep to the pectoralis major muscle and sustain the most damage.[8] These injuries include a decreased radial pulse, an axillary mass, an axillary bruit, or lateral chest wall bruising.[1] An angiogram is indicated if a vascular injury is suspected.

The subclavian vein is rarely injured. Direct injuries to venous vessels are atypical. The most common injury is a venous thrombosis.[113,114] Physical signs include extremity edema and occasionally paresthesias. However, these signs are typically seen days after the reduction. The diagnostic test of choice for venous evaluation is an ultrasound with Doppler study.[8]

NEUROLOGIC INJURY

Neurologic injury is seen in 5% to 12% of all shoulder dislocations.[8,11,50,56–59] **An evaluation for the signs of any neurologic injury should be sought before and after any reduction attempt.** Anterior shoulder dislocations with humeral fractures have a 45% incidence of nerve injury, with the axillary nerve being injured in up to 36% of cases.[8] Older patients tend to be more prone to nerve injury from the dislocation and the reduction techniques.[8] Of the techniques described, those that cause significant downward traction typically cause more reduction-induced neurologic injuries. Fortunately, most neurologic injuries are neuropraxias and will completely resolve within 2 to 5 months.[11,115–118] A small percentage of axillary nerve injuries that do not resolve may require nerve grafting. Brachial plexus injuries are much more common in posterior and inferior shoulder dislocations. Because the brachial plexus surrounds the axillary artery, injuries to the artery should raise the suspicion for a brachial plexus injury.

DISLOCATION RECURRENCE

The incidence of recurrence is variable, age-dependent, and gender-dependent.[54,60,119,120] Among patients under the age of 20 years, 90% will dislocate again, while only 14% of those over the age of 40 will redislocate.[1] Recurrences are much more common in men, with a ratio of 4:1 to 6:1 as compared to women.[11] Recurrent shoulder dislocations have other associated morbidities. A triad of lesions—including a detached labrum and anterior capsule, a Hill–Sachs deformity, and erosion of the anterior glenoid—develops in 85% of recurrent shoulder dislocations.[4] The methods for reduction are not different from those of a first-time shoulder dislocation. Patients who have had multiple shoulder dislocations are generally easier to reduce using nonanalgesic manipulation techniques. The orthopedic literature suggests that three shoulder dislocations in a single extremity indicate the need for surgical repair.[11]

HEMARTHROSIS

Blood collections in the shoulder joint are rare complications and are seen almost exclusively in traumatic shoulder dislocations associated with fractures. Typically, older patients (greater than 60 years of age) will return to the Emergency Department within 24 to 48 hours with a tense, swollen, painful shoulder. The shoulder joint should be aspirated. Refer to Chapter 77 for the complete details regarding shoulder arthrocentesis. Aspiration is usually sufficient to relieve pain and restore function.

INABILITY TO REDUCE

There are a few reasons for the inability to reduce a dislocated shoulder completely.[121,122] The most common is inadequate medication and sedation to overcome muscle spasm and pain. Occasionally, the humeral head may be "buttonholed" through the joint capsule.[11] A fracture fragment may be impinged or interposed between the humeral head and the glenoid cavity. Significant or complete disruption of ligamentous structures, as in an inferior or posterior dislocation, or soft tissue interposition will not allow the humeral head to remain in the glenoid cavity.[121] The inability to reduce a shoulder dislocation is an indication for reduction, open or closed, under general anesthesia in the Operating Room.

SUMMARY

Shoulder dislocations are common due to the inherent instability of the glenohumeral joint. There are three different types of dislocation, each of which has different mechanisms of injury and incidences of associated injuries. The vast majority are anterior shoulder dislocations. The diagnosis of a shoulder dislocation is generally uncomplicated given the history and patient presentation. The EP must be expeditious in reducing the dislocated joint once the patient is stabilized, other injuries have been ruled out, pain control has been addressed, and radiographs have been obtained to confirm the type of dislocation along with associated injuries.

Orthopedic Surgeons may need to be involved with the acute care of a dislocated shoulder. They should be involved in the initial reduction care of all posterior and inferior dislocations because of the rarity of these shoulder dislocations, the difficulty of reduction, the high incidence of associated injuries, and the need to operate to repair the associated injuries.

Multiple closed reduction techniques are available. They have similar success rates. The method chosen, as well as the decision to use analgesia, is individualized to the EP and the patient. Certain traditional techniques (e.g., Hippocratic and Kocher) have been demonstrated to have a higher incidence of complications and

should be avoided. Patients should be thoroughly evaluated before and after any closed reduction attempt for neurologic, vascular, soft tissue, or bony injury. The shoulder should be immobilized after it is reduced.

Patients should be instructed on proper aftercare and should be provided with adequate oral analgesia. This can be accomplished with nonsteroidal anti-inflammatory drugs supplemented with narcotics. All patients discharged from the Emergency Department should follow-up with an Orthopedic Surgeon within 24 hours to 5 days based on associated injuries and age.

82 Elbow Joint Dislocation Reduction

Angelique S. Kelly Campen

INTRODUCTION

The elbow is inherently subjected to dislocations because of its mechanical structure.[1] Elbow dislocations are one of the more common joint dislocations in the body, second only to dislocations of the shoulders and fingers.[2] Injuries to the elbow have a high potential for complications and residual disability.[3] **Timely reduction is imperative to relieve pain and reduce the possibility of neurovascular sequelae.**[3] Closed reduction of the elbow is unlikely to be successful if not performed promptly.[4]

The most common mechanism for a dislocation is a fall onto an extended and abducted arm. The patient usually presents with a swollen and painful arm that is held in flexion. Elbow dislocations require a significant amount of force. Up to 20% of elbow dislocations are associated with fractures.[2] Simple elbow dislocations have a better prognosis and are less likely to require surgical intervention than complex ones (fracture-dislocations). This chapter deals with the closed reduction of simple elbow dislocations.

One particular type of dislocation pertains primarily to the pediatric population. Subluxation of the radial head, often referred to as a "nursemaid's elbow," occurs commonly in preschool children. It is rarely seen after age 7 and represents 20% of upper extremity injuries in children.[5] It occurs after sudden traction on the radius with an extended elbow, as when an adult pulls a child up into a standing position by one arm. The annular ligament slips between the capitellum and the head of the radius, impeding supination of the arm. The patient will present with the arm held in slight flexion and pronation, usually in not much distress, and not using the affected arm. The simple reduction of this dislocation is also addressed.

ANATOMY AND PATHOPHYSIOLOGY

The elbow is a hinge joint comprising articulations between the humerus, the ulna, and the radius (**Figure 82-1**). The distal humerus consists of the extraarticular medial and lateral epicondyles, which are diverging columns separated by the intraarticular trochlea and capitellum. The trochlea articulates with the proximal ulna. The articular surfaces of the trochlea extend from the coronoid fossa anteriorly to the olecranon fossa posteriorly. The anterior and posterior fossae provide space for the coronoid and olecranon, respectively, at the extremes of motion. The capitellum is a spherical structure that articulates with the concave radial head.

Numerous neurovascular structures cross the elbow (**Figure 82-2**). The prominent medial epicondyle protects the ulnar nerve, which travels in its posterior sulcus. The radial nerve travels just anterior to the lateral epicondyle. The median nerve travels with the brachial artery through the antecubital fossa.

There are four ligamentous structures of importance in considering injuries to the elbow: the radial collateral ligament, the ulnar collateral ligament, the annular ligament, and the anterior capsule (**Figure 82-3**). The annular ligament and radial collateral ligament hold the radial head in position. The annular ligament allows the radial head to rotate under it during pronation and supination.

The relationship of the radius and ulna to the humerus is used to classify elbow dislocations into posterior, anterior, medial, lateral, and divergent (**Figure 82-4**). The majority of elbow dislocations are posterior in direction.[6] The other types of elbow dislocations are uncommon.[6] The radius and ulna are held tightly together by the annular ligament and the interosseous membrane (**Figure 82-3**). Posterior elbow dislocations result in the radius and ulna projecting posterior to the humerus (**Figures 82-4A & 82-5**). The radius and ulna may be slightly lateral or medial in posterior elbow dislocations in addition to being posteriorly displaced. This does not affect the management or prognosis. The presence of a fracture of the radial head or coronoid process may frequently render any attempt at reduction unstable and will usually require an open reduction.[7] Anterior elbow dislocations occur from traction

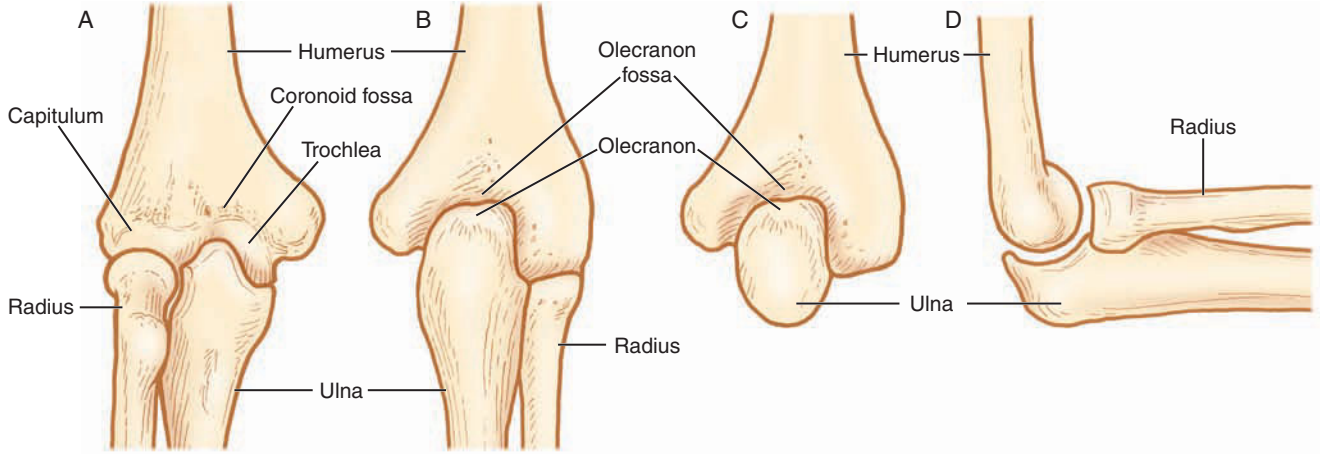

FIGURE 82-1. Bony anatomy of the elbow region. The right arm is demonstrated in these illustrations. **A.** Anterior view. **B.** Posterior view. **C.** Posterior view of the elbow in 90° of flexion. **D.** Lateral view of the elbow in 90° of flexion.

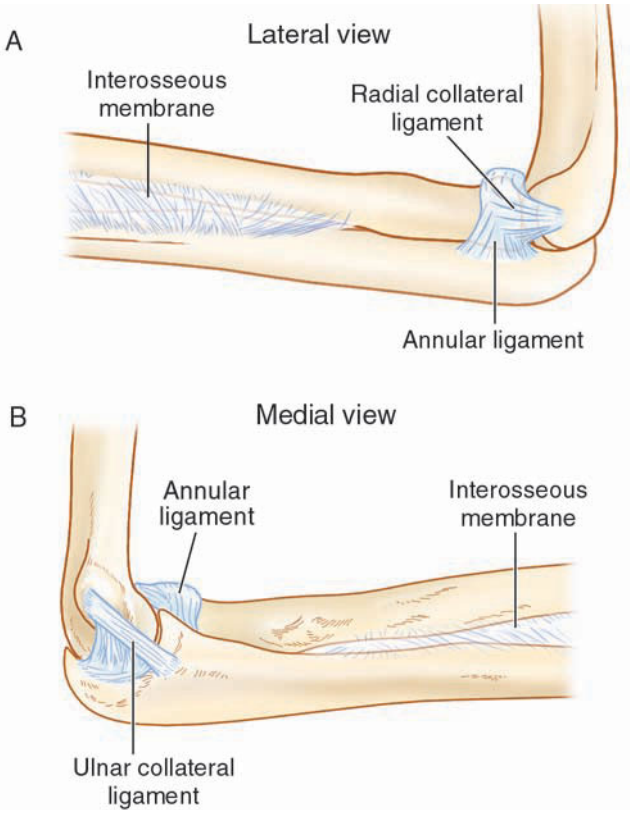

FIGURE 82-3. Major ligamentous structures of the elbow. **A.** Lateral view. **B.** Medial view.

of the forearm with the elbow extended or a blow to the posterior aspect of the flexed elbow. Anterior elbow dislocations result in the radius and ulna projecting anterior to the humerus (**Figure 82-4B**). Medial (**Figure 82-4C**) and lateral (**Figure 82-4D**) dislocations are rare injuries with poorer prognoses. Divergent dislocations (**Figure 82-4E**) are rare injuries that are distinct from the other types of elbow dislocations because there is dissociation of the radius and ulna. The annular ligament and interosseous membrane must be torn for a divergent dislocation to occur.

The patient usually presents with pain and swelling of the elbow. All elbow dislocations are characterized by loss of the normal relationship of the humeral epicondyles to the tip of the olecranon. The bony landmarks may be identified if the patient is seen immediately after the injury. However, the swelling and hemarthrosis that develop over time make it difficult to palpate these landmarks. Posterior dislocations are further apparent by a shortening of the forearm and the elbow being fixed in flexion.

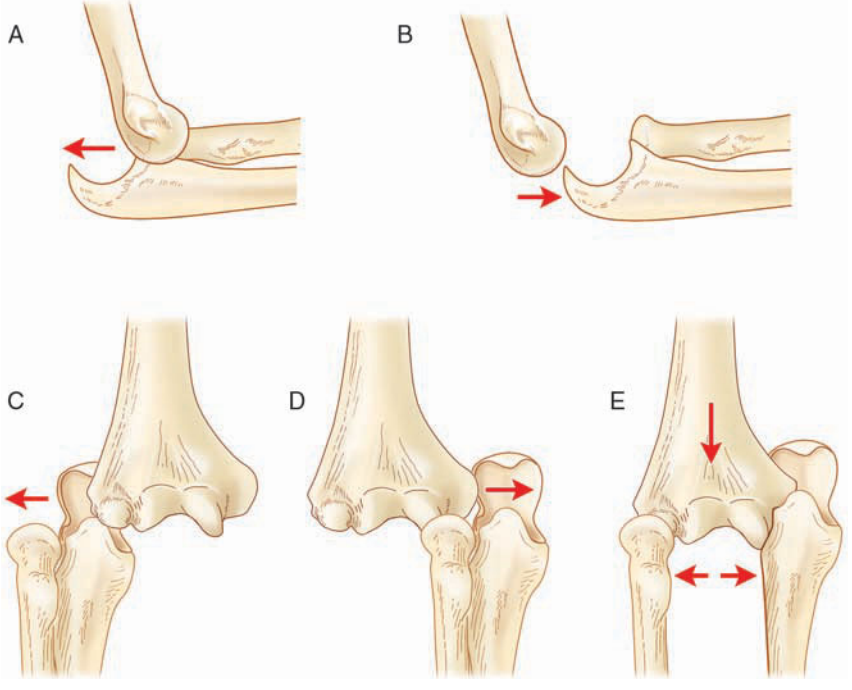

FIGURE 82-4. Classification of elbow dislocations. **A.** Posterior. **B.** Anterior. **C.** Lateral. **D.** Medial. **E.** Divergent.

FIGURE 82-5. Radiograph of a posterior elbow dislocation.

INDICATIONS

All elbow dislocations require reduction. **Early reduction of a dislocation, by open or closed means, is of paramount importance if good functional results are to be obtained.** Closed reduction is unlikely to be successful if attempted later than 14 days after the injury.[4] The more promptly the reduction is attempted, the more likely it is to be successful.

The vascular status of the extremity also dictates the need for emergent relocation. **Emergent and immediate relocation is necessary when there is neurologic or vascular compromise of the distal extremity.** Relocation can await titration of sedation and analgesia when the extremity is neurovascularly intact.

CONTRAINDICATIONS

There are no absolute contraindications to the closed reduction of an elbow dislocation. A relative contraindication to the procedure is when there is uncertainty, before radiographic evaluation, if the injury is a dislocation or a fracture. Closed reduction is not indicated if there is an interposed osteochondral fragment preventing concentric reduction or when there is a concomitant displaced fracture of the radial head or neck. Elbows that have been dislocated for a prolonged period of time may have closed reduction attempted but will most likely require an open procedure.

EQUIPMENT

- Towel or sheet to aid in applying traction
- Splinting materials
- Weight (sandbag, bucket with water, or any other weight)
- Procedural sedation supplies (see Chapter 129)

PATIENT PREPARATION

Explain the risks, benefits, and potential complications to the patient and/or their representative. The postprocedural care should also be discussed. Obtain an informed consent for the reduction procedure.

Carefully assess and document the preprocedural neurologic (median, radial, and ulnar nerves) and vascular (brachial, radial, and ulnar arteries) status of the extremity. Splint and/or sling the affected extremity until radiographs are obtained and a closed reduction can be performed. Obtain anteroposterior and lateral radiographs to confirm the diagnosis of an elbow dislocation. Oblique views may be helpful to further define the relationship between the distal humerus, radius, and ulna. **The only case for which a preprocedure radiograph is not indicated is when neurologic or vascular compromise exists in the distal extremity and an expeditious reduction is required.**

Closed reduction of elbow dislocations requires adequate analgesia and muscle relaxation. In most cases, procedural sedation is useful. Regional anesthesia (axillary nerve or Bier blocks) is useful if procedural sedation is contraindicated. Refer to Chapters 126 and 127 for details regarding regional anesthesia of the upper extremity. General anesthesia with fluoroscopy is rarely necessary unless the dislocation is associated with an undisplaced fracture of the radial head or neck.

TECHNIQUES

POSTERIOR ELBOW DISLOCATION REDUCTION TECHNIQUES

The goal of closed reduction is to distract the radius and ulna, allowing them to relocate. **The preferred technique that provides the least complications is a modification of the Stimson technique used for shoulder dislocations.**[8] Place the patient prone with the affected arm hanging off the gurney (**Figure 82-6**). Place padding anteriorly in front of the arm and shoulder so that the arm does not drag along the side of the gurney. **Care must be taken that the patient does not fall from the gurney.** Tie a sheet circumferentially around the patient's hips and the gurney. **Ensure that the patient does not have any respiratory difficulty while in the prone position.** Suspend a weight from the patient's wrist to apply traction to the arm (**Figure 82-6**). The weight should be approximately 5 pounds and may go up to 15 pounds, depending on the patient's musculature and weight. Allow the arm to dangle over the edge of

FIGURE 82-6. The modified Stimson technique for reducing posterior elbow dislocations.

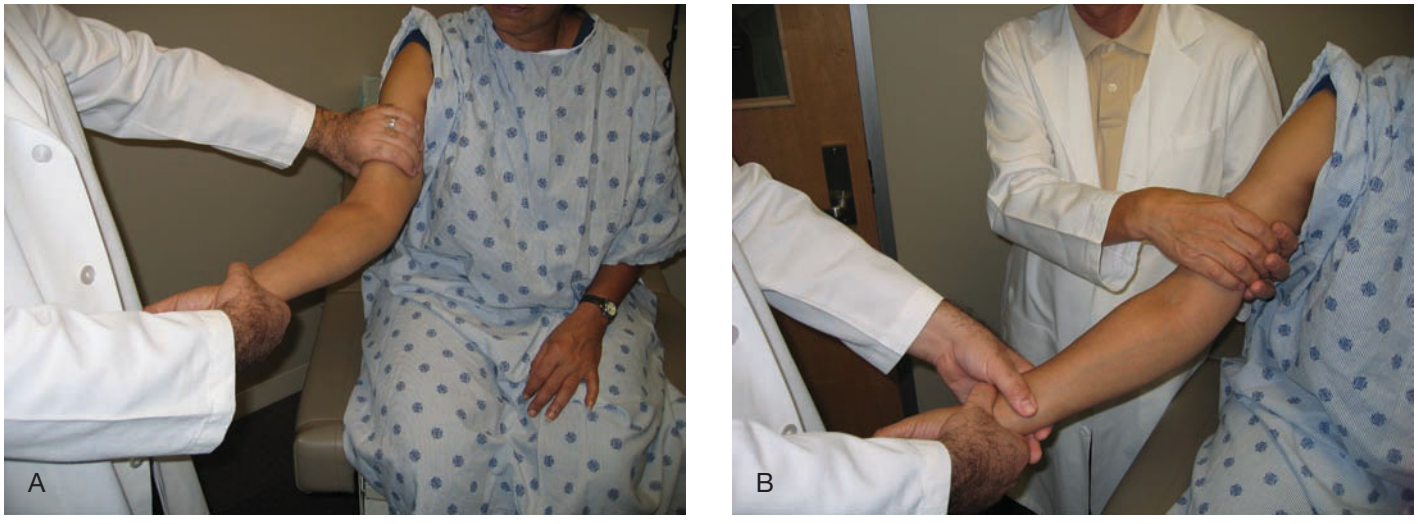

FIGURE 82-7. The traction-countertraction technique to reduce a posterior elbow dislocation. **A.** The one-person technique. The physician stabilizes the humerus with one hand and distracts the forearm with the other hand. **B.** The two-person technique. The assistant stabilizes the humerus and provides countertraction while the physician applies traction to the forearm.

the gurney for 10 minutes. If the elbow dislocation will not reduce, attempt the traction-countertraction technique.

The traction-countertraction technique can be performed but is not the optimal approach. Place the patient's arm in slight flexion. Grasp the patient's midhumerus with the nondominant hand and the patient's wrist with the dominant hand (**Figure 82-7A**). Alternatively, an assistant can grasp the humerus while the physician uses both hands to grasp the patient's wrist (**Figure 82-7B**). Stabilize the patient's humerus. Apply steady and constant traction to the patient's wrist to distract the coronoid process and allow it to slip past the humerus and back into anatomic position. The application of downward pressure on the proximal forearm can help to disengage the coronoid process from the olecranon fossa and ease the reduction.

MEDIAL AND LATERAL ELBOW DISLOCATION REDUCTION TECHNIQUE

Medial and lateral dislocations of the elbow are extraordinarily uncommon. They are usually associated with a posterior elbow dislocation. These dislocations can be reduced in a similar manner using the traction-countertraction technique for that of the posterior elbow dislocation. For lateral dislocations, apply traction to the patients wrist with one hand while using your other hand to guide the proximal ulna downward, then medially, and finally backward. For medial dislocations, apply traction to the patients wrist with one hand while using your other hand to guide the proximal ulna downward, then laterally.

Emergency Physicians should not reduce a medial or lateral elbow dislocation. They are uncommon, may be associated with neurovascular complications, have severe ligamentous tears, and should be reduced by an Orthopedic Surgeon. The only exception to this is if there is neurologic and/or vascular compromise of the distal extremity and no Orthopedic Surgeon is immediately available.

ANTERIOR ELBOW DISLOCATION REDUCTION TECHNIQUE

Anterior elbow dislocations are uncommon. They are often associated with intimal injuries to the brachial artery, from being stretched during the injury.

Anterior elbow dislocations should be reduced by an Orthopedic Surgeon for the same reasons as a medial or lateral elbow dislocation. The only exception to this is if there is neurologic and/or vascular compromise of the distal extremity and no Orthopedic Surgeon is immediately available.

DIVERGENT ELBOW DISLOCATION REDUCTION TECHNIQUE

Fortunately, divergent dislocations are exceedingly rare. They are commonly associated with severe articular damage, interosseous ligamentous tears, neurologic injuries, and vascular injuries. The reduction technique is complex; the elbow is reduced as a two-part dislocation and often requires surgical fixation to be stabilized. Simple traction can be applied to relieve stress on the neurovascular structures but will not reduce the dislocation due to the instability of the joint.

Divergent elbow dislocations should be reduced by an Orthopedic Surgeon in the Operating Room. The only exception to this is if there is neurologic and/or vascular compromise of the distal extremity and no Orthopedic Surgeon is immediately available.

RADIAL HEAD SUBLUXATION REDUCTION

This condition is also referred to as a "nursemaid's elbow." Reduction of a radial head subluxation is a maneuver involving supination and flexion of the affected forearm. The forearm is quickly supinated and the elbow flexed completely in one smooth motion. A pop or click is sometimes heard or felt by the Emergency Physician as the subluxation is reduced. Most patients are asymptomatic within 5 to 10 minutes and 90% within 30 minutes.[9] The Emergency Physician should leave the room for 5 to 10 minutes after the procedure. Ask the parents to distract the child to see if they begins to move the arm. A fearful child will often not use a successfully reduced arm in fear of pain. Place an object (e.g., car keys, popsicle, toy, or other object the child may want) within grasp of the reduced extremity to encourage the child to use the extremity. Refer to Chapter 83 for the complete details regarding the reduction of a radial head subluxation.

ASSESSMENT

After a reduction, gently move the joint through the entire range of motion to ensure smooth movement and proper joint reduction. This also tests for joint stability and whether or not the joint will easily re-dislocate. The joint may need to be repaired operatively if it dislocates during this examination. **The neurovascular status of the extremity must again be evaluated and documented.** The integrity of the median, ulnar, and radial nerves as well as the brachial artery and its distal branches must be evaluated and documented. All reductions except radial head subluxations should have postprocedural radiographs to ensure proper bony alignment and the lack of a fracture. If full and smooth passive range of motion is not possible, which is especially common in children, postreduction radiographs should be examined for entrapment of the medial epicondyle.

AFTERCARE

Place the reduced extremity in a posterior long arm splint, from the midhumerus to the base of the fingers, with the elbow in 90° of flexion. Do not apply a circumferential cast due to the subsequent swelling and edema. Suspend the arm with a sling to aid in elevating the extremity. The patient should be carefully observed for 12 to 36 hours for vascular impairment. Instruct the patient to return to the Emergency Department if they develop weakness, numbness, paresthesias, cold fingers, or cyanotic fingers. The patient should be admitted for observation if there is any question of neurovascular compromise. Gentle range-of-motion exercises can be started as early as 3 to 5 days postreduction if the elbow is stable.[10] Schedule follow-up with an Orthopedic Surgeon 3 to 4 days postreduction to test for joint stability. Prescribe nonsteroidal anti-inflammatory drugs supplemented with narcotic analgesics to control pain.

No immobilization is necessary for a radial head subluxation that is reduced. Immobilization in a sling with follow-up by an Orthopedic Surgeon is recommended only for recurrent radial head subluxations.

COMPLICATIONS

Several serious complications exist with elbow dislocations. The most serious and first to happen are ischemic complications. Damage to and obstruction of the brachial artery can occur with any of the elbow dislocations. Brachial artery injury occurs in 5% to 13% of patients with an elbow dislocation.[11] It is a serious complication that can occur even without an associated fracture.[11] **The presence of a distal pulse is not proof that there is no vascular injury.** Collateral circulation around the elbow can result in a distal pulse despite a complete brachial artery laceration or occlusion.[12] Signs of an arterial injury include: cyanosis, an expanding hematoma, pallor, pulselessness, and severe pain. Any suspicion of a brachial artery injury necessitates prompt angiography.[12,13]

The second serious complication resulting from an elbow dislocation is nerve injury from traction or entrapment. Loss of median nerve function postreduction should prompt an immediate consultation with an Orthopedic Surgeon. The ulnar nerve is most commonly injured.[14] It is seen in 8% to 20% of patients with posterior elbow dislocations.[14]

Fractures commonly occur with elbow dislocations. **Radiographs should always be obtained before and after any attempt at reduction. The only exception to obtaining prereduction radiographs is if the extremity has signs of distal neurovascular compromise and obtaining radiographs will delay the reduction.** A fractured coronoid process can sometimes become entrapped in the joint, requiring an open reduction. Fractures of the coronoid process are commonly associated injuries and will usually come into near-normal opposition once reduction occurs (**Figure 82-8**). Large fragments that are displaced may require operative fixation.

FIGURE 82-8. Postreduction radiograph demonstrating a fracture of the coronoid process.

Late complications of elbow dislocations include posttraumatic stiffness, posterolateral joint instability, ectopic ossification, and occult distal radioulnar joint disruption.[15]

SUMMARY

Elbow dislocations are the second most common large joint dislocations that occur in adults. The majority of dislocations are posterior elbow dislocations, although the radius and ulna can dislocate into just about any other position. Relocation involves distracting the forearm while stabilizing the humerus and putting pressure counter to the direction of the dislocation. It is not uncommon to have associated fractures, so radiographic studies are imperative. The neurovascular status of the extremity must be carefully monitored and documented both before and after any attempts at reduction. Splint the elbow in flexion postreduction. Follow-up with an Orthopedic Surgeon and early range-of-motion exercises are recommended to ensure proper joint function.

83 Radial Head Subluxation ("Nursemaid's Elbow") Reduction

Mark P. Kling and Eric F. Reichman

INTRODUCTION

Subluxation of the radial head is one of the most common pediatric orthopedic injuries. This can occur in children whose age ranges from less than 6 months to the preteens. The majority of radial head subluxations occur between 1 and 3 years of age.[1] It is a rare injury before 1 year of age and after 8 years of age.

ANATOMY AND PATHOPHYSIOLOGY

Historically, the classic mechanism involves axial or longitudinal traction on an extended elbow with the forearm pronated. This often occurs while someone is holding onto the child by the hand

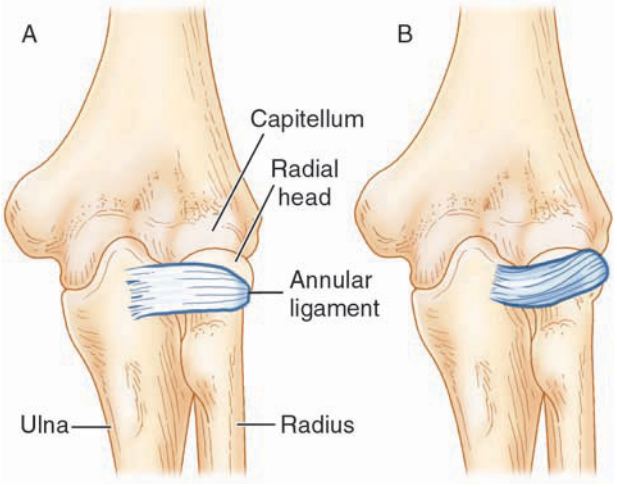

FIGURE 83-1. Anatomy of the elbow region. **A.** Normal anatomy. **B.** A radial head subluxation. Note the entrapped annular ligament.

or wrist. While being held, the child is then pulled or the child falls and is suspended by the arm. The subluxation is seen more often in the left arm than the right. This is due to more people being right-handed and holding the child's left hand or wrist while walking. It is not uncommon, however, for the child to present with a history of a fall or rolling over in bed.[1]

This orthopedic injury involves the region of the elbow (**Figure 83-1**). The annular ligament is a thick band that wraps around the upper radial neck and radial head (**Figure 83-1A**). It guides the radial head as the forearm moves through pronation and supination. The injury causes the radial head to become partially dislocated from its articulation with the ulna and the capitellum of the humerus while the forearm is in a pronated state. The annular ligament then slips proximally and its lateral end becomes entrapped between the radial head and the capitellum (**Figure 83-1B**). The forearm becomes locked in pronation due to the entrapped annular ligament. This condition is painless as long as the forearm is held in pronation. Supination of the forearm causes pain, so the child holds the extremity in pronation. The act of supination would also spontaneously return the annular ligament to its anatomic position and reduce the subluxation.

Children will present in no apparent distress.[2] They are usually resting comfortably and have some reservation in using the affected extremity. The arm will be held with slight flexion of the elbow and pronation of the forearm (**Figure 83-2A**). The child may point to an area of pain, but this is not often the case. A child may be much more comfortable with the parent examining and questioning areas of tenderness as opposed to the unknown and sometimes intimidating Emergency Physician.

Radiographs are not required unless other trauma or diagnoses are suspected. If radiographs are obtained, the child often returns from the radiology suite using the affected extremity. Radial head subluxations often reduce spontaneously during positioning for radiographs (**Figure 83-2B**).

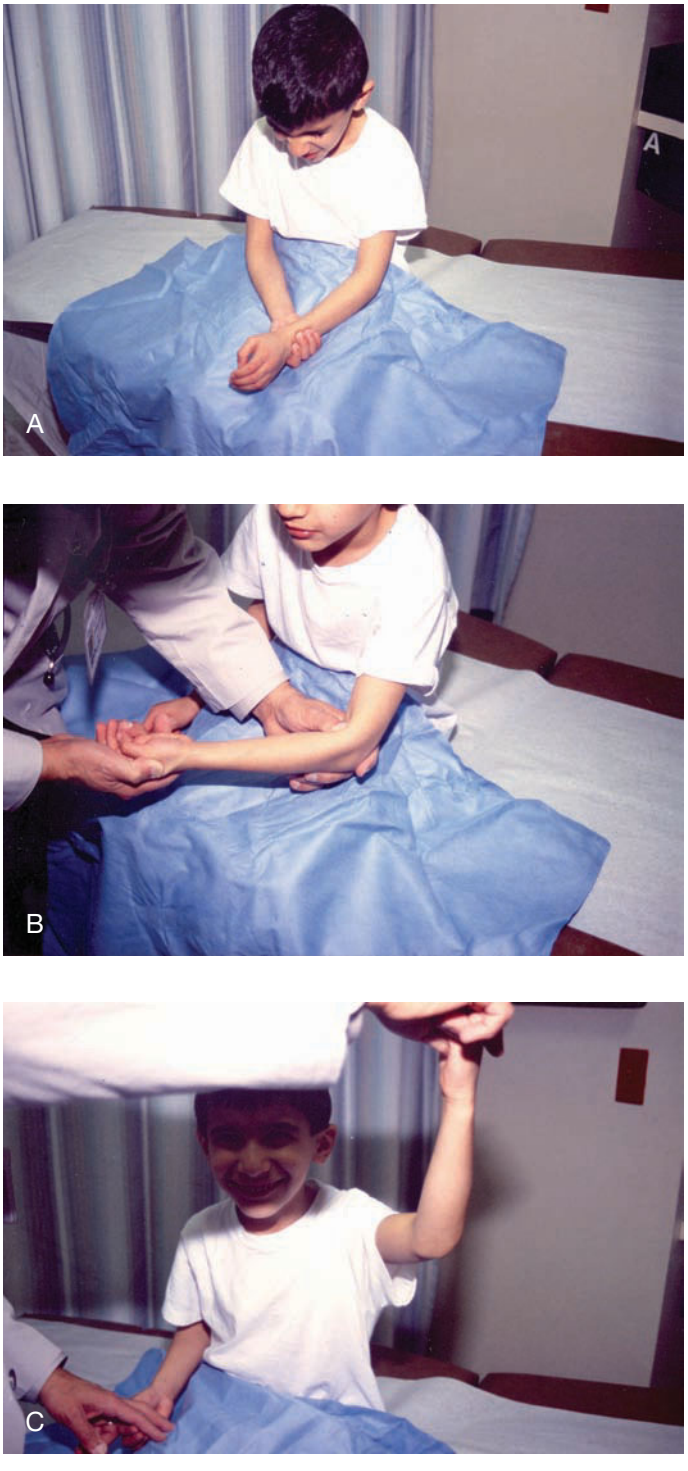

FIGURE 83-2. A child with a radial head subluxation. **A.** The subluxed left forearm is held flexed, pronated, and adducted. **B.** Reduction technique. **C.** Postreduction. The forearm is freely mobile with normal extension and abduction.

INDICATIONS

Any child presenting with the inability to utilize the partially flexed elbow, the forearm pronated and adducted, and a mechanism for a radial head subluxation should be reduced. Many Emergency Physicians may be hesitant to repeat the procedure multiple times if a child was not utilizing the arm normally within 15 to 30 minutes after a clinically successful reduction. However, if the radiographs appear normal and a repeat history and physical examination are consistent with the original diagnosis, a decision to repeat the reduction should be considered.

CONTRAINDICATIONS

The presence of edema, ecchymoses, tenderness other than over the radial head, suspicion of a fracture, or a mechanism of injury not consistent with a radial head subluxation should first be

evaluated radiographically.[2,8] The presence of any distal neurologic or vascular compromise excludes the diagnosis of a radial head subluxation.

EQUIPMENT

No equipment is required for the reduction of a radial head subluxation.

PATIENT PREPARATION

Explain the risks, benefits, potential complications, and aftercare of the procedure to the child and their representative. Obtain a signed consent to perform the reduction. Place the patient sitting in the parent's lap or supine on an examination table or gurney. No premedication is required.

TECHNIQUES

SUPINATION AND FLEXION

Place one hand on the child's elbow with the thumb over the radial head (**Figure 83-3A**). This will aid in palpation of the traditional "click" of reduction. Gently grasp the child's wrist with the other hand (**Figure 83-3A**). Perform the following maneuvers in one smooth motion to reduce the subluxation. Apply distal traction while supinating the forearm (**Figure 83-3B**), followed by flexion of the elbow (**Figure 83-3C**). A click may be felt as the radial head is reduced.[1,4] If not, flex the forearm until the hand is upright. Other methods of reduction are often compared to this method.[3,5]

If you feel the traditional click or feel satisfied with the attempted reduction, allow 5 to 15 minutes to pass and return for a repeat examination. Children may cry at the end of the procedure but will generally only do so for a moment. As the child feels more comfortable, they will proceed to use the arm (**Figure 83-2C**). This freedom of use can be accelerated by the caregiver or physician stimulating the patient to use the arm with an incentive (e.g., by offering candy, a pen, or a popsicle for the child to grab).

HYPERPRONATION

Position the patient as described above. There are two variations on this technique. The first holds the child's elbow at 90° of flexion and hyperpronates the forearm without any additional flexion at the elbow (**Figure 83-4**).[5] The second holds the child's elbow at 90° of flexion and hyperpronates the forearm while simultaneously fully flexing the elbow (**Figure 83-5**).[9] Both of these techniques can successfully reduce a radial head subluxation. Some feel that hyperpronation causes less pain to the child than the supination technique.[5,9–11] This is because the arm is already being held in pronation and the additional pronation (hyperpronation) requires less force and motion than the supination technique.

ASSESSMENT

The child should have uninhibited use of the forearm within 30 minutes. If not, reconsider the diagnosis. Alternative diagnoses include clavicular fractures, distal humeral fractures, osteomyelitis, radial head fractures, septic arthritis, and stress fractures. Reevaluate the elbow joint for signs of trauma. Obtain plain radiographs if not done previously. Full recovery may take 24 to 48 hours if the reduction is delayed for more than 8 hours from the time of injury.

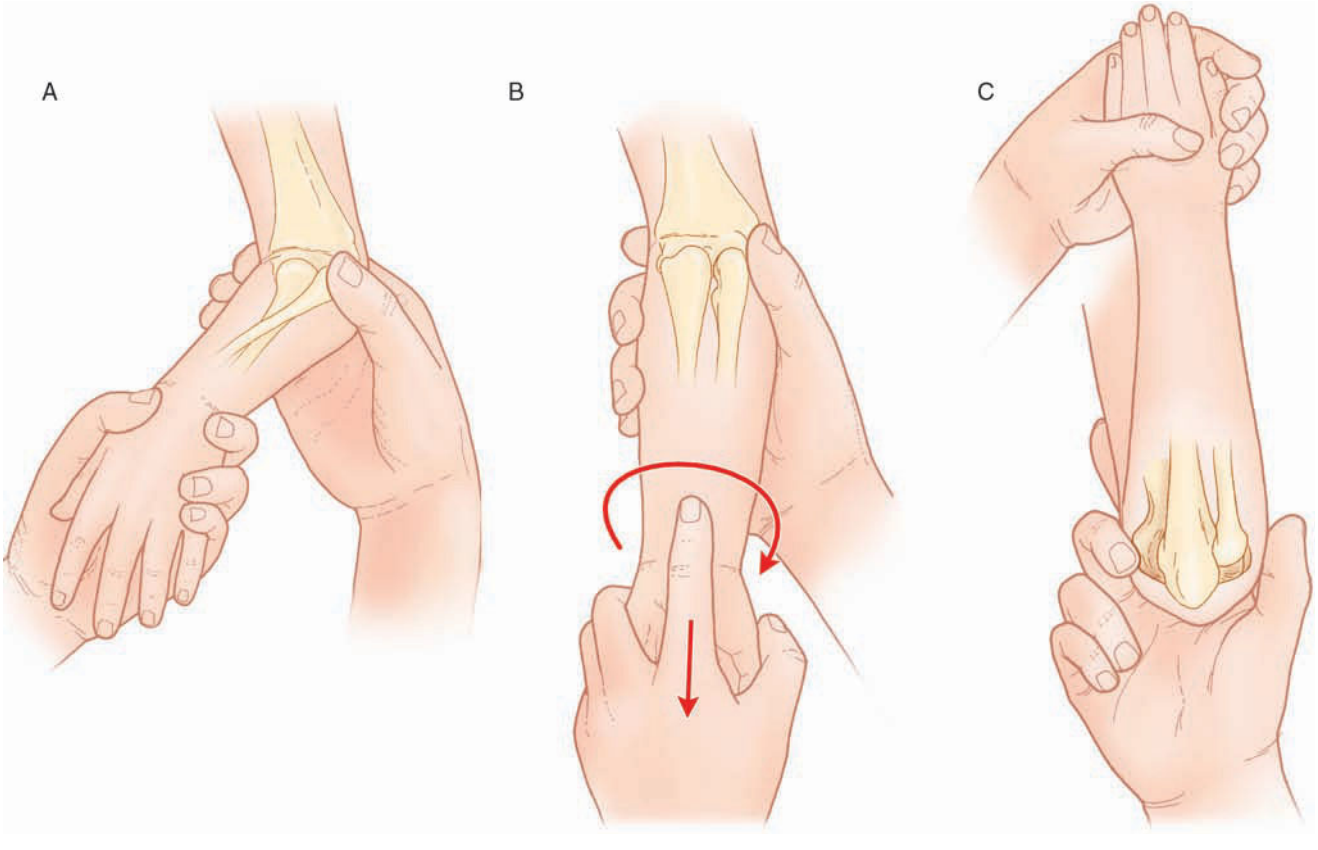

FIGURE 83-3. Reduction of a radial head subluxation using supination and flexion. **A.** Positioning of the physician's hands. **B.** Distal traction is applied (*straight arrow*) while supinating the forearm (*curved arrow*). **C.** The forearm is maximally flexed.

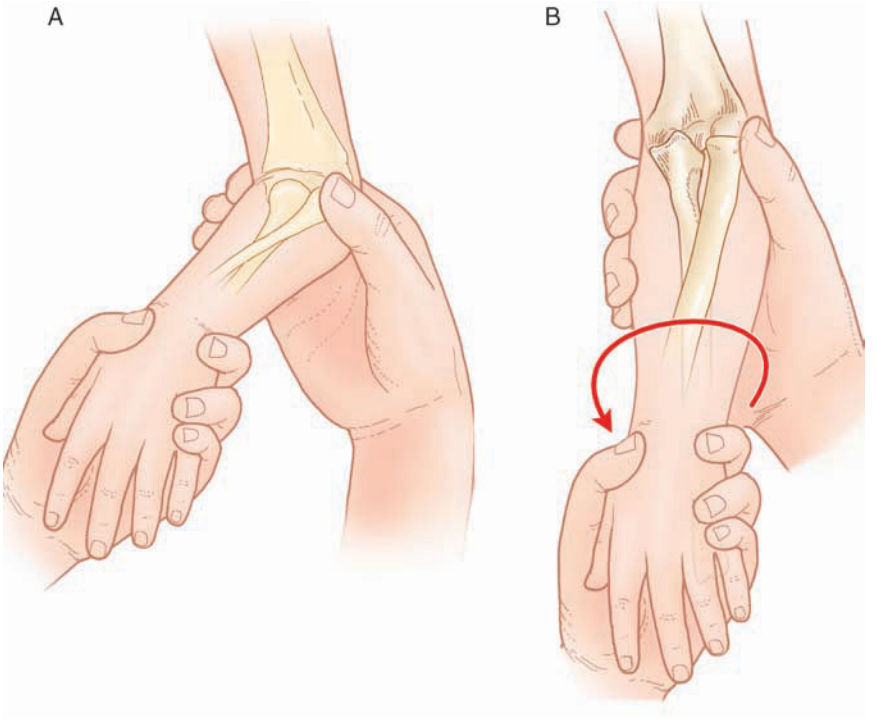

FIGURE 83-4. Reduction of a radial head subluxation using hyperpronation. **A.** Positioning of the physician's hands. **B.** Hyperpronation of the forearm.

AFTERCARE

Radiographs, immobilization, splinting, analgesics, and orthopedic follow-up are not necessary if the subluxation is reduced and the child is using their arm. Educate the caregiver regarding the mechanism of injury and prevention of future subluxations.[6,7]

Phone consultation with an Orthopedic Surgeon is recommended if the reduction is unsuccessful. It is not unusual to have a spontaneous reduction on repeat examination and follow-up. Immobilize the arm until the child is evaluated by an Orthopedic Surgeon. Immobilization will aid in pain relief. Consider the use of nonsteroidal anti-inflammatory drugs.

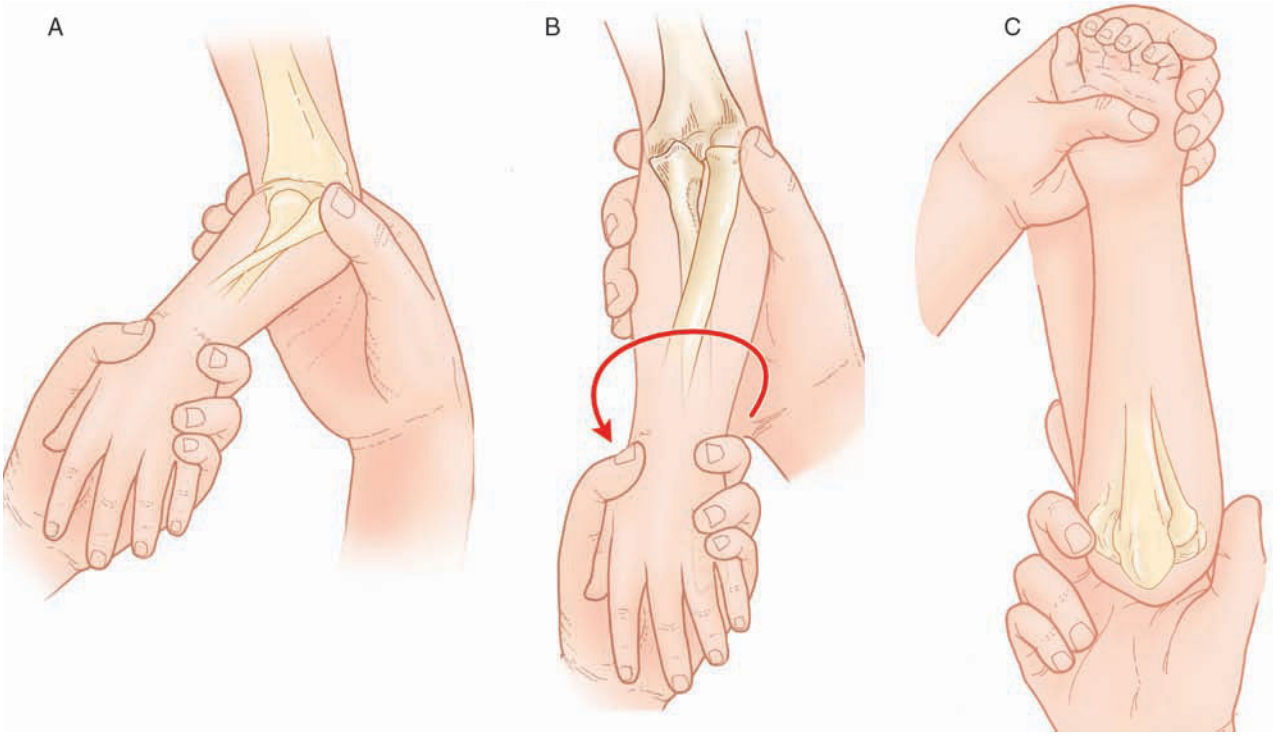

FIGURE 83-5. Reduction of a radial head subluxation using hyperpronation and flexion. **A.** Positioning of the physician's hands. **B.** Hyperpronation of the forearm. **C.** Flexion of the hyperpronated forearm.

COMPLICATIONS

There are no complications associated with the reduction of a radial head subluxation.

SUMMARY

A radial head subluxation is one of the more common orthopedic injuries of childhood. Children present with the inability to utilize the affected upper extremity. They hold the forearm flexed, pronated, and adducted. The reduction technique is quick and simple. It is important to educate the caregivers regarding the mechanism of injury and prevention of future subluxations.

84 Metacarpophalangeal Joint Dislocation Reduction

Michael Bublewicz and Antonio E. Muñiz

INTRODUCTION

Hand injuries are among the most common injuries encountered in the Emergency Department (ED). They are responsible for 5% to 10% of ED visits, with approximately 6% of these patients having significant injuries.[1,2] Many hand injuries occur from sports-related events or in the workplace. Data suggest that hand injuries account for 19% of lost-time injuries and 9% of workers' compensation cases.[3] Approximately 3 to 4 million working days are lost each year as a result of hand injuries.[4] It is estimated that 10% of patients with hand injuries require referral to a hand specialist.[5] Proper motion and function of the hand are intimately related to normal anatomic alignment. The Emergency Physician (EP) must be skilled in the diagnosis and management of injuries about the hand. An improperly managed hand injury can result in significant disability that the patient is reminded of on a daily basis and may include chronic pain, decrease range of motion, stiffness, joint swelling, deformity, or early degenerative arthritis.

Dislocations of the metacarpophalangeal (MCP) joint are relatively uncommon due to the protected location of this joint in the hand.[6] Injuries to the MCP joint of the thumb are more common than the other digits. Most of these injuries are to the collateral ligaments rather than a true dorsal or volar dislocation.[7] The spectrum of injury to the ligaments extends from a minor stretch or sprain to a complete disruption.

The deformity caused by a joint dislocation is classified by the position of the distal skeletal unit in relation to its proximal counterpart. A dorsal MCP joint dislocation describes a dislocation in which the proximal phalanx is displaced in a dorsal direction relative to the metacarpal bone (**Figure 84-1A**). A volar MCP joint dislocation describes a dislocation in which the proximal phalanx is displaced in a volar direction relative to the metacarpal bone (**Figure 84-1B**).

ANATOMY AND PATHOPHYSIOLOGY

FUNCTIONAL ANATOMY

The metacarpals are tubular bones structurally divided into a head, neck, shaft, and base. When viewed in the sagittal plane, the metacarpal head has an increasing diameter beginning dorsally and extending along the articular surface to the volar side. When viewed in the coronal plane, the metacarpal head is pear-shaped or dumbbell-shaped, with the volar surface extending out of each side. The metacarpal head is broader in volar orientation, which results in increasing bony stability as the joint is flexed. The volar plate, collateral ligaments, dorsal capsule, deep transverse intermetacarpal ligament, extensor tendon, and intrinsic tendons provide additional support and stability to the MCP joint.

The MCP joints are resistant to ligamentous injury and dislocation because of their inherent ligamentous structure, their surrounding supporting structures, and their protected position at the base of the fingers. The volar plate is a fibrocartilaginous structure that is attached firmly to the base of the proximal phalanx. It originates just proximal to the metacarpal head where it is thin and transparent. This allows for hyperextension of the MCP joint yet makes it vulnerable to injury during dorsal dislocations.

Side-to-side stability of the MCP joint is provided mainly by the collateral and accessory collateral ligaments, and to some extent by the lumbrical and the interossei muscles and tendons.[8] The collateral ligaments originate from the mediolateral recesses in the metacarpal head and travel to insert onto the base of the proximal phalanx. The eccentric configuration of the metacarpal head and the relatively fixed length of the collateral ligaments cause it to tighten when the joint is in flexion (**Figure 84-2**). This accounts for the limited abduction and adduction of the MCP joint in flexion as compared to the laxity in extension. The collateral ligaments of the MCP joint are most vulnerable to injury from forces directed ulnarly and dorsally. The accessory collateral ligament spans from the true collateral ligament to the volar plate, providing additional joint stability in extension. The central extensor tendon and sagittal band augment the thin dorsal capsule. The tendons of the palmar and dorsal interossei add a small degree of dynamic stability.

The interphalangeal (IP) joints are hinges and motion only occurs as flexion and extension while the MCP joints are condyloid joints. The range of motion about the MCP joint includes 120° of flexion and 30° of hyperextension. It has up to 30° of additional mediolateral laxity and a small degree of rotational laxity to facilitate an efficient grasp.[9] **The clinical importance of these**

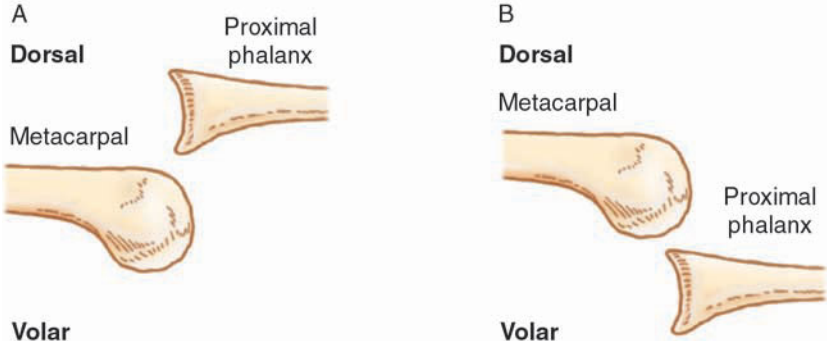

FIGURE 84-1. Dislocations are classified by the position of the distal skeletal unit in relation to its proximal counterpart. **A.** Dorsal MCP joint dislocation. **B.** Volar MCP joint dislocation.

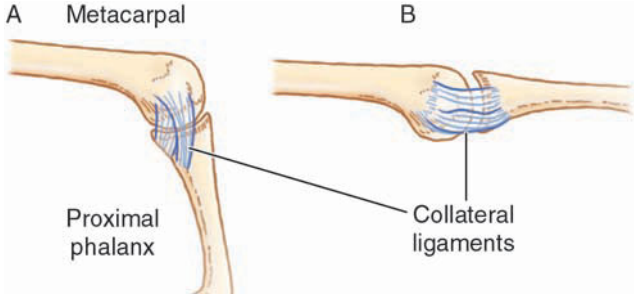

FIGURE 84-2. The shape of the metacarpal head is eccentric, making the collateral ligaments tighter in flexion (**A**) than in extension (**B**).

differences is that to minimize the development of contractures after joint injuries. The preferred position of immobilization of the IP joints is in extension, whereas the MCP joints are immobilized in flexion.

The opposable thumb is an essential structure for countless activities. Despite its strong ligamentous and capsular support, the exposed positioning of the thumb makes it a frequent site of dislocations and subluxations. The MCP joint of the thumb is similar to those of the fingers but has a stronger volar plate and collateral ligaments with less side-to-side mobility.[2] The MCP joint of the thumb is also a condyloid joint with a quadrilateral rather than a spherical metacarpal head that allows mainly flexion and extension. However, it also permits some degree of abduction, adduction, and rotation. There is a large variability among individuals in its range of flexion and extension.

The metacarpal head is bicondylar, with the radial condyle being slightly larger. This structural difference provides the thumb proximal phalanx with a modest degree of pronation during flexion. Its range of motion consists of 15° to 20° of extension and 80° of flexion. However, the range of motion of the MCP joint of the thumb is restricted, especially in lateral motion with only 10° of adduction and abduction.

PATTERNS OF INJURY

MCP joint dislocations are considerably less common than dislocations of the IP joints. Most MCP joint dislocations are dorsal. These were first described by Kaplan in 1957.[10] A volar MCP joint dislocation is a rare finding.[11] Dislocation of any of the MCP joints is possible from hyperextension injuries. The dorsal dislocation of the thumb MCP joint is the most common type of MCP joint dislocation.

Hyperextension of the MCP joint results in the rupture of the volar plate. Injuries are classified as simple (reducible with closed technique) or complex (irreducible with closed technique). Unless there is associated twisting of the finger, the collateral ligaments remain intact. Clinical and radiographic features can be used to differentiate simple from complex dislocations. In cases of simple dislocations, the joint usually hyperextends to approximately 90° and the volar plate is not interposed between the dislocated bones.[12] The deformity is obvious with the finger in a claw position of extreme dorsiflexion at the MCP joint. In complex dislocations, the metacarpal and proximal phalanx usually lie more parallel to each other, with the metacarpal head causing a dimple on the volar skin and palpable underneath the skin. Clinical features that suggest a complex MCP dislocation include a proximal phalanx that is less acutely angulated than with a simple dislocation.[2] The volar plate, sesamoids, flexor tendon, adductor tendons, extensor expansion, collateral ligaments, or capsule may become entrapped and prevent reduction.[2] A widened joint space is seen on radiographs when the volar plate is interposed in the joint. Complex MCP dislocations occur more frequently in the index finger. They can be difficult to manage because reduction is often blocked by the interposed soft tissue.[13]

The MCP joint of the thumb is very mobile. Dislocations of the thumb MCP joint are more common than the MCP joints of the fingers. The MCP joint can be dorsally dislocated by a hyperextension injury or shearing forces that ruptures the volar plate, joint capsule, and at least part of the collateral ligament. The proximal phalanx will come to rest in a position dorsal to the first metacarpal. Displacement of the proximal phalanx varies from a subluxation to the complete dislocation. For the latter to occur, the volar plate and the collateral ligaments must completely tear. Volar dislocations are rare and result from extensive tearing of the dorsal capsule and the extensor pollicis brevis tendon, leaving the joint very unstable.[14]

A simple MCP joint dislocation can be converted into a complex one during prolonged or repeated reduction attempts, especially those in which axial traction is the primary component.[2] This should not deter the EP from attempting a closed reduction for any MCP dislocation.

RADIOGRAPHIC EVALUATION

Radiographic evaluation of all hand injuries is relatively straightforward. It should include at least three views (i.e., anteroposterior, oblique, and lateral) of the injured area. The most important radiographic error in evaluating joint injuries of the hand is failing to get a true lateral view of the injured joint. This may result in missing a fracture or a loose body in the joint.[2] Radiographic examination will show an obvious dislocation in the lateral view. Anteroposterior views may reveal widening of the joint space in complex dislocations. In addition, the sesamoid bones may be seen in the joint space, a pathognomonic sign for a complex MCP joint dislocation.

INDICATIONS

All MCP joint dislocations should have an initial attempt at reduction in the ED unless they are unstable, chronic, open, or associated with a fracture. This is true even if it is suspected to be a complex MCP joint dislocation.[15] Reduction of the dislocation will provide significant pain relief. If a Hand Surgeon is not immediately available, an open MCP joint dislocation should be reduced after copious irrigation with sterile saline to remove any dirt and debris.

CONTRAINDICATIONS

Certain MCP joint dislocations require an immediate evaluation by a Hand Surgeon for open reduction and repair of any ligamentous or associated injuries. Closed reduction of an MCP joint dislocation should not be performed in the ED for unstable, chronic, and open injuries or if it is associated with a fracture. Instability in a joint through active range of motion indicates complete and multiple ligament disruption requiring an open surgical repair.[2,17] Chronic injuries greater than 3 weeks old generally require surgical repair.[16]

If the closed reduction attempt is unsuccessful, repeated attempts at reduction are contraindicated as a simple dislocation can be converted to a complex dislocation requiring an open surgical reduction. The ligaments, tendons, or sesamoid bones may become entrapped by bony and soft tissue structures in and around the MCP joint and prevent the reduction. Complex dislocations usually require open surgical reduction.[15,18] Open MCP joint dislocations, whether reduced in the ED or not, will require operative management after initiation of antibiotics in the ED.

There are few contraindications to the use of local anesthesia solutions.[19] Relative contraindications include injection through infected skin, history of coagulopathy from heparin or warfarin therapy, factor deficiencies, liver dysfunction or bleeding disorder, or an allergy to the anesthetic medication. Another relative contraindication includes preexisting neurovascular damage prior to the procedure. Uncooperative patients can make the injection procedure technically more difficult and dangerous to perform. Procedural sedation should be considered for these patients and children.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- 18 gauge needle to draw up the local anesthetic solution
- 27 or 30 gauge needle, 2 in. long
- 10 mL syringe
- Alcohol swab
- Sterile gloves
- Sterile drapes
- Local anesthetic solution without epinephrine
- Equipment and supplies for procedural sedation (Chapter 129)
- Adhesive tape, ½ in.
- Webril padding
- Casting material
- Ace bandage
- Scissors

PATIENT PREPARATION

Explain the risks, benefits, potential complications, and aftercare of the reduction to the patient and/or their representative. The patient must be aware that irreducible dislocations will require an open surgical reduction and possible repair of damaged structures within and surrounding the joint. Inform the patient that the injury can result in joint swelling for weeks to months and possibly permanent joint enlargement. Loss of motion with stiffness and residual soreness may last for months. Obtain an informed consent for the reduction procedure. An informed consent should also be obtained for procedural sedation (Chapter 129) and/or the intraarticular injection (Chapter 77) if they are performed in addition to the reduction procedure.

Clean the involved joint of any dirt or debris. Apply povidone iodine or chlorhexidine solution and allow it to dry. Perform a wrist block (Chapter 126), the instillation of the local anesthetic solution into the joint (Chapter 77), and/or procedural sedation and analgesia (Chapter 129).

TECHNIQUES

Early closed reduction may be easy provided that the thumb is maintained in adduction, the fingers are flexed, and the wrist is flexed to relax the intrinsic hand muscles. The major obstruction preventing reduction of the dislocated MCP joint is the displaced volar fibrocartilaginous plate lying dorsal to the metacarpal head. Approximately 50% of MCP joint dislocations can be reduced in the ED using the closed method.

DORSAL MCP JOINT DISLOCATIONS

Dorsal MCP joint dislocations (Figure 84-3A) require minimal, if any, distally applied traction for reduction. It is important to remember that applying simple traction alone as an initial maneuver risks trapping the volar plate and transforming a simple dislocation into a complex dislocation.

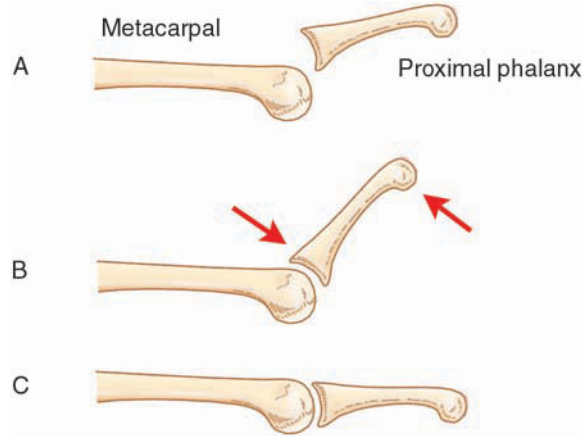

FIGURE 84-3. Reduction of a dorsal MCP joint dislocation. **A.** Dorsal dislocation of the MCP joint. **B.** The deformity is exaggerated by hyperextension of the MCP joint as the proximal end of the proximal phalanx is pushed volarly and over the metacarpal head while simultaneously flexing the IP joint to relax the flexor tendons. **C.** The reduced MCP joint.

Hyperextend the MCP joint while simultaneously pushing the proximal end of the proximal phalanx volarly and over the metacarpal head (**Figure 83-3B**). This maneuver diminishes the buttonhole effect on the metacarpal neck that is accentuated by traction. Flex the MCP joint as the proximal phalanx returns to position (**Figure 84-3C**). Simultaneously flexing the IP joint and wrist can help to relax the flexor tendons and make the reduction easier. This maneuver can sometimes trap the displaced fibrocartilaginous plate and carry it to its normal position anterior to the metacarpal head.

If the reduction is unsuccessful, repeated attempts to reduce the dislocation are contraindicated. Consider open reduction to disengage the metacarpal head from a probable buttonhole slit in the anterior capsule and from the surrounding muscles and tendons. Consult a Hand Surgeon for these MCP joint dislocations that cannot be reduced after one attempt in the ED.

VOLAR MCP JOINT DISLOCATIONS

Volar MCP joint dislocations (**Figure 84-4A**) are generally associated with collateral ligament ruptures. They are commonly irreducible due to interposition of the extensor tendons and the dorsal joint capsule. Consultation with a Hand Surgeon is often required for operative reduction.

Volar MCP joint dislocations require minimal, if any, distally applied traction for reduction. It is important to remember that applying simple traction alone as an initial maneuver risks trapping the volar plate and transforming a simple dislocation into a complex dislocation. Flex the MCP joint while simultaneously pushing the proximal end of the proximal phalanx dorsally and over the metacarpal head (**Figure 84-4B**). Extend the MCP joint as the proximal phalanx returns to position (**Figure 84-4C**).

If the reduction is unsuccessful, repeated attempts to reduce the dislocation are contraindicated. Consider open reduction to disengage the metacarpal head from a probable buttonhole slit in the anterior capsule and from the surrounding muscles and tendons. Consult a Hand Surgeon for these MCP joint dislocations that cannot be reduced after one attempt in the ED.

ASSESSMENT

CLINICAL ASSESSMENT

Assess the collateral ligaments for stability. **Because the goal of treatment is to restore functional stability, it is essential to perform a systematic evaluation of joint stability.** An accurate assessment generally requires adequate pain control, even in the most cooperative patients. Active stability is tested by allowing the patient to move the joint through the normal range of motion. Completion of a full range without displacement indicates adequate joint stability. Passive stability is assessed by applying gentle radial and ulnar stress to each collateral ligament and posteroanterior stress to assess volar plate integrity. Stress testing should be performed in extension and flexion to avoid the stabilizing effect of the volar plate. Comparisons with the same joint of the uninvolved hand may assist in the diagnosis.[2] Stability of the joint provides strong evidence that optimal functional recovery would result from short-term immobilization rather than surgical intervention.

Joint stability of the thumb MCP joint is tested in full extension as well as in 30° of flexion. Complete ligament disruption is suspected if the joint can be stressed in a radial direction 25° to 35° beyond a similar stress to the patient's opposite thumb MCP joint. This instability should be demonstrated in both full extension and 30° of flexion. Flexion at 30° lessens the stabilizing effects of the volar plate.[2] The presence of ecchymosis suggests a complete ligament tear as well as a volar subluxation of the proximal phalanx.[19]

RADIOGRAPHIC ASSESSMENT

Postreduction radiographs are essential to demonstrate adequate reduction. Occasionally, a fracture is only visible on these views and not on the prereduction films.[1,20] Joint subluxation after reduction is associated with interposed soft-tissue or severe capsular injury.

AFTERCARE

Splinting of any MCP joint dislocation should provide adequate immobilization and protection. Splinting is maintained for at least 1 week to no more than 3 weeks to prevent joint stiffness. Simple dorsal finger MCP joint dislocation injuries generally require splinting for 1 to 3 weeks with the joints in 45° to 50° of flexion.[2] Volar finger MCP joint dislocations require splinting in extension for 1 to 3 weeks. The thumb should be immobilized in a thumb spica splint in 20° of flexion for dorsal dislocations and in extension for volar dislocations for 3 weeks. A proper program of gradual active range-of-motion exercises should follow splinting.[18] With adequate protection and splinting of uncomplicated dislocations, athletes may return to activities within 1 to 2 weeks, sooner for low-risk sports with minor injuries, and longer for more serious injuries requiring surgery.[20]

COMPLICATIONS

Allergic reactions can occur from hypersensitivity to the local anesthetic solution. Symptoms can range from mild pruritus and urticarial rash to circulatory collapse and even death. Severe allergic reactions are extremely rare. Taking a thorough history might prevent such a reaction. The preservative in the anesthetic is often the culprit. The possibility of injury to structures in the joint may occur from improper insertion of the needle or needle movement within the joint cavity. Infection of the joint can occur when the needle penetrates unclean skin, infected skin, or infected subcutaneous tissue. If proper aseptic technique is followed, the risk of infection is negligible. Please refer to Chapters 77 and 123 regarding the complete details of local anesthetic complications and joint injection complications.

Complications of the reduction procedure are primarily related to failure of reduction, especially complex dislocations. Entrapment of ligaments, tendons, or sesamoid bones leads to an unsuccessful reduction. A simple MCP joint dislocation can be converted into a complex one during prolonged or repeated reduction attempts, especially those in which axial traction is the primary component.[2] Irreducible MCP joint dislocations require an immediate evaluation by a Hand Surgeon.

Collateral ligament injuries occur infrequently and are often missed in the acute setting. The presence of an avulsion fracture from the metacarpal head or corner fracture of the base of the proximal phalanx suggests a collateral ligament injury. Consultation with a Hand Surgeon is recommended for patients with a collateral ligament injury. Some surgeons prefer immediate operative repair of these injuries. ED care involves immobilization in a gutter splint, with the MCP joint in 45° to 50° of flexion, and appropriate referral.

Ulnar collateral ligament of the thumb rupture, also known as gamekeeper's or skier's thumb, results from a laterally directed force at the thumb MCP joint. The ligament is important to the grasping function of the thumb. **Early recognition of this injury is key.** The diagnosis is generally made through stress testing of the reduced MCP joint. Radiographs occasionally demonstrate an avulsion-type fracture. Treatment of partial ligament tears requires splinting in a thumb spica for 6 weeks, while complete rupture requires operative repair.

Radial collateral ligament injuries of the MCP joint of the thumb are less common but equally debilitating. The usual mechanism is forced adduction with or without hyperextension. The diagnosis is generally made through stress testing of the reduced MCP joint. Radiographs occasionally demonstrate an avulsion-type fracture. Treatment of partial ligament tears requires splinting in a thumb spica for 6 weeks, while complete rupture requires operative repair.

Degenerative arthritis may occur after multiple closed reductions or an unrecognized chronic dislocation.[21] Inadequate immobilization or early return to high-stress activities may result in ligamentous laxity or recurrent instability. Excessive joint contractures unresponsive to physical therapy may require surgical release.

SUMMARY

Injuries to the MCP joints of the hand are occasionally encountered in the ED. They may be associated with significant morbidity if not properly managed. The most common dorsal MCP joint dislocation seen is that of the thumb. Volar dislocations of the MCP joints are rarely seen. A thorough understanding of the anatomy and function of the MCP joint is essential to diagnose and manage these injuries. A detailed physical assessment of the soft tissues, bones, and neurovascular structures is essential to prevent occult injuries. Radiographic evaluation is required for all potential injuries. This should include anteroposterior, lateral, and obliques views in order to not miss associated avulsion fractures or evidence of complex dislocations. All MCP joint dislocations should have an attempt at reduction, except those that are unstable, chronic, open, or associated with a fracture. A Hand Surgeon should evaluate any unstable, chronic, open, or irreducible dislocation. MCP joint dislocations reduced in the ED must be appropriately splinted and follow-up arranged with a Hand Surgeon.

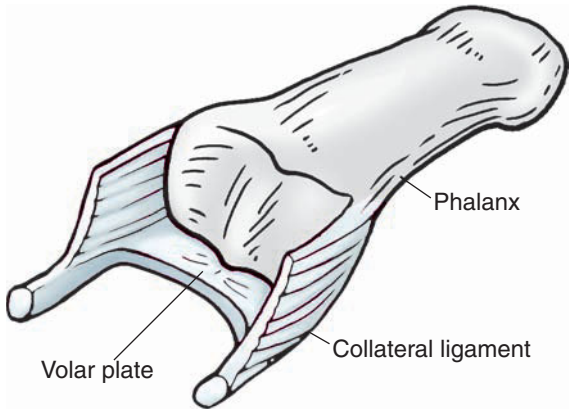

FIGURE 85-1. A schematic drawing of the box complex surrounding the PIP joint.

85 Interphalangeal Joint Dislocation Reduction

Matt Kleinmaier and Sanjeev Malik

INTRODUCTION

Dislocation of the interphalangeal (IP) joints is one of the most common orthopedic injuries seen in the Emergency Department (ED).[1–3] Most of these injuries occur during athletic activities. The proximal interphalangeal (PIP) joint is especially susceptible to injury during ball-handling sports.[2–4] An epidemiologic study of injuries in the National Football League over a 10-year period from 1996 to 2005 showed that PIP dislocations accounted for 17% of all hand injuries, making it the second most common hand injury in professional football.[14] Among dislocations, IP joint injuries are second only to shoulder dislocations in incidence.[4] While IP joint dislocations are generally easy to reduce, improperly treated injuries can result in chronic pain, swelling, restricted range of motion, deformity, and early degenerative arthritis.[1,5,6] The Emergency Physician (EP) must be proficient in diagnosing and treating IP joint dislocations.

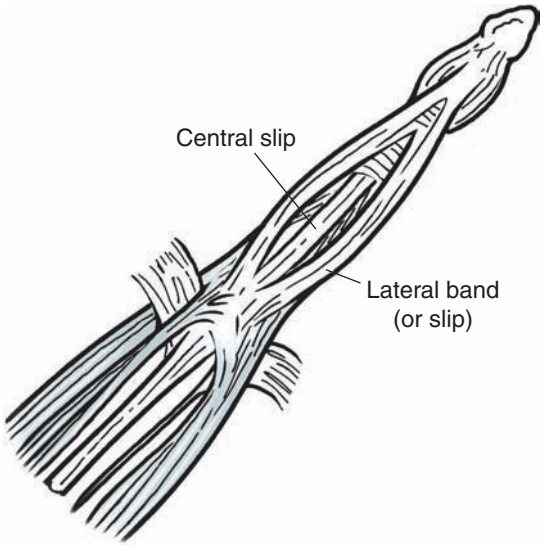

FIGURE 85-2. Dorsal view of the extensor mechanism.

ANATOMY AND PATHOPHYSIOLOGY

The bicondylar conformation of the PIP joint creates an inherently stable hinge joint with movement restricted to flexion and extension from 0° to 120°.[1,7,8] Additional stability comes from the complex of ligaments and tendons, which form a box around the joint (**Figure 85-1**). The elements of this complex include the volar plate, lateral and collateral accessory ligaments, and the extensor tendon dorsally. The volar plate's dense, fibrous distal aspect attaches firmly to the middle phalanx, while its more membranous proximal portion is continuous with the synovial reflection. This conformation resists dorsal dislocation at the joint.[4] The three bands of the extensor tendon mechanism (the central slip with a lateral band on each side) provide dorsal support which resists joint dislocation (**Figures 85-2 & 85-3**). Lateral collateral ligaments bridge the PIP on the radial and ulnar sides, stabilizing it against lateral dislocation.[3]

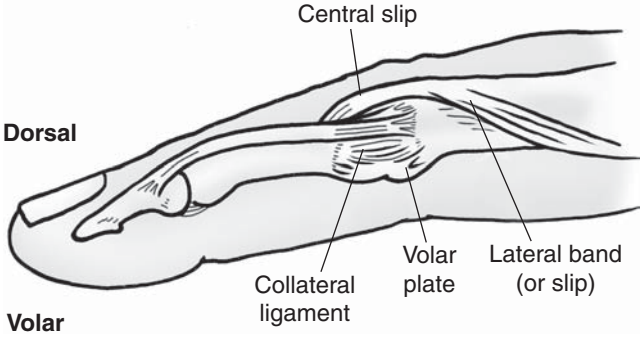

FIGURE 85-3. Lateral view demonstrating the anatomy of supporting structures. The volar plate and collateral ligaments form a box around three sides of the joint, while the extensor mechanism (consisting of central and lateral slips) lies along the dorsal aspect of the joint.

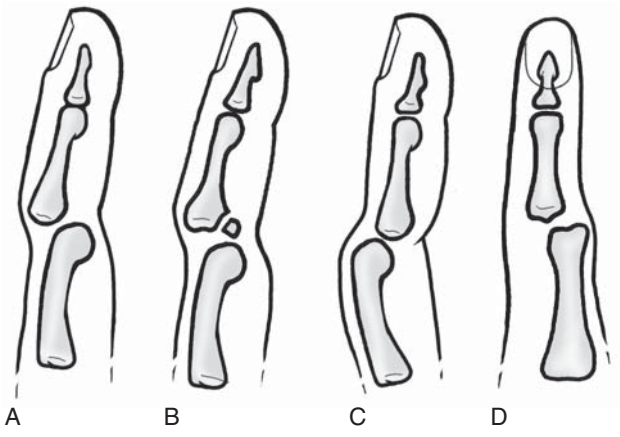

FIGURE 85-4. Dislocations of the PIP joint. They are classified based on the relationship of the distal bone to the proximal bone. **A.** Dorsal or posterior dislocation. **B.** Dorsal dislocation with an associated fracture. **C.** Volar, ventral, or anterior dislocation. **D.** Lateral dislocation.

The less-commonly dislocated IP joints (finger DIP and thumb IP joint) are similar in anatomy to one another. They are more broad-based than the PIP and range from 0° in extension to 90° in flexion, with no significant lateral or rotary movement.[3] The distal phalanx in both joints is firmly attached to the skin, accounting for the high percentage of open dislocations involving these joints.

Dislocations of the PIP joint are the most common and may be classified as dorsal, volar, and lateral (**Figure 85-4**).[1,4] Each type of dislocation results from a different mechanism of injury and has specific associated complications.

Dorsal (or posterior) dislocations are the most common type of PIP joint dislocation (**Figures 85-4A**). They usually result from hyperextension injuries.[4,7,8] A dorsal dislocation occurs when the middle phalanx is displaced dorsally from the proximal phalanx. These dislocations involve injury to the volar plate and may be associated with an avulsion fracture of the base of the middle phalanx (**Figures 85-4B & 85-5**). Avulsion fractures involving greater than 30% of the articular surface are considered unstable and require immediate referral to an Orthopedic or Hand Surgeon.[4]

Volar (or anterior) PIP joint dislocations are far less common and are more severe than dorsal PIP joint dislocations (**Figures 85-4C & 85-6**). They occur from a simultaneous axial load and a rotational force on the IP joint. Volar PIP joint dislocations are associated with rupture of the collateral ligament and disruption of the central slip of the extensor tendon mechanism. These injuries may preclude closed reduction.[4] These injuries can be more difficult to diagnose

FIGURE 85-5. Lateral view of dorsal dislocation with a minor avulsion fracture involving less than 30% of the articular surface. This is a stable fracture-dislocation.

FIGURE 85-6. Volar dislocation with an associated fracture of the middle phalanx.

than other types of dislocation, often presenting as subtle subluxation at the PIP joint with rotational deformity of the middle and distal phalanx seen on plain films.[9]

If left untreated, volar PIP joint dislocations may result in a boutonniere deformity (**Figure 85-7**).[1] This injury should be suspected in patients with pain over the PIP joint and the inability to fully extend the digit against active resistance. Plain films are usually unremarkable. Splinting in full extension with early follow-up with an Orthopedic or Hand Surgeon is mandatory in all suspected cases.

Lateral PIP joint dislocations are uncommon (**Figure 85-4D**).[3] They result from a pure radial or ulnar force on the joint with either partial or complete rupture of the collateral ligament. Ulnar dislocation with radial collateral ligament injury is six times more common than radial dislocation with ulnar collateral ligament disruption.[3] Lateral PIP joint dislocations are often reducible by closed methods.

Distal IP joint dislocations and IP joint dislocations of the thumb (**Figure 85-8**) are rare. They are often due to a direct blow to the distal portion of the digit.[7] They are most often dorsally dislocated and frequently open due to the firm attachment of the distal phalanx to the subcutaneous tissue and skin. All open dislocations require immediate orthopedic consultation.

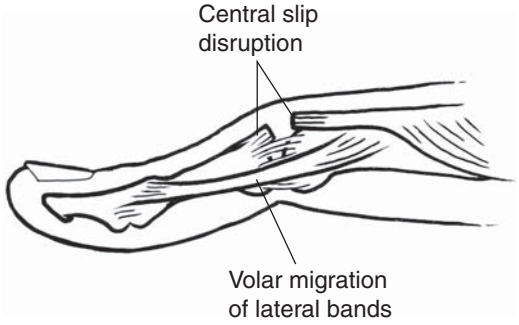

FIGURE 85-7. The boutonniere deformity.

IP joint dislocations of the toes are primarily dorsal. They occur secondary to an axial compression load to the digit, such as kicking a toe against a wall. IP joint dislocations of the toe are reduced similarly to dorsal IP dislocations of the finger.

INDICATIONS

Most IP joint dislocations that present to the ED are amenable to closed reduction by the EP. Factors to be considered include time from injury, closed versus open dislocation, associated fracture patterns, and direction of dislocation. The majority of IP joint dislocations present within hours of the injury, and closed reduction may be safely performed up to 3 weeks from the time of injury.[6] If there is no disruption of the skin overlying an IP joint dislocation, it is considered a closed injury and suitable for closed reduction. Small fractures involving less than 30% of the joint surface are considered stable for closed reduction.[3]

The direction of the dislocation should also be considered prior to any attempted reduction. Most dorsal dislocations are reducible by closed methods. Open reduction is occasionally necessary due to interposition of the ruptured volar plate or trapping of the proximal phalanx between the volar plate and flexor tendon.[10] Lateral dislocations are almost always successfully managed by closed reduction.[10]

The management of volar dislocations is more controversial. These injuries are often irreducible with closed methods due to trapping of soft tissue in the joint space (usually the ruptured extensor mechanism) or are unstable after reduction due to extensive damage to the supporting ligaments.[10] A single attempt at closed reduction may be performed. If successful, splint the finger in extension and consult an Orthopedic or Hand Surgeon as open repair of the extensor mechanism is usually required to prevent boutonniere deformity.[9,10] All irreducible injuries require emergent consultation with an Orthopedic or Hand Surgeon.

CONTRAINDICATIONS

Contraindications to closed reduction of IP joint dislocations include chronic dislocations, open dislocations, unstable dislocations, or complex dislocations. A chronic dislocation is defined as an IP joint dislocation of longer than 3 weeks duration. These injuries generally require open reduction and should not be reduced in the ED.[7] Careful inspection of the digit should be made looking for any breaks in skin integrity. Any skin wound, especially in the direction of the dislocation, mandates treatment as an open dislocation by an Orthopedic or Hand Surgeon. Unstable injuries are generally fracture-dislocations involving greater than 30% of the articular surface.[3] Complex injuries involve complete disruption of multiple ligaments or tendons surrounding the joint and often require open reduction and repair due to interposition of disrupted soft tissues between the articular surfaces of the IP joint.[1,7,11,12]

FIGURE 85-8. Dorsal dislocation of the thumb IP joint.

EQUIPMENT

Digital Block

- Povidone iodine or chlorhexidine solution
- 27 gauge needle, 2 in. long
- 5 mL syringe
- Alcohol swab
- Local anesthetic solution without epinephrine (1% lidocaine, 0.25% or 0.5% bupivacaine)

Postreduction Splint

- Aluminum finger splint with foam padding
- Gauze padding
- Adhesive tape, ½ in.
- Scissors

PATIENT PREPARATION

Explain the risks and benefits of the procedure to the patient and/or their representative. Obtain a written consent for the reduction procedure. Inform the patient that up to 30% of PIP and DIP joint injuries may remain swollen for many months and will likely result in permanent joint enlargement. Loss of motion and residual soreness may last several months.[1,6]

The use of local anesthesia is based on EP and patient preference. Many EPs and patients believe that the pain of reduction is less than that of a digital block and more tolerable. For this reason, many EPs will reduce an IP joint dislocation without the use of local anesthesia.

Clean the finger of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry. Insert a 27 gauge needle into the lateral aspect of the base of the proximal phalanx. Inject 0.5 mL of local anesthetic solution. Redirect the needle dorsally while depositing 1 mL of local anesthetic solution. Withdraw the needle and redirect it volarly while depositing 1 mL of local anesthetic solution. Repeat the procedure on the medial aspect of the base of the proximal phalanx. Refer to Chapter 126 for a more detailed description of the methods to anesthetize a finger.

TECHNIQUES

DORSAL DISLOCATION OF THE PIP JOINT

A dorsal dislocation of the PIP joint involves a partial or complete disruption of the volar plate. Most dorsal dislocations of the PIP joint are easily reduced (**Figure 85-9**). Firmly grasp the middle phalanx of the affected finger with the dominant hand. Grasp the base of the proximal phalanx with the nondominant hand. Hyperextend the PIP joint and apply longitudinal traction to separate the articular surfaces (**Figure 85-9B**). The nondominant hand is used to stabilize the proximal phalanx and apply countertraction. Flex the PIP joint while maintaining traction and apply dorsal pressure on the base of the middle phalanx (**Figure 85-9C**). This should restore the proper alignment of the proximal and middle phalanx.

Immobilize the reduced PIP joint in 30° of flexion for approximately 3 weeks (**Figure 85-9D**). Alternatively, tape the injured finger to an adjacent unaffected finger ("buddy taping"). Gauze padding must be placed between the fingers before buddy taping to prevent skin breakdown. During immobilization, it is important to avoid hyperextension if the finger is buddy taped, as this may lead to further injury of the volar plate. The presence of an avulsion fracture involving less than 30% of the articular surface does not alter this management plan.

Rarely, a dorsal dislocation can be irreducible due to interposed soft tissue or impingement of the proximal phalangeal head between the central slip and the lateral bands.[9] This type of dislocation is referred to as "complex." Failure of two or three attempts at closed reduction should raise the suspicion of an irreducible joint and an Orthopedic or Hand Surgeon should be consulted.

VOLAR DISLOCATION OF THE PIP JOINT

Volar dislocations of the PIP joint are almost always accompanied by an injury to the central slip of the extensor tendon, causing an inability to extend the PIP joint (**Figure 85-7**). These dislocations are generally irreducible and need early consultation with an Orthopedic or Hand Surgeon for operative repair due to the extensive soft tissue damage. Although controversial, some authors recommend a single attempt at closed reduction by applying a longitudinal (distal) force, hyperextending the joint, and applying dorsal pressure to the base of the middle phalanx. During this procedure, the metacarpophalangeal and DIP joints should be flexed and the wrist extended to relax the anteriorly displaced lateral bands and extensor mechanism. Splint the joint in extension and arrange for early follow-up with an Orthopedic or Hand Surgeon if closed reduction is achieved. **It is important to note that splinting in even mild flexion or "buddy taping" may lead to a boutonniere deformity (Figure 85-7).**

LATERAL DISLOCATION OF THE PIP JOINT

Lateral dislocations of the PIP joint involve a partial or complete rupture of the radial and ulnar collateral ligaments. There is a 6:1 ratio of radial to ulnar collateral ligament tears with the digit being displaced in the opposite direction of the ligament rupture.[3] Generally, reduction is easy and the joint is stable after the procedure. Recreate

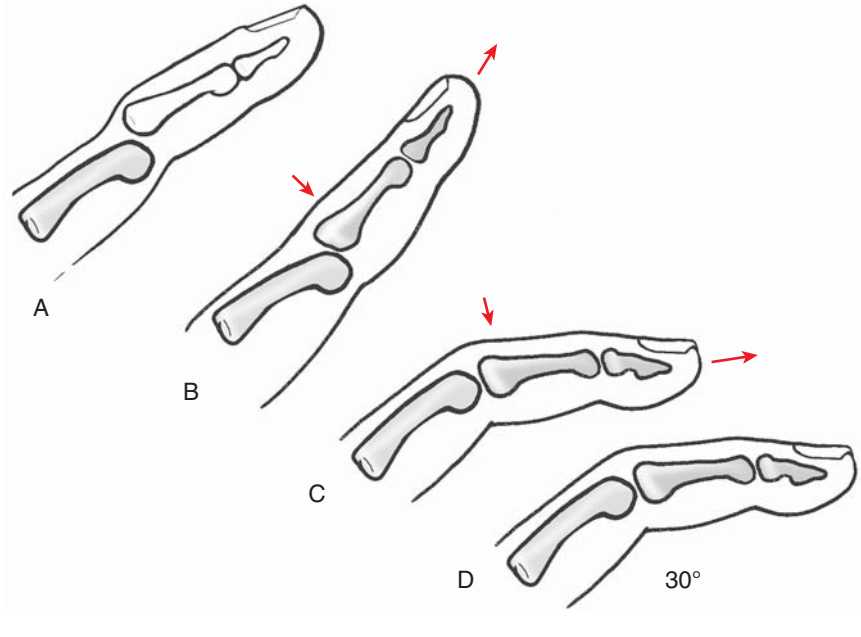

FIGURE 85-9. Reduction technique for an IP joint dislocation. **A.** Dorsal PIP joint dislocation. **B.** Exaggerate the deformity by hyperextending the middle phalanx and applying longitudinal traction distal to the injury. **C.** Flex the PIP joint while applying pressure to the dorsum of the middle phalanx with continued traction. **D.** The PIP joint is placed in 30° of flexion for splinting.

the injury and apply longitudinal (distal) traction to the finger. Bring (move) the distal phalanx in line with the proximal phalanx.

After reduction, determine by physical examination if the collateral ligaments are partially or completely torn. Buddy tape the finger to the adjacent finger for 3 weeks for incomplete collateral ligament tears. Early active motion of the finger is encouraged after this time. Complete collateral ligament tears are repaired operatively and require early consultation by an Orthopedic or Hand Surgeon.

INTERPHALANGEAL JOINT OF THE THUMB DISLOCATION

Dislocations of the IP joint of the thumb are rare. The injury is usually dorsal and open. If the dislocation is closed, the joint can be reduced in the same manner as PIP dislocations of the fingers.[11] Splint the reduced joint in slight flexion and arrange for early follow-up by an Orthopedic or Hand Surgeon.

DISTAL INTERPHALANGEAL JOINT DISLOCATION

DIP joint dislocations are rare, usually dorsal, and open. They are easily reduced in a similar manner to other IP joint dislocations and are generally stable after reduction.[12] Reduction is accomplished by application of longitudinal (distal) traction, hyperextension of the distal phalanx, and the application of dorsal pressure on the base of the distal phalanx. Immobilize only the DIP joint with a dorsal splint in 5° to 10° of flexion. Arrange for follow-up with an Orthopedic or Hand Surgeon.

The DIP joint may be irreducible if there is an avulsion and entrapment of the volar plate in the joint, entrapment of the long flexor tendon in the joint, or entrapment of a bony fragment. Immediate consultation with an Orthopedic or Hand Surgeon should be sought if the DIP joint is irreducible.

ASSESSMENT

Fully evaluate the finger after the reduction or any reduction attempt. **Perform and document a complete neurologic and vascular exam of the finger. An Orthopedic or Hand Surgeon should be consulted immediately if any neurologic or vascular deficits are identified.** Obtain postreduction radiographs of the digit to identify an avulsion injury or an incomplete reduction. Test the joint for functional stability by having the patient actively move the injured finger through a full range of motion. Stability of the joint is maintained if the collateral ligaments and volar plate are intact and no subluxation or dislocation occurs. Test the collateral ligaments by applying radially and ulnarly directed stresses with the joint in 20° of flexion. Test the integrity of the volar plate by having the patient hyperextend the joint and comparing the range of motion to that of the other fingers. The joint is considered stable if there is no displacement during active range of motion and passive stressing of the joint. If stable, place the joint in an appropriate splint and refer the patient to an Orthopedic or Hand Surgeon for follow-up. Immediately consult an Orthopedic or Hand Surgeon if the joint is not easily reduced or if it is not stable after the reduction. All open dislocations require immediate evaluation by an Orthopedic or Hand Surgeon for irrigation, reduction, and closure.

AFTERCARE

Splinting of any finger injury should provide adequate immobilization and protection while allowing maximal range of motion of the unaffected joints. The method of splinting for each specific dislocation is described in the "Techniques" section for each type of dislocation.

COMPLICATIONS

Most complications of IP joint dislocations are secondary to the injury itself rather than the reduction procedure. Even seemingly minor injuries can have complications such as prolonged swelling, pain, and stiffness. A thorough evaluation of the digit, prompt diagnosis, and proper treatment will help minimize these complications.

Complications of the reduction procedure are primarily related to failure of reduction.[13] Entrapment of soft tissues should be suspected in cases with multiple failed attempts at reduction. Numerous attempts at reduction may lead to trauma at the articular surface, predisposing to the development of premature degenerative arthritis. Irreducible or complex IP joint dislocations require an immediate evaluation by an Orthopedic or Hand Surgeon.

Prolonged or improper splinting of a joint can lead to chronic complications. Extended splinting and immobilization can lead to permanent joint stiffness. In general, IP joints should not be immobilized for greater than 3 weeks. Inappropriate splinting of a volar dislocation in even mild flexion may lead to long-term complications such as the boutonniere deformity.

SUMMARY

Injuries to the IP joints of the hand are commonly encountered in the ED and may be associated with significant morbidity. The most common injury encountered is a dorsal IP joint dislocation. Other dislocations include volar and lateral IP joint dislocations. A thorough understanding of the anatomy and function of the IP joint is essential to diagnose and treat these common injuries appropriately. A detailed physical examination of the soft tissues, bones, and neurovascular structures is necessary. Radiographic evaluation is required for all potential injuries, including an anteroposterior and a lateral view of the affected digit. Acute stable dislocations can be reduced immediately in the ED. An Orthopedic or Hand Surgeon should evaluate any unstable, chronic, open, or complex dislocation. Joints reduced in the ED must be splinted and appropriate follow-up arranged.

86 Hip Joint Dislocation Reduction

George Chiampas and Steve Zahn

INTRODUCTION

Hip dislocations are true orthopedic emergencies. The Emergency Physician (EP) must be capable of reducing a dislocated hip. Neurovascular damage to the hip and leg is a consequence of a hip dislocation. Avascular necrosis (AVN) may occur in up to 20% of patients with a hip dislocation. Other studies show that AVN following a hip dislocation is a time-dependent phenomenon. **The longer a hip is dislocated, the higher the incidence of avascular necrosis.** Dislocation of a hip for more than 6 hours almost universally results in this devastating complication.

The main etiologies of a hip dislocation are traumatic dislocations of a normal hip, mechanical dislocations of a prosthetic hip, spontaneous dislocations, and pathologic dislocations. Less impressive mechanisms may result in hip dislocations in the young and the elderly. A simple fall from standing may dislocate a geriatric hip. Dislocations may occur with minor force in children, as during athletic activities.

Many techniques have been described to reduce dislocated hips.[1–7] The EP must be familiar with some of these methods and how to apply them appropriately to optimize patient management and outcome. Dislocations of both normal and prosthetic hips are seen in the Emergency Department. Dislocations of prosthetic hips are now more common than those of normal hips.[8] While these are not associated with avascular necrosis, the pressure from the dislocated prosthetic head may result in other neurovascular complications.

ANATOMY AND PATHOPHYSIOLOGY

Ball-and-socket joints are inherently stable. The strong muscles, ligaments, and fibrous joint capsule of the hip reinforce this innate stability. Consequently, in the average adult, a great deal of force must be transmitted to dislocate the hip. This is significant, as the patient with a hip dislocation may have other life-threatening injuries that take precedence over the management of the hip dislocation. The mortality associated with a hip dislocation results from associated injuries of the head, thorax, or pelvis.

Hip dislocations are classified into anterior, posterior, and central based upon the relationship of the dislocated femoral head to the acetabulum. Anterior hip dislocations occur with the leg in a neutral or abducted position. The femoral head is pushed anterior to the coronal plane of the acetabulum. These patients present in extreme pain with the hip and knee flexed 90°. The leg will be held in external rotation. A slight shortening of the leg may be noted, but this is difficult to detect with the knee in flexion. There are three subtypes of an anterior hip dislocation: anterior obturator, anterior iliac, and anterior pubic. The femoral head displaces medially and lies in the obturator canal in anterior obturator dislocations. The femoral head moves superiorly and lies over the iliac wing in anterior iliac dislocations. The femoral head moves inferiorly over the pubic ramus in anterior pubic dislocations.

Posterior hip dislocations are the most common type. They account for nearly 90% of all hip dislocations. This is because the posterolateral half of the femoral neck lies outside the joint capsule and the weaker posterior support of the hip. Posterior dislocations result from force transmitted along the femoral shaft with the leg adducted. The most common mechanism of injury is a motor vehicle collision where the knees strike the dashboard and the femoral head is pushed posterior to the coronal plane of the acetabulum. The presentation of a posterior dislocation is of a patient in extreme pain. The leg will be internally rotated with marked knee flexion and adduction of the thigh. The femoral head is rarely visible but may be palpable in the buttock region. Posterior hip dislocations are further categorized into posterior ischial and posterior iliac sub-types. The femoral head is displaced inferiorly and lies over the ischium in posterior ischial dislocations. The femoral head is displaced superiorly and lies over the iliac wing in posterior iliac dislocations.

Central hip dislocations are the rarest form. The femoral head remains on the same coronal plane as the acetabulum in central dislocations. However, it is displaced superiorly. Most central hip dislocations are associated with acetabular fractures.

INDICATIONS

All hip dislocations must be reduced. **Emergent hip reduction by the EP is indicated when distal neurologic or vascular deficits are present or if the Orthopedic Surgeon is not immediately available.** The incidence of avascular necrosis is time-dependent and necessitates reduction as soon as possible to limit this complication.

CONTRAINDICATIONS

Any life-threatening conditions must be treated before the hip is reduced. Closed reduction is contraindicated if a surgical indication for repair exists. Surgical exploration is required for hip dislocations associated with femoral head fractures, femoral shaft fractures, or the finding of sciatic nerve dysfunction. Surgery is also indicated for an irreducible dislocation, persistent instability of the joint after closed reduction, and for any postreduction neurovascular deficits.

EQUIPMENT

- Procedural sedation equipment and supplies (Chapter 129)
- Assistants
- Sheets

PATIENT PREPARATION

The patient must be appropriately stabilized with prioritization of the ABCs (airway, breathing, and circulation). Life-threatening associated injuries and comorbid conditions must be adequately addressed. Obtain plain radiographs to define the anatomic dislocation pattern, to rule out any associated fractures, and to guide relocation attempts.

Explain the risks, benefits, complications, and aftercare of the reduction procedure and obtain an informed consent from the patient and/or their representative. **The patient must be sedated to achieve optimal muscle relaxation and pain control.** Perform procedural sedation after obtaining a separate informed consent for this procedure.

TECHNIQUES

Hip reduction techniques have been described with the patient in every imaginable position.[1–9] The relative success rates for each technique have not been reliably reported.[8] Therefore EPs typically use the technique(s) that was demonstrated to them during their residency training. **The editor recommends using the Allis maneuver as the treatment of choice for the reduction of posterior hip dislocations.** The other techniques are described in the text primarily for historical information, to give the reader full information regarding procedures that have been used and described for the reduction of this common problem, and as alternative techniques if the Allis maneuver is not successful in reducing the hip.

ALLIS MANEUVER

This is the most common hip reduction method (**Figure 86-1A**). It was described by Allis in 1893.[1] The technique has been improved by the addition of procedural sedation. Place the patient supine and perform procedural sedation. Instruct an assistant to stabilize the patients pelvis to the gurney by pressing down on the anterior superior iliac spines. It may be necessary for the assistant to use both hands on the side of the pelvis associated with the hip dislocation to stabilize the pelvis. Flex the affected knee and hip 90°. Grasp the affected knee with both hands. Apply axial traction to the thigh with incrementally increasing force. Simultaneously rotate the femur laterally and medially until the hip relocates.

If relocation is not easily accomplished, instruct a second assistant to apply lateral traction to the inner thigh of the affected proximal femur (**Figure 86-1B**). Repeat the entire procedure with the addition of lateral traction to reduce the dislocation.

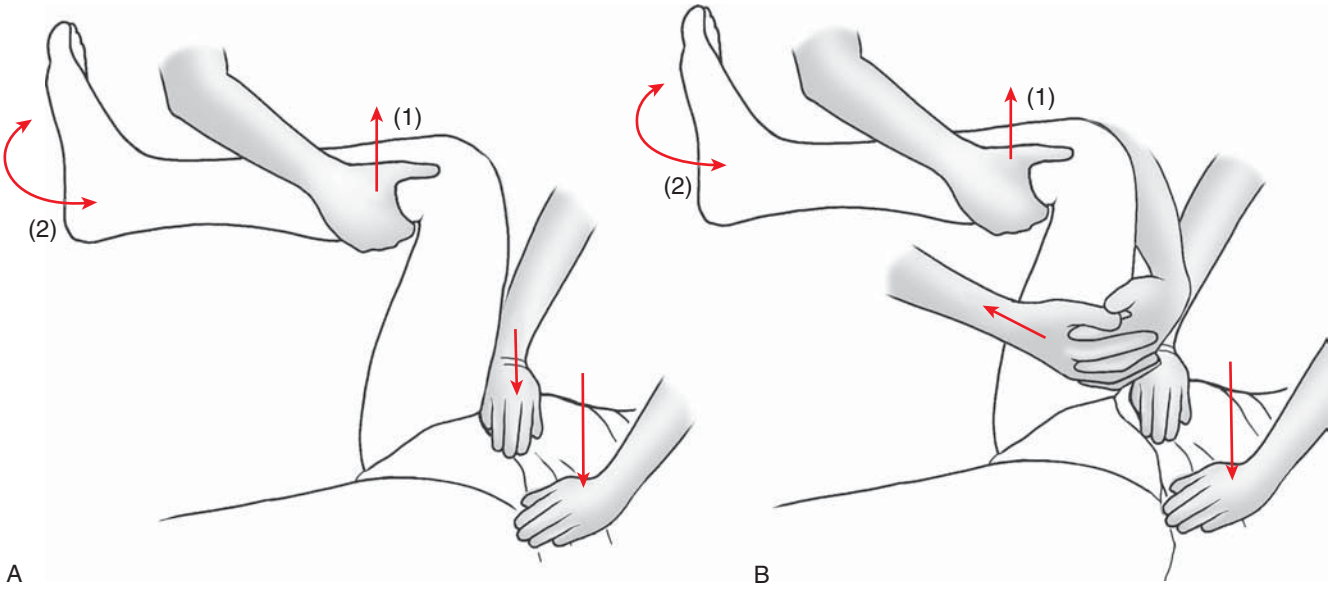

FIGURE 86-1. The Allis maneuver. **A.** An assistant stabilizes the pelvis. The EP simultaneously distracts the femur (1) and rocks it medial to lateral (2, *curved arrow*). **B.** The same maneuver with the addition of a second assistant to apply lateral traction to the thigh.

MODIFIED ALLIS MANEUVER

This technique incorporates all of the maneuvers described above. Additionally, place the hip in maximum adduction. Apply longitudinal traction to the femur while an assistant presses down on the pelvis with one hand and pushes the head of the affected femur toward the acetabulum with the other hand.

GRAVITY METHOD OF STIMSON

Place the patient prone on the gurney. Perform procedural sedation. Monitoring may be more difficult due to the prone positioning. **Extra attention must be paid to the patient's airway and breathing when placed prone.** Associated injuries may preclude prone positioning of the patient.

Place the affected leg hanging over the side of the gurney with the knee and hip each flexed 90°. Alternatively, hang both legs off the distal edge of the gurney with the knees and hips flexed 90° (**Figure 86-2A**). Instruct an assistant to hold the patient down on the gurney by applying downward pressure on the posterior pelvis at the posterior superior iliac spines.

Grasp the ankle in one hand to support the limb and to be able to apply internal and external rotation to the extremity (**Figure 86-2A**). Place the other hand on the proximal posterior calf. Exert gradual longitudinal traction on the femur by placing pressure on the affected calf until the hip is felt to pop into place.

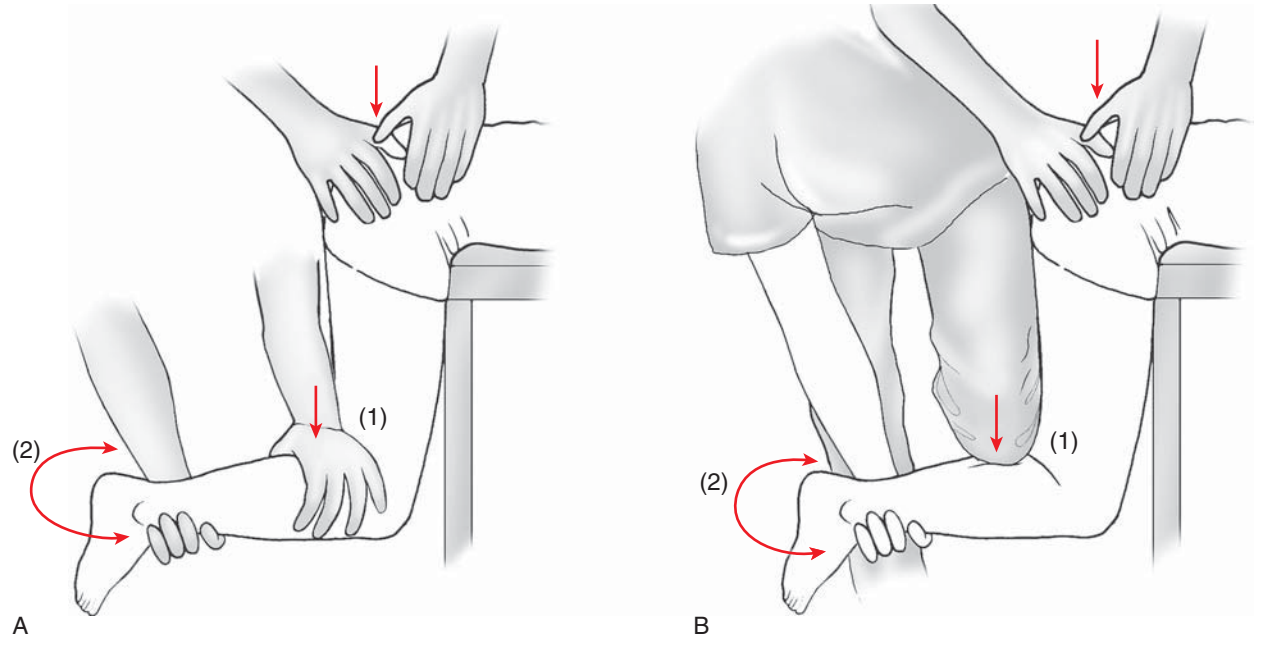

FIGURE 86-2. The gravity method of Stimson. **A.** An assistant stabilizes the pelvis. The EP applies downward pressure on the calf (1, *straight arrow*) while applying subtle and external rotation to the femur (2, *curved arrow*). **B.** An alternative method.

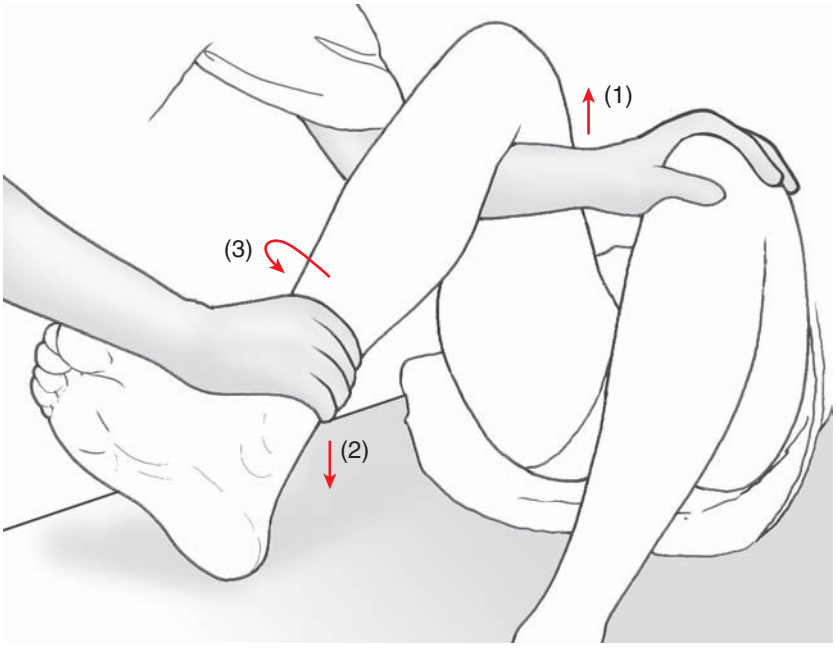

FIGURE 86-3. The Whistler (or Rochester, or Tulsa) technique. Elevation of the EPs shoulder (1) while simultaneously flexing the patient's knee (2) moves the femoral head anteriorly and around the acetabular rim. Externally rotating the patient's leg (3, *curved arrow*) by swinging the ankle laterally allows the femoral head to reduce.

A subtle internal and external rotary motion may help to move the femoral head over the acetabular rim. **Care must be taken not to compress the structures in the popliteal fossa with excessive pressure behind the knee.**

A much greater degree of force can be applied to the hip if the EP, instead of generating traction with their arm, places a knee in the affected popliteal fossa (**Figure 86-2B**). Pull the affected ankle upward while simultaneously exerting downward force on the calf to reduce the dislocation.

WHISTLER/ROCHESTER/TULSA TECHNIQUE

This technique was described at three separate sites (**Figure 86-3**). Whistler Healthcare Center in Vancouver, Canada, described it in 1997.[10] The Orthopedic Associates of Rochester described it in 1999. Vosburgh described it in 1995 as the "Tulsa method."[11] It is reported as being easier to implement than the other techniques and appropriate for use in the Emergency Department.[10,11] Another advantage is that it can be performed without the aid of an assistant. Pelvic stabilization is provided by a counterforce on the uninjured knee. The force and counterforce occur through the same fulcrum and are therefore exactly equivalent.[9]

Place the patient supine. Perform procedural sedation. Stand to the side of the affected hip. Flex the unaffected knee 130°. Place your elbow under the affected knee, allowing the leg to dangle over your forearm. Reach to grasp the flexed unaffected knee with the palm. Grasp the affected ankle with your other hand in order to flex the knee and rotate the hip. The hold is now established (**Figure 86-3**).

Elevate the affected knee by raising your shoulder and using your arm as a lever (**Figure 86-3(1)**). Simultaneously apply a longitudinal force by progressively flexing the patient's knee over your arm (**Figure 86-3(2)**). This applies traction to the femoral head, moving it anteriorly and around the acetabular rim. Once the acetabular rim is cleared, externally rotate the leg to allow the femoral head to reduce (**Figure 86-3(3)**). External rotation is achieved by swinging the ankle laterally. A pop should be felt as the femoral head falls into the acetabulum. Reduction can be verified by internal and external rotation of the hip. An assistant may occasionally be required to stabilize the pelvis.

FULCRUM TECHNIQUE

Lefkowitz described this technique in 1993 and Bergman described it in 1994.[6] The advantage of this technique is that leverage allows greater reduction forces to be applied to the hip with less strength and effort on the part of the EP (**Figure 86-4**). A steady and constant force can easily be applied that reduces the risk of fractures and nerve injuries. This constant traction is superior to the sudden jerks that are inevitable in some of the other reduction techniques.[6]

Place the patient supine and perform procedural sedation. Secure the patient to the gurney with a sheet or use an assistant to stabilize

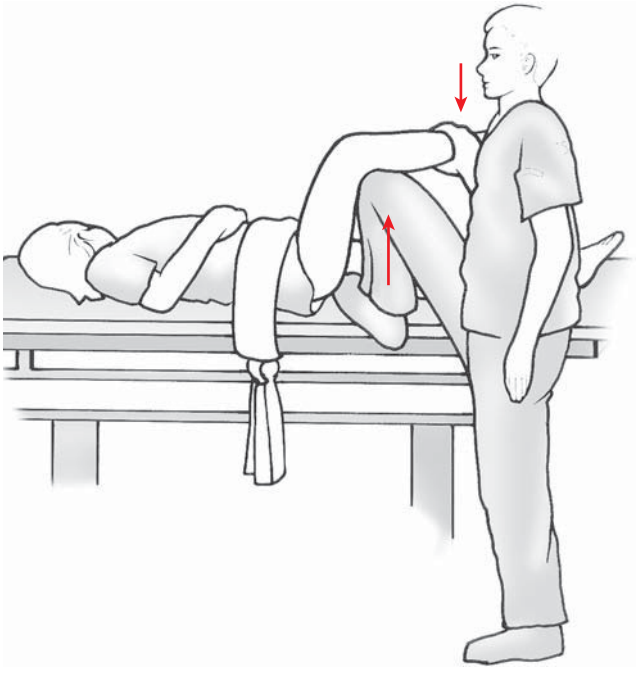

FIGURE 86-4. The fulcrum technique. The EP applies downward pressure on the patient's ankle while simultaneously plantarflexing their foot to move the femoral head around the acetabular rim and reduce the hip.

the patient's pelvis. Lower the bed, preferably to within 2 to 3 feet of the floor. Stand on the side of the affected hip. Place one foot on the edge of the bed at the level of the patient's hip. A platform or footstool may be used to gain a mechanical advantage if the level of the bed is too high or you are too short.

Flex the affected knee 90° over your knee (**Figure 86-4**). Grasp and hold the affected ankle. Apply steady, gentle downward traction on the ankle to flex the knee while simultaneously plantarflexing your foot on the gurney. This will cause the knee to exert an upward force on the patient's knee, raising the femoral head around the edge of the acetabulum and reducing the hip. It may be necessary to gently rotate the affected foot internally and externally if the hip does not reduce easily.

SIMPLE LONGITUDINAL TRACTION

This technique is similar to the reduction of a shoulder dislocation (**Figure 86-5**). Place the patient supine and perform procedural sedation. Extend the affected lower extremity at the hip and knee. Wrap a sheet around the affected proximal thigh. Grasp the patient's ankle with both hands. **Do not grasp the foot, as this can result in secondary injury.** Instruct an assistant to apply lateral traction to the sheet and proximal thigh to move the femoral head over the acetabular rim while simultaneously exerting longitudinal traction to the leg by pulling on the patient's ankle to reduce the hip (**Figure 86-5**).

The editor prefers to use a padded leather restraint around the affected ankle. Wrap the two ties of the restraint around your hips and secure them with a knot. You can then slowly lean backward to allow your body weight to reduce the hip. This method is especially useful if you are small in stature or do not have significant upper body strength. Do not wrap the ties around your waist, as this can cause low back strain.

BIGELOW MANEUVER

Bigelow described this technique in the literature in 1870 (**Figure 86-6**). It was the first documented hip reduction technique. Perform procedural sedation. Place the patient supine with the affected hip and knee flexed 90°. Hold the affected knee in the crook of your flexed elbow with the patient's foot in the opposite hand (**Figure 86-6A**). Instruct an assistant to stabilize the pelvis by applying downward pressure to the anterior superior iliac spines. Lift your shoulder and arm supporting the patient's knee to apply distal traction to the femur (**Figure 86-6A**). Externally rotate and extend the hip while distracting the femur to reduce the hip (**Figure 86-6B**).

This is considered the "classic" reduction technique. Its disadvantages are that it requires great strength on the part of the EP to reduce the hip. The force applied is often jerking and inconsistent. The aid of a strong assistant is required to stabilize the pelvis.

LATERAL REDUCTION TECHNIQUE

This technique was described in 1986 by Skoff.[8,12] It gives a mechanical advantage to the EP, as most of the force exerted is by the EPs own body weight (**Figure 86-7**). It also capitalizes on the principle of recreating the position of injury in order to exactly reverse the forces of the injury to produce the reduction.

Place the patient in the lateral decubitus position lying on the unaffected extremity. Perform procedural sedation. Flex the affected hip 100° and allow it to gravitate to adduction. This position recreates the typical position of the hip during the dislocation. Internally rotate the patients hip 45° while maintaining 45° of adduction to exaggerate the hip dislocation. Place a looped sheet around the patient's hips and an assistant's hips. Place a second looped sheet around the patient's knee and your own hips. The

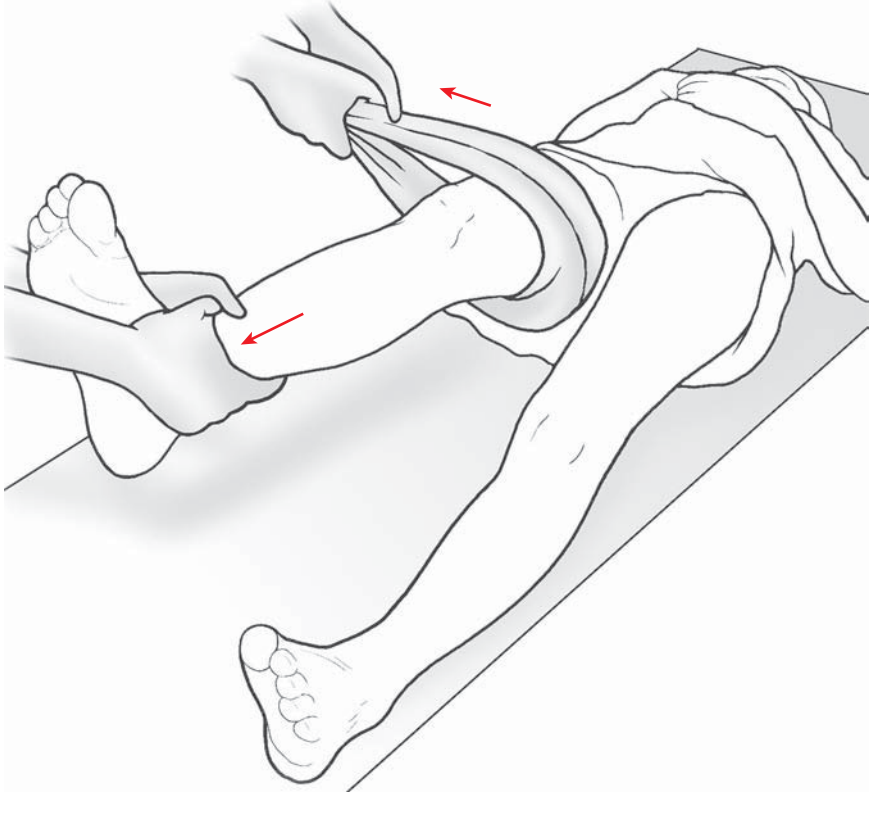

FIGURE 86-5. The simple longitudinal traction technique. An assistant applies lateral traction to the thigh while the EP simultaneously applies in-line traction to the leg.

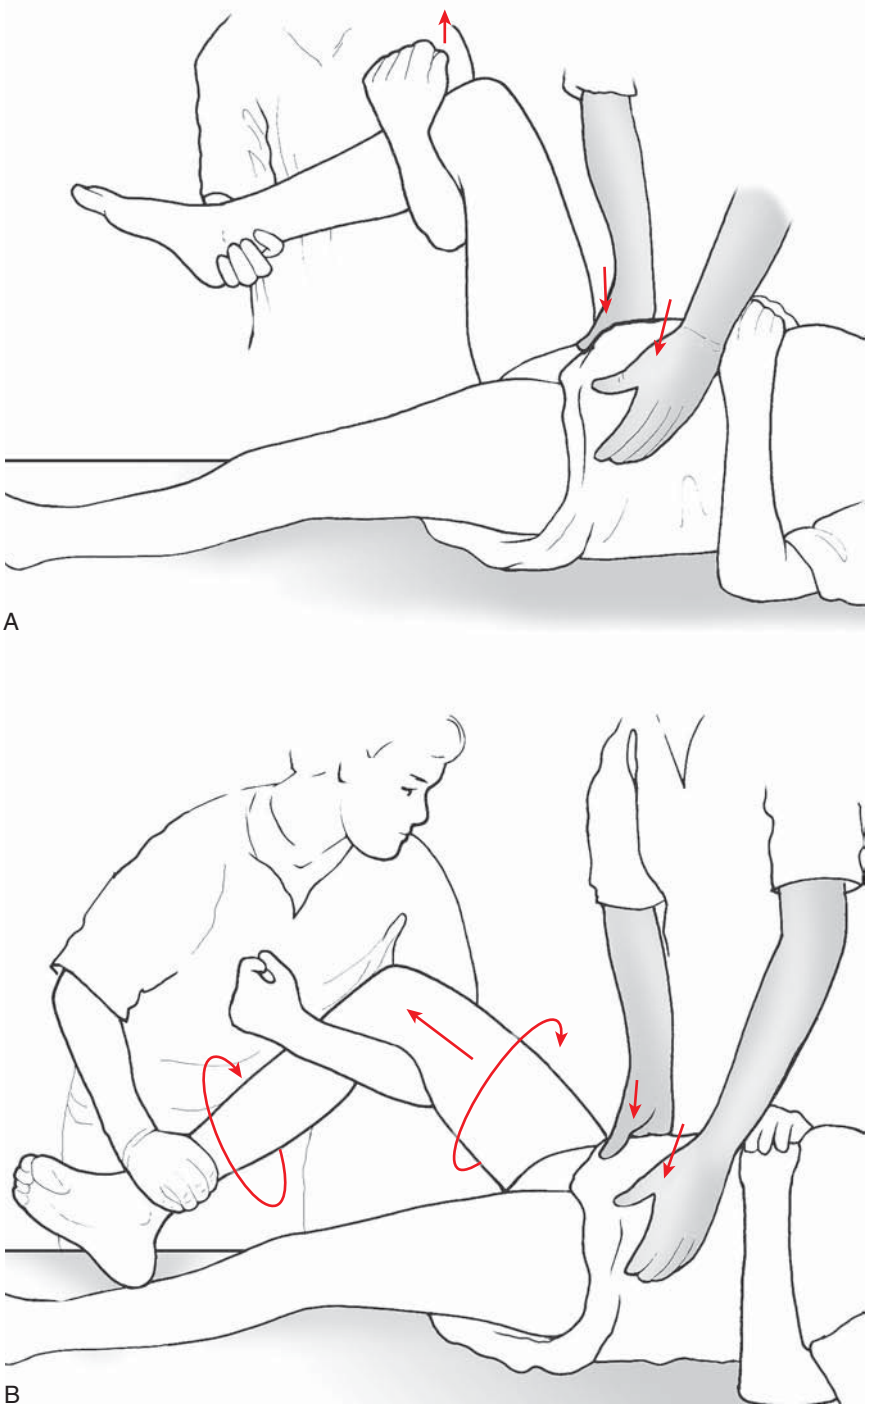

FIGURE 86-6. The Bigelow maneuver. **A.** The EP applies upward traction on the femur while an assistant stabilizes the pelvis. **B.** The hip is externally rotated and extended while the femur is distracted.

use of sheets allows optimal leverage by using body weight as the reduction force. Grasp the affected ankle to maintain the patient's knee flexed 90°. Apply distal traction to the femur by slowly leaning backward while the assistant simultaneously applies posteriorly directed countertraction to the femoral head. The assistant can use their hands to apply a distally directed force to the femoral head to assist in the reduction.

ASSESSMENT

The appropriate evaluation of any dislocation requires a thorough pre- and postreduction neurologic and vascular examination of the distal extremity. Any neurologic or vascular deficits require immediate evaluation by an Orthopedic Surgeon. Obtain a postreduction radiograph to confirm the reduction and rule out any fractures missed on the initial radiographs or as a result of the reduction procedure. Monitor the patient until they recover from the procedural sedation. A computed tomography scan may help identify any acetabular or osteochondral fractures.

AFTERCARE

All patients with a hip dislocation require an evaluation by an Orthopedic Surgeon. All native hip dislocations and most prosthetic hip dislocations require hospitalization and traction after reduction.[13]

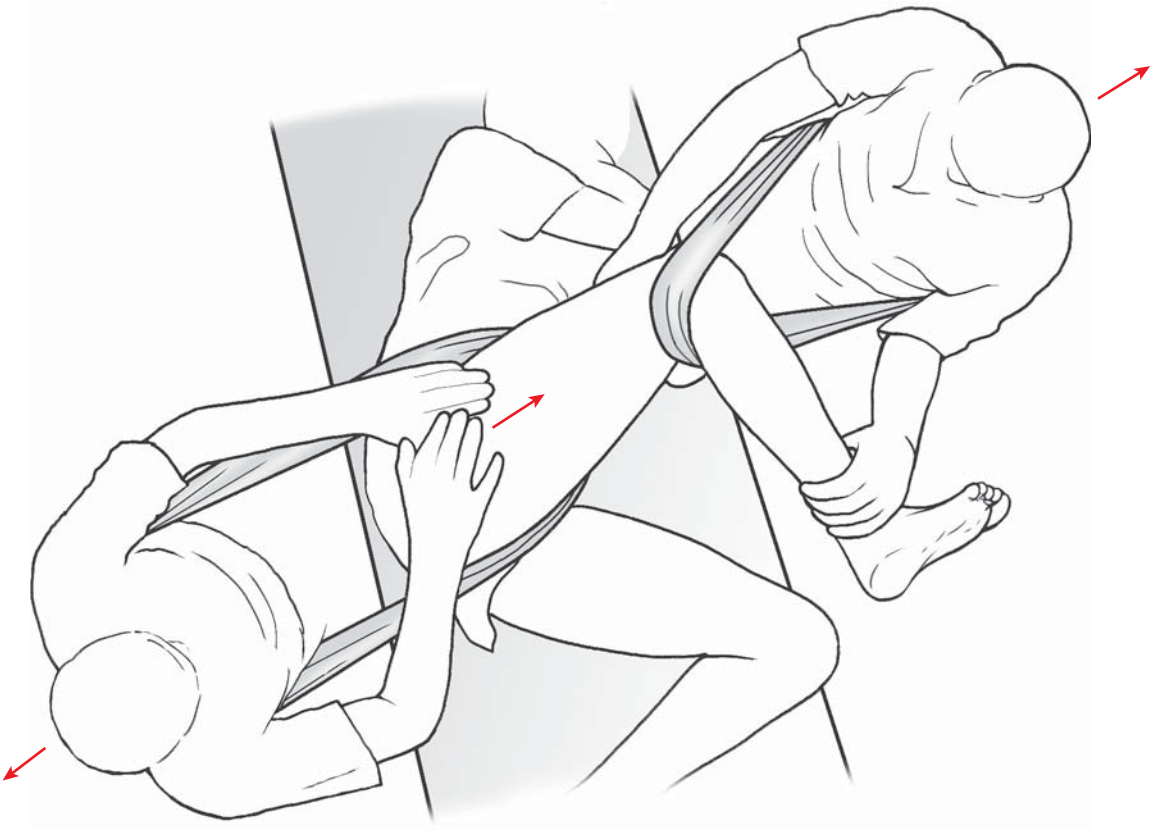

FIGURE 86-7. The lateral reduction technique. The hip is flexed 100°, adducted 45°, and rotated internally 45°. The EP applies traction to the femur. The assistant applies countertraction while simultaneously applying distally directed pressure on the femoral head with their hands.

COMPLICATIONS

The complications of a hip dislocation itself are fractures, avascular necrosis of the femoral head, injury to the sciatic and femoral nerve, and injury to the femoral artery. Posttraumatic arthritis, recurrent dislocation, and myositis ossificans can also occur.[13] Complications may occur despite the most expedient treatment, and prosthetic hip replacement may become necessary.

The complication of avascular necrosis is time-dependent. Reductions delayed over 6 hours are at an extreme risk for avascular necrosis. The risk of avascular necrosis increases as the time of the dislocation increases. Reductions that apply steady, non-jerking force to the limb have a lower incidence of associated fractures as well as fewer neurovascular complications. Multiple attempts at reduction are also associated with an increase risk of avascular necrosis. More than three attempts at closed reduction are associated with an increase risk of avascular necrosis and should prompt the EP to seek orthopedic consultation.[14]

Neurologic injury is one of the most common complications of hip dislocations, even when successful closed reduction is achieved. Sciatic neurapraxia, from peroneal branch damage, occurs in up to 15% of adult traumatic dislocations though symptoms resolve in 60% to 70% of cases.[15] Sciatic dysfunction may lead to an equinus deformity and will need immediate consultation with an Orthopedic Surgeon.[15]

SUMMARY

Multiple techniques exist to reduce hip dislocations. The EP should master one or two methods in order to provide essential care to these patients, limit complications, and enhance outcomes. The sooner a dislocated hip is reduced, the fewer the potential complications.

87 Patellar Dislocation Reduction

Mark P. Kling

INTRODUCTION

Dislocation of the patella generally results from a traumatic event.[1–9] It is most commonly due to a direct blow to the flexed knee. It may also occur from a forceful quadriceps contraction while the femur is internally rotated on the tibia. Many patients may not notice the dislocation as it may spontaneously reduce immediately after the injury. There are numerous theories as to the predisposition, if any, to a patella dislocation.[1,2] These include adolescents, females, flat intercondylar groove, joint laxity, "knock-knees" or genu valgus, large Q-angles, obesity, and vastus medialis muscle atrophy. This condition is most commonly seen in adolescents and females.

ANATOMY AND PATHOPHYSIOLOGY

The knee consists of the patellofemoral and the tibiofemoral joints. The patellofemoral joint is a gliding joint. The patella is an oval-shaped sesamoid bone that develops in the tendon of the quadriceps muscle. It is suspended between the quadriceps superiorly and

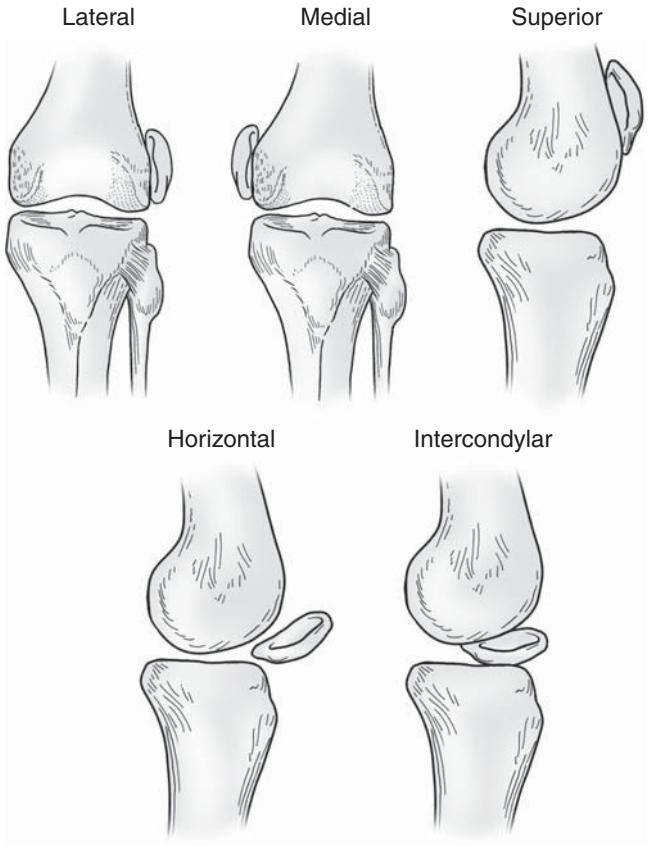

FIGURE 87-1. Types of patellar dislocations.

the tibial tuberosity inferiorly. The patella articulates between the femoral condyles. It is held in place by the vastus medialis muscle, the medial retinaculum, the medial and lateral patellofemoral ligaments, and the patellotibial ligament.

The patella may dislocate in numerous directions (**Figure 87-1**). Lateral dislocations are the most common type (**Figure 87-2**). The patella usually dislocates laterally due to its asymmetrical shape and the normal upward and lateral pull of the quadriceps muscle. The patella may also dislocate superiorly, medially, and intraarticularly in rare instances.[3,4]

The clinical determination of a lateral patellar dislocation is usually simple and quite obvious (**Figure 87-3**). The knee is held in partial flexion. The patella can be seen and palpated on the lateral surface of the knee. This may be accompanied by edema and/or ecchymoses over the anterolateral knee.

Pain over the parapatellar ligaments may be the only clinical sign in patients whose patellar dislocation has spontaneously reduced. The physical examination usually reveals mild edema in the parapatellar recesses. There is often laxity in the tendons and ligaments surrounding the patella. A patellar apprehension test is generally positive. The knee joint is usually stable.

The pathophysiology of this dislocation may include abnormalities secondary to malalignment, laxity, and hyper-elasticity of the joint. Osteochondral fractures are common but seen only on arthroscopy.[1,2,5] Magnetic resonance imaging, bone scans, and arthroscopy are considerations for further evaluation and diagnosis of the patellofemoral joint by the Orthopedic Surgeon.

Prereduction radiographs should be obtained to document patellar fractures or other bony abnormalities prior to the reduction. These may be difficult to obtain if the patient has significant discomfort and may be delayed until after the reduction. Radiographs may also be used to identify a foreign body if abrasions or lacerations are present over the knee. The patella often reduces spontaneously in the radiology suite as the leg is extended to obtain the radiographs.

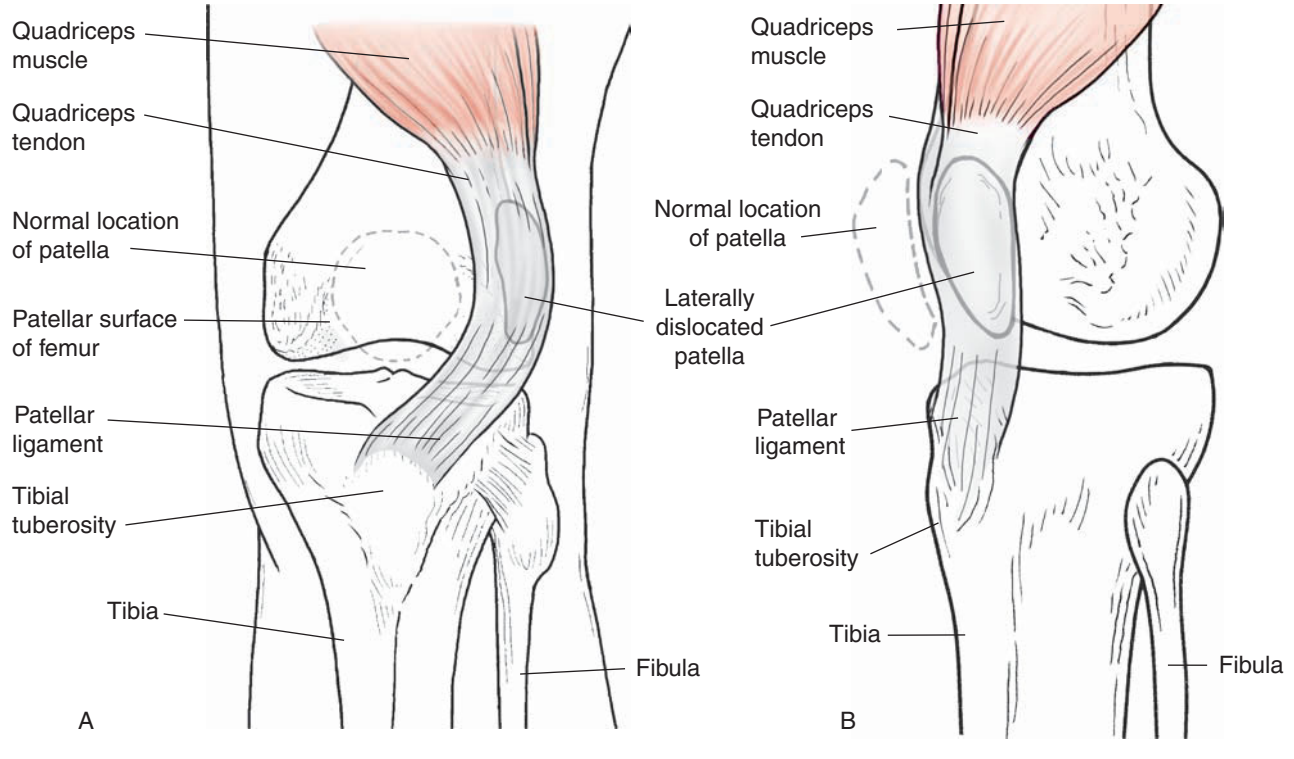

FIGURE 87-2. Anatomy of a lateral patellar dislocation. **A.** Anteroposterior view. **B.** Lateral view.

FIGURE 87-3. The lateral patellar dislocation. The presentation is often clinically dramatic. (Photograph courtesy of Dr. Robert R. Simon.)

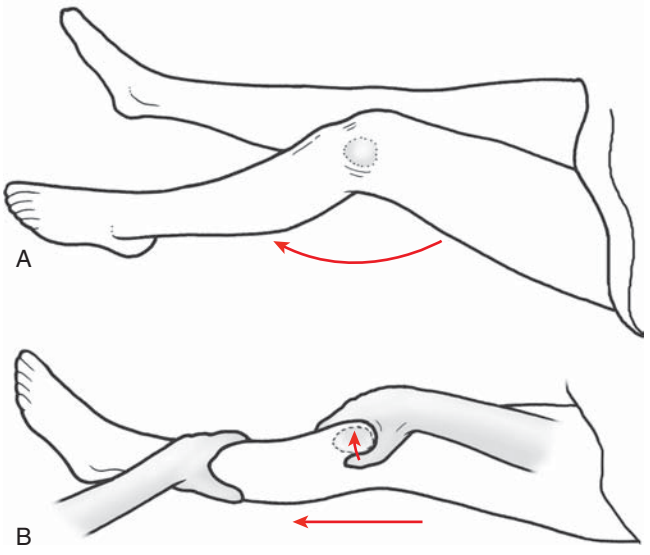

FIGURE 87-4. Reduction of a lateral patellar dislocation. **A.** Manipulation of the knee begins with gradual extension. **B.** Medially directed pressure applied to the patella when the knee is fully extended reduces the dislocation.

INDICATIONS

Any medial or lateral patellar dislocation that does not reduce spontaneously should be reduced manually.

CONTRAINDICATIONS

As with any traumatic injury, the evaluation and management of the patient's airway, breathing, circulation, and other significant injuries take priority over the reduction of a patellar dislocation. There are a few relative contraindications to the reduction of a patellar dislocation. An Orthopedic Surgeon should be consulted for the evaluation and reduction if the dislocation is superior, horizontal, intercondylar, or associated with fractures of the distal femur or proximal tibia. **The only exception to this is if there is neurologic and/or vascular compromise of the distal extremity.** This requires immediate reduction by the Emergency Physician if, after phone consultation, the Orthopedic Surgeon is not immediately available to perform the reduction.

EQUIPMENT

No special equipment is required for the reduction of the dislocation. A knee immobilizer or splinting material (plaster, fiberglass, and prepackaged splints) should be available to temporarily splint the patella and knee after the reduction.

PATIENT PREPARATION

Patient preparation is minimal in the case of a lateral or medial patellar dislocation. Explain the risks, benefits, complications, and aftercare to the patient and/of their representative. Obtain an informed consent prior to performing the procedure. Verbal consent is usually sufficient, since the reduction of a patellar dislocation is relatively simple, with infrequent complications. Place the patient supine on a gurney. No premedication or sedation is required for this procedure.

TECHNIQUES

The technique for the reduction of a lateral patellar dislocation is rather simple (**Figure 87-4**). Slightly flex the patient's hip to release the tension on the quadriceps muscles. Slowly and gently extend the knee (**Figure 87-4A**). The patella may relocate spontaneously by simply extending the knee. If it is still dislocated, apply gentle and medially directed pressure to the lateral surface of the patella (**Figure 87-4B**). This will allow the patella to move into its normal anatomic position in the intercondylar fossa of the femur. The technique to reduce a medially dislocated patella is similar with the exception of the application of a laterally directed force on the patella.

Intraarticular and horizontal patellar dislocations are sometimes reduced by closed manipulation, although most require open reduction. Superior patellar dislocations require operative reduction. These dislocations should not be reduced in the Emergency Department. Patients with these types of patellar dislocations require urgent consultation with an Orthopedic Surgeon and hospital admission for reduction.

AFTERCARE

Obtain a postreduction radiograph to rule out any osteochondral fractures that were not diagnosed initially and to ensure positioning of the patella. Maintain the knee in extension by immobilization with a long leg splint or knee immobilizer until follow-up for reevaluation. The Orthopedic Surgeon may elect to take a conservative approach with the leg in a long leg cast and the knee in full extension for 6 weeks.[6] Some Orthopedic Surgeons believe that all first-time dislocations should be repaired surgically. Thus, phone consultation with an Orthopedic Surgeon is recommended before the patient is discharged home.

The general principles of orthopedic care can be applied. These include rest, ice, elevation, and nonsteroidal anti-inflammatory drugs. Narcotic analgesics are not necessary or required in most cases. The patient should follow up with an Orthopedic Surgeon in 5 to 7 days. The patient will most likely need physical therapy. The instability and resultant tracking abnormalities will require strength, proprioceptive, and isometric rehabilitation.[7] Patients who are placed in splints or casts should use crutches and not bear weight on the affected extremity. Crutches may be of use to those placed in a knee immobilizer.

COMPLICATIONS

Patellar dislocations are subject to degenerative arthritis, osteochondral fractures (which may be difficult to diagnosis initially), and recurrent dislocations or subluxations. No complications are associated with the reduction procedure.

SUMMARY

Patellar dislocations are common. The reduction of a lateral or medial patellar dislocation is a safe, simple, and gratifying procedure. Education of the patient and follow-up with an Orthopedic Surgeon is a requirement for successful rehabilitation.

88 Knee Joint Dislocation Reduction

Sharad Pandit and Zach Kassutto

INTRODUCTION

Dislocations of the knee are rare. They are true orthopedic emergencies and have a significant association with soft tissue injuries and neurovascular compromise. A dislocated knee occurs most commonly after a major force is applied to the knee joint from motor vehicle trauma, pedestrian–vehicle collisions, bicycle collisions, or motorcycle collisions. The forces necessary to cause a dislocation of the knee joint often fracture the bones of the leg.

Complete dislocation of the knee joint results in a gross deformity that is confirmed by plain radiographs. Reduction by the Emergency Physician (EP) may be reasonable if the Orthopedic Surgeon is not immediately available and/or if the injured extremity shows signs of distal neurologic or vascular compromise.

A careful examination of the distal extremity must be performed and documented. **It must include an assessment of the capillary refill, the dorsalis pedis pulse, the posterior tibial pulse, peroneal nerve function, and tibial nerve function.**

ANATOMY AND PATHOPHYSIOLOGY

A knee dislocation is the displacement of the tibiofemoral articulation (**Figure 88-1**). It involves the rupture of the anterior cruciate ligament, the posterior cruciate ligament, the joint capsule, and/or the collateral ligaments of the knee. Anterior knee dislocations are the most common type of knee dislocation. This injury is defined as anterior displacement of the tibia relative to the femur (**Figure 88-1A**). It results from an acute hyperextension injury to the knee joint that ruptures the anterior cruciate ligament completely, the posterior cruciate ligament partially, and the posterior joint capsule. The distal femur is driven posterior to the proximal tibia. The collateral ligaments usually remain intact. Tibial spine fractures, osteochondral fractures of the tibia or femur, and meniscal injuries are avulsion-type fractures resulting from the rupture of the anterior cruciate ligament. Distal femoral epiphyseal separation, rather than complete dislocation, as a result of a hyperextension injury is more common in children.

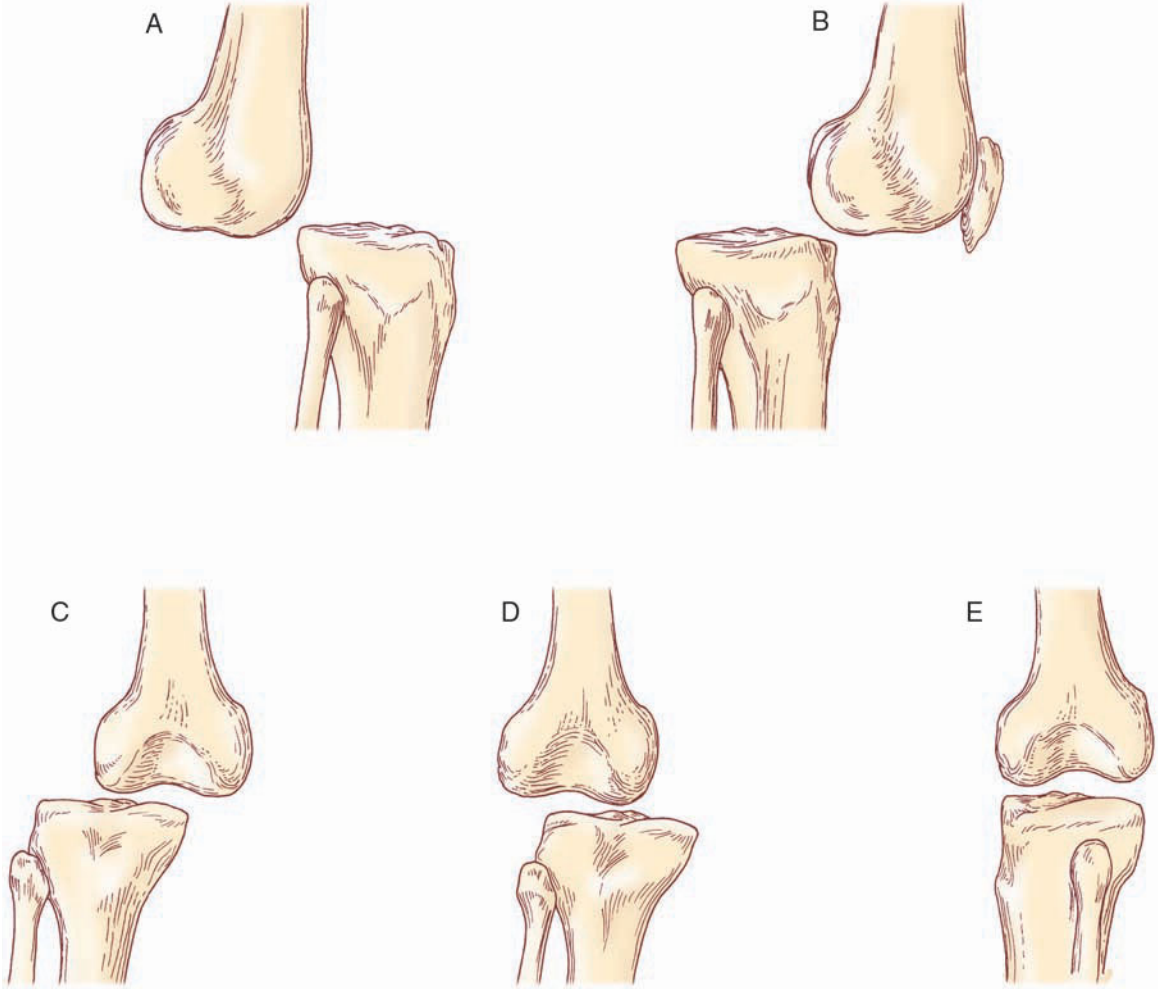

FIGURE 88-1. The classification of knee dislocations. **A.** Anterior. **B.** Posterior. **C.** Lateral. **D.** Medial. **E.** Rotary.

An anterior knee dislocation is associated with a popliteal artery injury in 30% to 40% of patients.[1] The popliteal artery is at particular risk for injury because it is anchored proximally at the adductor hiatus and distally at the soleus arch. The collateral circulation around the knee joint is relatively poor. Therefore disruption of the popliteal artery may result in distal ischemia and limb loss if the reduction is delayed. **It is important to note that the presence of distal peripheral pulses and capillary refill does not preclude an arterial injury.**

The peroneal nerve is tethered as it winds around the fibular neck. With knee dislocations, the peroneal nerve is at risk. Peroneal nerve injury may occur in up to 23% of patients with knee dislocations. Nearly one-half of the patients with peroneal nerve injuries have a permanent deficit.[10]

A posterior knee dislocation is defined as the posterior displacement of the tibia relative to the femur (**Figure 88-1B**). It occurs less commonly than an anterior knee dislocation. It results from a direct force applied to the anterior tibia with the knee slightly flexed, which ruptures the posterior joint capsule and both cruciate ligaments. The collateral ligaments usually remain intact. It is associated with popliteal artery damage and disruption of the extensor mechanism of the knee joint.

A posterolateral knee dislocation is a rare type of knee dislocation that is associated with peroneal nerve injury in up to 35% of patients.[2–4] These patients must be examined for peroneal nerve dysfunction (i.e., anesthesia or paresthesia on the lateral aspect of the leg and impaired dorsiflexion of the foot).

Medial, lateral, and rotary dislocations of the knee joint are less common than anterior or posterior knee dislocations (**Figures 88-1C, D, & E**). Medial knee dislocations result from an adduction force on the tibia that ruptures the lateral collateral ligament, the posterior joint capsule, and both cruciates. Damage to the peroneal nerve is common, while injury to the popliteal artery is not. Lateral knee dislocations result from an abduction force on the tibia that ruptures the medial collateral ligament, the posteromedial joint capsule, and both cruciates. Neurovascular injuries are uncommon with a lateral knee dislocation.

Rotary dislocations are subdivided into posterolateral and posteromedial types. Posterolateral rotary dislocations result from an anteromedial force on the tibia that ruptures the posterior and medial joint capsule, partially avulses the gastrocnemius, damages the menisci, and has an associated chondral fracture. Posteromedial rotary dislocations result from an anterolateral force on the tibia that ruptures both cruciates, the medial collateral ligament, the posteromedial joint capsule, partially avulses the gastrocnemius, damages the menisci, and has an associated chondral fracture. Both of these rotary dislocations are associated with peroneal nerve and popliteal artery injuries.

Medial, lateral, and rotary dislocations of the knee are uncommon injuries that should be managed by an Orthopedic Surgeon. The reduction technique for these dislocations is quite similar to that for the reduction of anterior or posterior knee dislocations.

Although the presentation of a knee dislocation is usually clinically obvious, it can also occur with a spontaneous reduction. **This type of injury is classified as an occult dislocation and can be easily missed if the patient is not thoroughly examined.**

Anteroposterior and lateral radiographs of the knee will confirm the diagnosis of a knee dislocation. Postreduction films in two planes will detect any occult fractures of the tibial spine, the distal femoral physis, or the proximal tibial physis. Obtain postreduction stress views if damage to the collateral ligaments is suspected. Radiographs of the pelvis and hip should also be considered to rule out any associated injuries.

INDICATIONS

Any dislocation of the knee joint requires prompt reduction in order to reestablish the normal anatomy of the knee joint. The reduction should ideally be accomplished within 6 to 8 hours after the injury. The incidence of limb loss is greater than 85% if the knee is dislocated longer than 6 to 8 hours.[5] **Knee dislocations associated with distal neurologic or vascular insufficiency require immediate and emergent reduction.**

CONTRAINDICATIONS

There are no absolute contraindications to the reduction of a dislocated knee joint. Reduction of the knee joint may be performed intraoperatively if the patient requires surgery for other reasons. An Orthopedic Surgeon should reduce the knee if it is dislocated medially, laterally, or rotatorily; if it is associated with fractures of the extremity; or if the joint is open. **Emergent reduction by the EP is indicated if the Orthopedic Surgeon is not immediately available and/or if there is evidence of distal neurologic or vascular compromise.**

EQUIPMENT

- Procedural sedation equipment and supplies (Chapter 129)
- Assistants
- Compressive cotton wrap (Webril)
- Splinting material
- Elastic bandage

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. The necessary postprocedural care should also be discussed. Obtain an informed consent for the reduction procedure as well as for the procedural sedation. Place the patient supine on a gurney. Apply procedural sedation. **The key to performing this procedure is to have the patient adequately sedated and their muscles relaxed.**

TECHNIQUES

ANTERIOR KNEE DISLOCATION REDUCTION

Reduction of an anterior knee dislocation is usually performed without difficulty using a modified traction-countertraction technique (**Figure 88-2**). Instruct an assistant to grasp the tibia and apply in-line traction while a second assistant grasps the thigh and applies countertraction. **It is extremely important to avoid putting pressure over the popliteal fossa as this could injure the structures traversing that space.** The EP then pushes the proximal tibia posteriorly (**Figure 88-2(1)**) while the distal femur is simultaneously lifted anteriorly into anatomic position (**Figure 88-2(2)**). **Do not allow the knee to become hyperextended during the reduction as this may further injure neurovascular structures.**

Some EPs feel that the reduction procedure may be easier to perform if the patient is in the prone position. Performing the procedure in the prone position is quite cumbersome, it is a difficult position to attain if other injuries are present, and it makes monitoring patients undergoing procedural sedation difficult. Therefore placing the patient in the prone position is not recommended.

FIGURE 88-2. Reduction of an anterior knee dislocation. An assistant applies inline traction to the tibia while a second assistant applies countertraction to the femur. The proximal tibia is pushed posteriorly (1) while the distal femur is pulled anteriorly (2) to reduce the dislocation.

POSTERIOR KNEE DISLOCATION REDUCTION

Reduction of a posterior knee dislocation is similar to that of an anterior knee dislocation. The two assistants provide in-line traction and countertraction while the EP grasps the proximal tibia and pulls it anteriorly into anatomic position (**Figure 88-3**).

MEDIAL KNEE DISLOCATION REDUCTION

Reduction of a medial knee dislocation is similar to that of the anterior knee dislocation. The two assistants provide in-line traction and countertraction while the EP grasps the proximal tibia and pulls it laterally into anatomic position.

LATERAL KNEE DISLOCATION REDUCTION

Reduction of a lateral knee dislocation is similar to that of the anterior knee dislocation. The two assistants provide in-line traction and countertraction while the EP grasps the proximal tibia and pulls it medially into anatomic position.

ROTARY KNEE DISLOCATION REDUCTION

Reduction of a posteromedial knee dislocation is similar to that of the anterior knee dislocation. The two assistants provide in-line traction and countertraction while the EP grasps the proximal tibia and simultaneously externally rotates and lifts it upward into anatomic position.

Reduction of a posterolateral knee dislocation should be performed in the Operating Room. These dislocations are irreducible using closed reduction techniques. The medial femoral condyle evaginates through the medial joint capsule in a process known as "buttonholing." This dislocation requires open reduction under general anesthesia.

ASSESSMENT

Immediately evaluate and document the neurologic and vascular status of the distal extremity after any attempts at reduction. Any diminished or absent sensation, motor deficits, and/or pulses require immediate angiography and operative intervention. Obtain postreduction radiographs to confirm proper anatomic reduction, to rule out any fractures not evident on the prereduction radiographs, and to rule out the displacement of any fracture fragments. Stress radiographs are recommended if injury to the collateral ligaments is suspected.

AFTERCARE

The postprocedural care of the knee joint is as important as the initial reduction. Immobilize the extremity in a posterior long leg splint with the knee in 15° of flexion. Administer intravenous and/or oral analgesics as necessary to control the patient's pain. All patients require admission to the hospital for observation and monitoring of the distal neurovascular status of the extremity. Arteriography should be obtained to exclude injury to the popliteal artery, especially if there is any irregularity in the dorsalis pedis or posterior tibial pulse before or after the reduction. Arteriography may not be necessary if the distal pulses are normal before and after the reduction; however, the vascular status should be closely monitored for 48 to 72 hours after the reduction.[6]

The mandatory use of arteriography to evaluate vascular injuries in patients with a normal postreduction physical examination may not be necessary.[13,14] These select patients who have a normal physical examination and a normal ankle brachial index may not require angiography and its associated complications. This is a decision that must be made in consultation with the Orthopedic Surgeon who will be managing the patient.

An inpatient magnetic resonance imaging (MRI) scan of the knee joint should be obtained to evaluate ligamentous injury. The patient may require reconstructive surgery on the knee joint. This is especially true if they are young, physically active, and well motivated to cooperate with rehabilitation therapy.[7]

COMPLICATIONS

Knee dislocations are true orthopedic emergencies because of the potential for associated vascular and neurological injuries. Complications are primarily related to injuries of the neurovascular

FIGURE 88-3. Reduction of a posterior knee dislocation. An assistant applies inline traction to the tibia while a second assistant applies countertraction to the femur. The proximal tibia is pulled anteriorly to reduce the dislocation.

structures crossing the popliteal fossa. These include popliteal arterial injury and peroneal nerve injury, as well as knee instability, knee arthrosis, knee stiffness, and chronic pain.[11,12]

Anterior knee dislocations have a high incidence (up to 40%) of associated vascular injuries usually involving the popliteal artery, and of these, up to one-half can result in amputation of the leg.[8] Nerve damage has been reported in the literature to occur in 20% to 40% of knee dislocations.[9] **These injuries and any associated fractures should not be missed. Pressure to the popliteal fossa during the reduction and hyperextension of the knee postreduction must be avoided to prevent iatrogenic neurovascular damage.** Injuries to neurologic and vascular structures can occur during the reduction. These include lacerations, traction injuries, and nerve or vascular entrapment between the tibial plateau and the femoral condyles.

Irreducible dislocations may be secondary to interposed soft tissue, ligamentous instability, buttonhole tears in the medial joint capsule, or entrapment of the medial femoral condyle. These patients require operative reduction under general anesthesia by an Orthopedic Surgeon.

SUMMARY

Knee dislocations occur after significant trauma to the knee joint. Fortunately, knee dislocations are rare events. They are associated with significant morbidity and require prompt reduction to restore the normal alignment of the bony structures. Arteriography to rule out damage to the popliteal artery and an MRI scan to rule out soft tissue injuries should be performed after the knee joint has been reduced and adequately splinted. All patients require admission for observation and eventual reconstructive surgery. Frequent neurovascular evaluation is extremely important during the hospitalization. Evidence of distal leg ischemia requires immediate surgical exploration.

89 Ankle Joint Dislocation Reduction

Jim Comes

INTRODUCTION

The foot and the ankle are the most frequently injured parts of the body. Fractures of the ankle associated with dislocations of the ankle joint (fracture-dislocations) are serious injuries that can lead to long-term morbidity. They occur most commonly in young people who participate in sports, in those suffering from falls, or in those involved in motor vehicle collisions. The ankle mortise and surrounding ligaments make the ankle joint strong and stable. As a result, isolated ankle dislocations are uncommon. Ankle dislocations are usually associated with malleolar fractures or a fracture of the tip of the tibia. They are open 25% of the time. While there are limited data on the mechanism of injury, most ankle dislocations lead to posterior or posteromedial displacement and occur from a force against a plantarflexed foot. Fracture-dislocations are often treated definitively in the Operating Room. Despite this, patients benefit from early analgesia and prompt reduction.

Ankle dislocations can be successfully reduced in the Emergency Department with the use of procedural sedation and longitudinal traction-countertraction.[1] Postreduction management invariably involves leg immobilization and consultation with an Orthopedic Surgeon. Some closed ankle dislocations may be managed nonoperatively with good long-term results from a closed reduction and casting for 6 to 9 weeks.[2–5]

ANATOMY AND PATHOPHYSIOLOGY

The ankle joint is composed of the talus, tibia, and fibula. The inferior articular surface of the tibia is concave in both the coronal and sagittal planes. The articular surface of the talus is broader anteriorly and longer on its medial and lateral aspects.[6] The ankle mortise limits rotation of the talus, making the ankle joint inherently stable.

There are three groups of ligaments that provide added stability to the ankle joint. It is stabilized laterally by the anterior talofibular, the calcaneofibular, and the posterior talofibular ligaments (**Figure 89-1**). It is stabilized medially by the deltoid ligament, which comprises a group of four adjoining ligaments: the anterior and posterior tibiotalar, the tibionavicular, and the tibiocalcaneal ligaments (**Figure 89-2**). The third group of ligaments stabilizes the tibia to the fibula and forms the tibiofibular syndesmosis. This includes the anterior and posterior tibiofibular ligaments.

Almost all ankle dislocations are associated with ligamentous ruptures, either partial or complete (**Figure 89-3**). They are often associated with malleolar and distal fibula fractures. While posterior or posteromedial ankle dislocations are the most commonly described dislocations of the ankle joint[4,7] (**Figures 89-3A & 89-4**). The most common ankle dislocations seen by the editor are lateral ankle fracture-dislocations (**Figure 89-3B**). Posterior ankle dislocations are associated with posterior marginal fractures of the tibia. An anterior ankle dislocation is rare and usually associated with a fracture of the anterior margin of the tibia (**Figure 89-3C**). The talus may also dislocate laterally or medially if the tibiofibular ligaments are disrupted or a fracture of one or both malleoli occurs. The medial and lateral ligamentous complexes are usually stronger than the malleoli. This results in one or both malleoli fracturing, rather than the ligaments tearing, with a lateral fracture-dislocation.[8]

Due to the low incidence of reported ankle dislocations without fractures, data on the mechanism of injury are incomplete.[9] A posteromedial ankle dislocation occurs when a force is applied against the posterior distal tibia with the foot plantarflexed. Anterior ankle dislocations occur from a forcible dorsiflexion of the foot (e.g., fall on the heel with the foot dorsiflexed) or from a force applied to the distal anterior tibia while the foot is fixed. Injury to the tibiofibular joint is variable, and the fibula may be dislocated posteriorly or anteriorly. Diastasis of the tibiofibular syndesmosis is uncommon. Lateral ankle dislocations are always associated with fractures of the malleoli. They occur from a force on the distal fibula with the foot fixed to the ground. Superior ankle dislocations are uncommon (**Figure 89-3D**). They occur when a force from above is driven through the leg and to the ankle (e.g., a fall from a height).

Physical examination often reveals the type of ankle dislocation. Prominence of the talus and a change in the length of the foot are common. Neurovascular injury is uncommon, although there is a higher incidence of this with open dislocations. Ankle dislocations are associated with a risk of vascular injury and the development of a compartment syndrome from severe swelling.[7] Most vascular injuries are to the dorsalis pedis or posterior tibial vessels and may be accompanied by damage to the adjacent superficial peroneal nerve or sural nerve, respectively.[1,6] Tibiotalar dislocations rarely result in avascular necrosis.

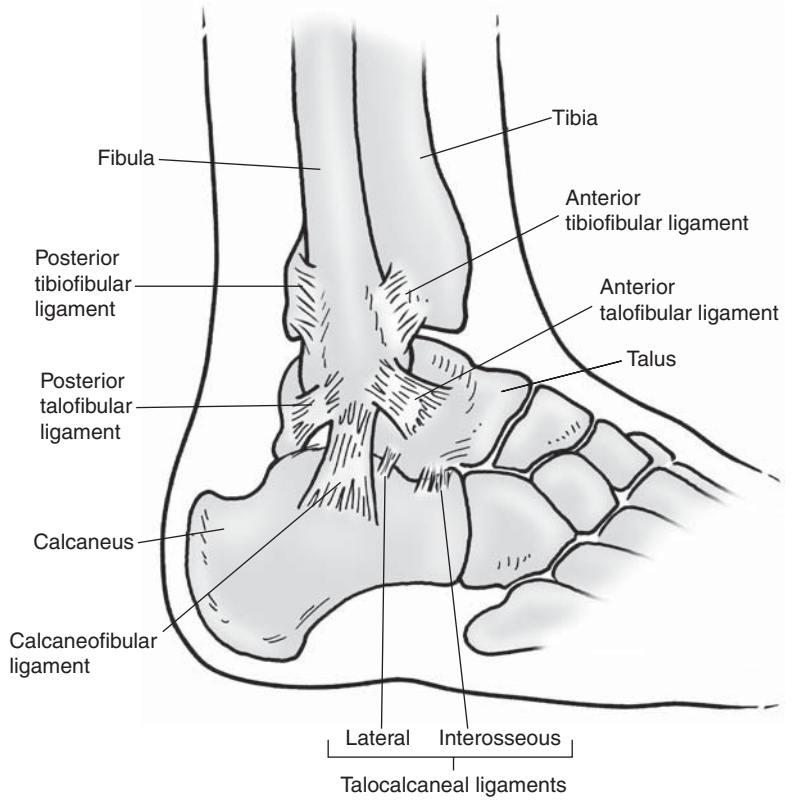

FIGURE 89-1. The bony and ligamentous structures of the lateral ankle.

INDICATIONS

All closed ankle fracture-dislocations and isolated dislocations should be reduced urgently not only to protect the soft tissues and decrease swelling, but also to minimize articular injury. Some authors recommend reduction prior to radiography.[10] **Any dislocation, open or closed, that has evidence of distal neurologic or vascular compromise must be reduced emergently.** Extreme lateral deviation may compromise the dorsalis pedis artery and requires prompt reduction.[10] All open dislocations require intravenous antibiotics, irrigation, surgical debridement, and reduction by an Orthopedic Surgeon in the Operating Room. However, reduction

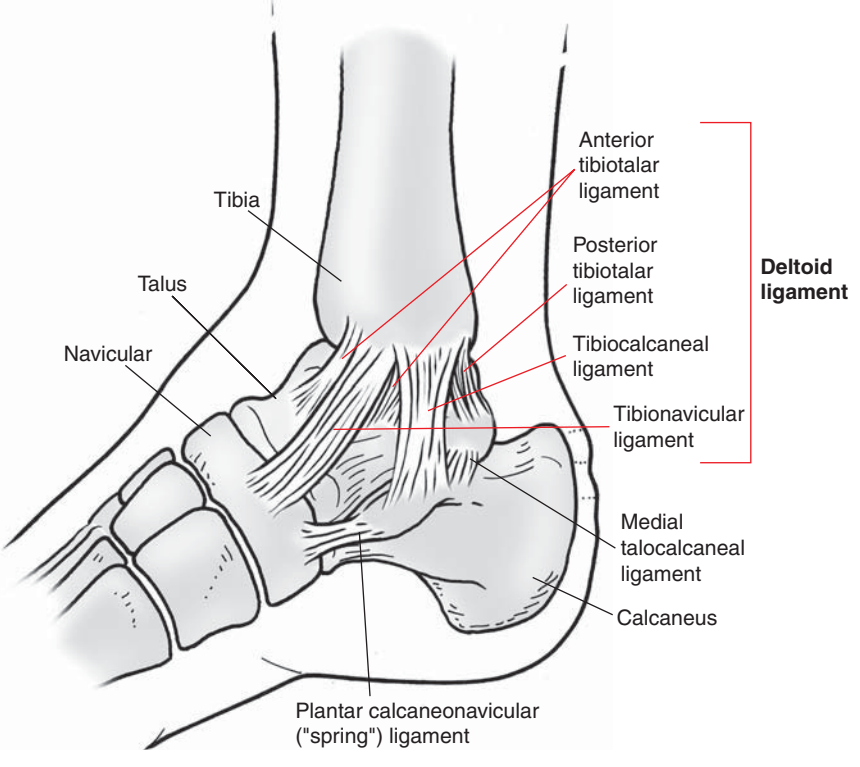

FIGURE 89-2. The bony and ligamentous structures of the medial ankle.

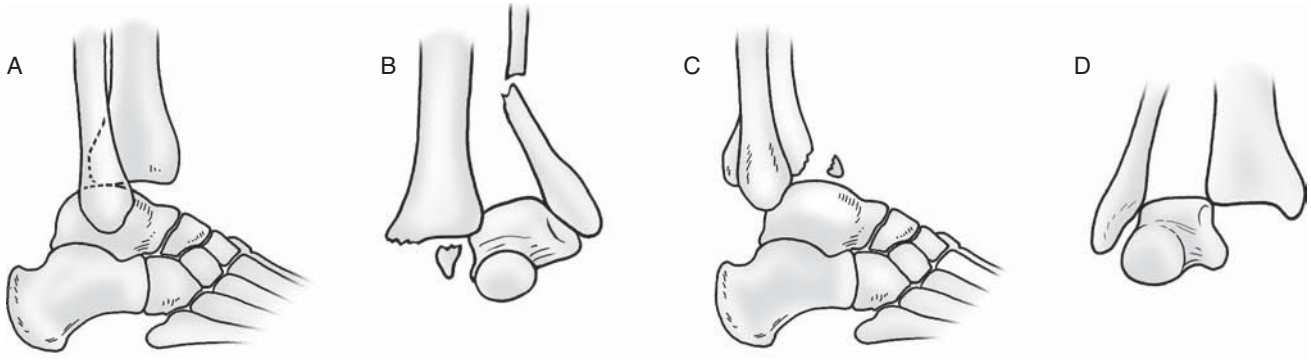

FIGURE 89-3. Types of ankle dislocations. **A.** Posterior. **B.** Lateral. **C.** Anterior. **D.** Superior.

should occur in the Emergency Department if the Orthopedic Surgeon or the Operating Room is not immediately available.[3]

CONTRAINDICATIONS

There are no absolute contraindications to reducing a dislocated ankle. Some authors would not recommend Emergency Department reduction of an open fracture-dislocation without evidence of neurovascular compromise or in a setting where immediate orthopedic and operative intervention was available.

FIGURE 89-4. Radiograph of a posterior ankle dislocation.

EQUIPMENT

- Local anesthetic solution
- 18 gauge needle
- 22 gauge needle, 2 in. long
- Equipment and supplies for procedural sedation (Chapter 129)
- Equipment and supplies for IV regional anesthesia (Chapter 127)
- Stockinette
- Compressive wrap (Webril)
- Plaster, fiberglass, or commercially prepared splinting material
- Elastic bandage

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the reduction procedure and the procedural sedation to the patient and/or their representative. Obtain an informed consent for both procedures. Place the patient supine with the affected foot at the edge of the gurney. Patients should be premedicated with an opioid analgesic prior to the procedure and ideally prior to radiography. Procedural sedation (Chapter 129) provides excellent analgesia, muscle relaxation, and sedation, allowing the reduction procedure to be more tolerable for both the patient and the physician. Intra-articular lidocaine has been reported as an effective alternative to conscious sedation for closed reduction of ankle fracture dislocations.[11] Please refer to Chapter 77 regarding the details of ankle arthrocentesis. An additional alternative is IV regional anesthesia (Bier block) of the lower leg (Chapter 127).

TECHNIQUES

The techniques described below to reduce ankle dislocations have three things in common. The hip and knee are flexed to relieve the tension on the gastrocnemius and soleus muscles. The foot is flexed (plantarflexed or dorsiflexed) to unlock or disengage the talus. Finally, the talus is maneuvered into its proper anatomic position.

LATERAL ANKLE DISLOCATIONS

Flex the patient's hip and knee by placing a pillow behind their knee. Grasp the calcaneus with one hand and the forefoot with the other hand (**Figure 89-5A**). Instruct an assistant to grasp the patient's calf. Apply distal traction to the heel while the assistant provides countertraction to the leg (**Figure 89-5A**). The next step is to rotate the

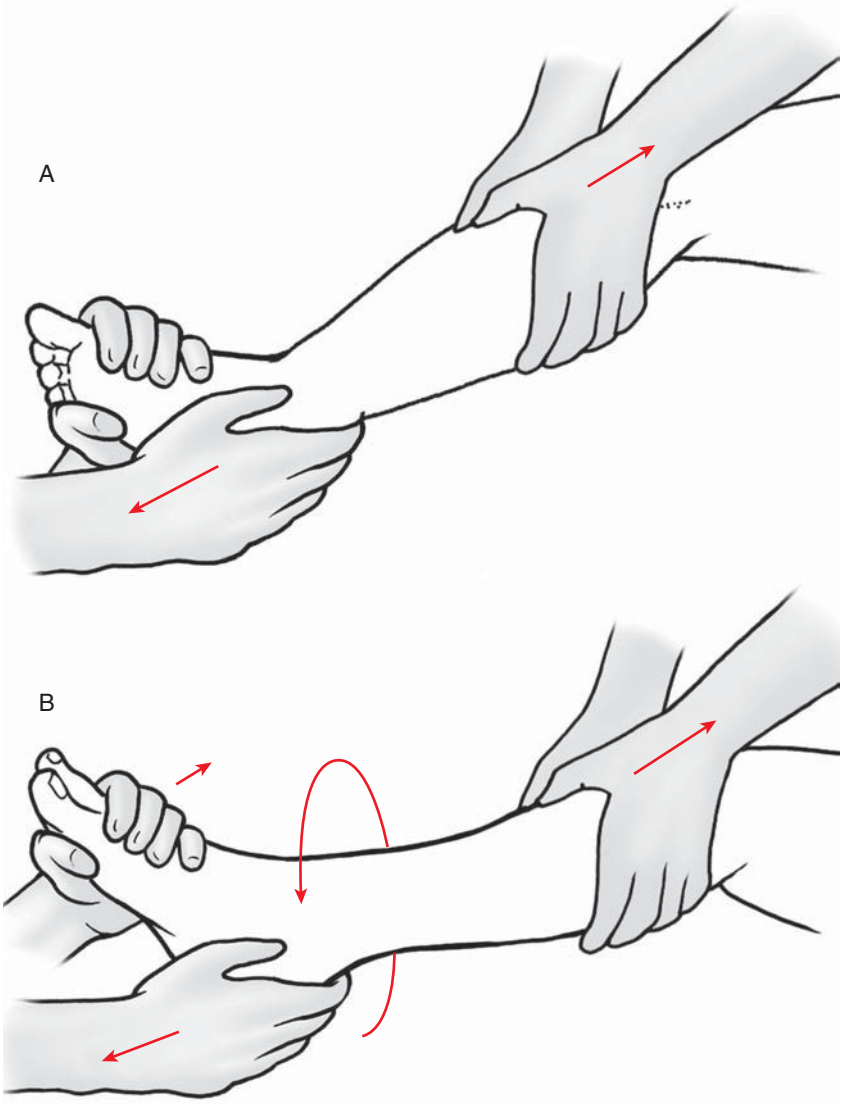

FIGURE 89-5. Closed reduction of a lateral ankle dislocation. **A.** The heel is distracted while an assistant provides countertraction. **B.** Simultaneously, medially rotate and dorsiflex the foot while distracting the heel.

foot medially so that the great toe is in alignment with the anterior tibia while simultaneously dorsiflexing the foot and distracting the heel (**Figure 89-5B**). The talus will reduce easily with a palpable and audible "clunk."

POSTERIOR ANKLE DISLOCATIONS

Flex the patient's hip and knee by placing a pillow behind their knee. Grasp the calcaneus with one hand and the forefoot with the other hand (**Figure 89-6A**). Instruct an assistant to grasp the patient's calf. Simultaneously apply distal traction to the heel and plantarflex the foot while the assistant provides countertraction to the leg (**Figure 89-6A**). The next step is to dorsiflex the foot while distracting the heel and a second assistant provides posteriorly directed pressure on the distal leg (**Figure 89-6B**). The talus will reduce with a palpable and audible "clunk."

ANTERIOR ANKLE DISLOCATIONS

Flex the patient's hip and knee by placing a pillow behind their knee. Grasp the calcaneus with one hand and the forefoot with the other hand (**Figure 89-7A**). Instruct an assistant to grasp the patient's calf. Simultaneously apply distal traction to the heel and dorsiflex the foot until the toes point upright while the assistant provides countertraction to the leg (**Figure 89-7A**). The next step is to push the foot posteriorly while distracting the heel and a second assistant provides anteriorly directed pressure on the distal leg (**Figure 89-7B**). The talus will reduce with a palpable and audible "clunk."

SUPERIOR ANKLE DISLOCATIONS

Superior ankle dislocations are associated with significant soft tissue and articular damage. Neurovascular injury is uncommon with these dislocations. Superior ankle dislocations should be reduced, splinted, and managed by an Orthopedic Surgeon. The only exception to this is if there is neurologic and/or vascular compromise of the distal extremity and no Orthopedic Surgeon is immediately available.

OPEN ANKLE DISLOCATIONS

The Emergency Physician occasionally reduces open ankle dislocations if neurologic and/or vascular compromise of the foot is present and an Orthopedic Surgeon is not immediately available. Copiously irrigate the wound with sterile saline before attempting the reduction. The technique to reduce an open ankle dislocation is the same as that for a closed ankle dislocation.

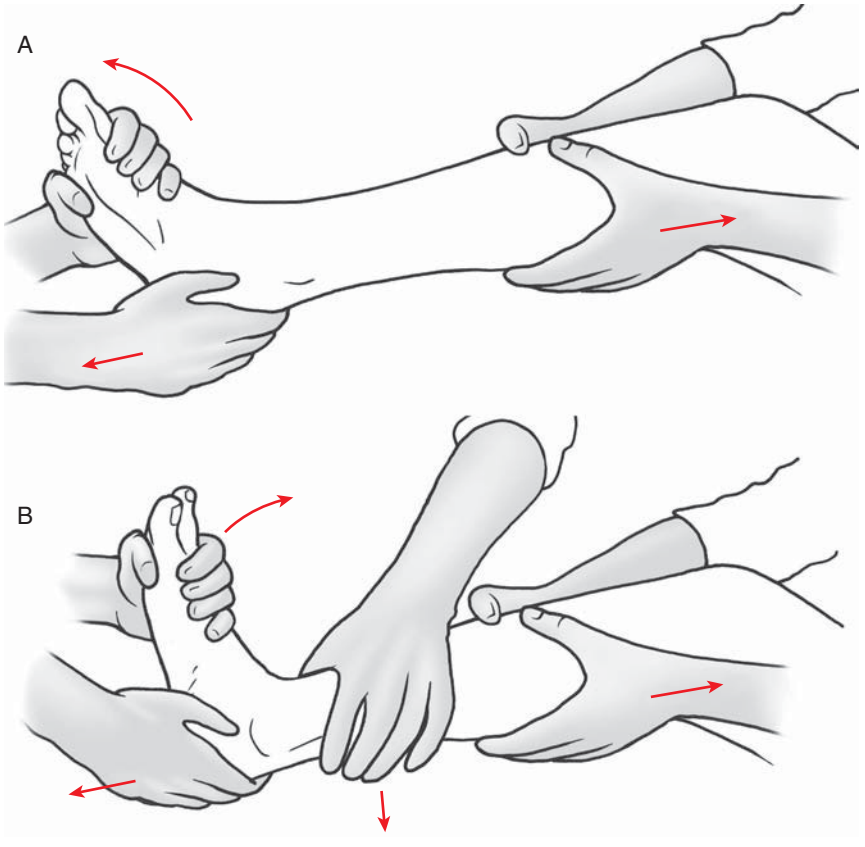

FIGURE 89-6. Closed reduction of a posterior ankle dislocation. **A.** The heel is distracted and the foot is plantarflexed while an assistant provides countertraction. **B.** The foot is dorsiflexed while the heel is distracted and a second assistant applies posterior traction on the distal leg.

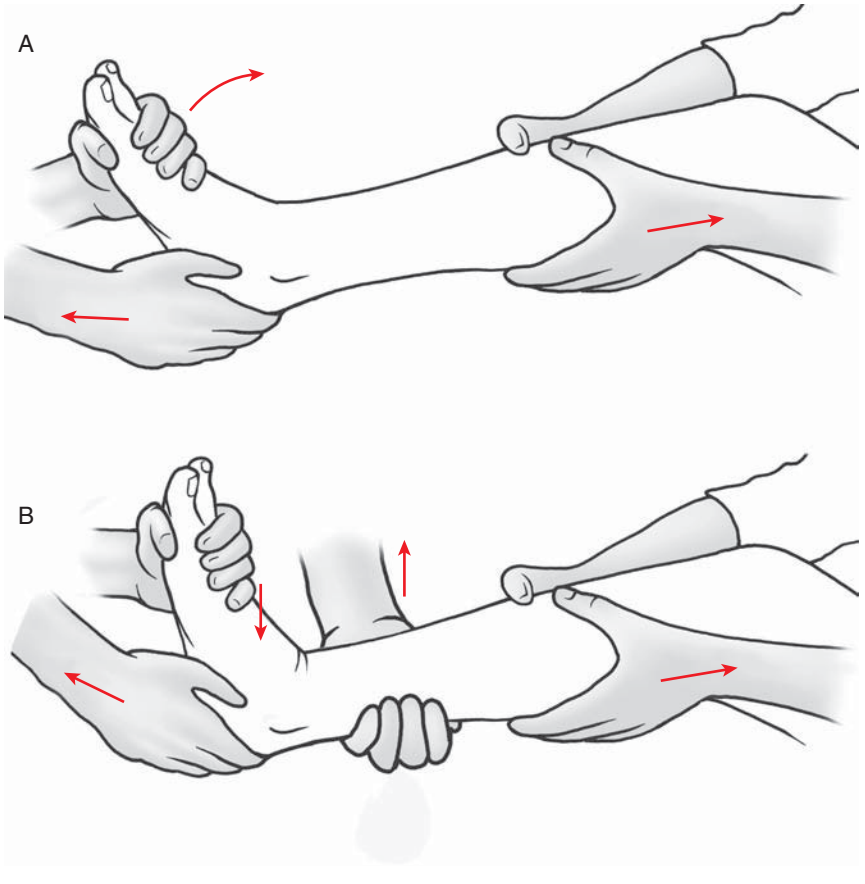

FIGURE 89-7. Closed reduction of an anterior ankle dislocation. **A.** The heel is distracted and the foot is dorsiflexed until the toes are upright, while an assistant provides countertraction. **B.** The foot is pushed posteriorly while the heel is distracted and a second assistant applies anterior traction on the distal leg.

ASSESSMENT

Verify and document the neurologic and vascular status of the foot before and after any attempts at reduction. Any diminution or the absence of normal neurologic or vascular signs requires emergent consultation with an Orthopedic Surgeon.

AFTERCARE

Splint the extremity. Apply a three-sided short leg splint from the base of the toes to just below the knee for posterior, lateral, and superior ankle dislocations that have been reduced. Immobilize the ankle in 90° of flexion and in a neutral position with respect to inversion and eversion.[7] Immobilize the reduced anterior ankle dislocation with the ankle in slight plantarflexion. The limb should be elevated, not bear weight, have frequent neurologic and vascular checks, and have frequent assessments for the development of the signs associated with a compartment syndrome.[7]

COMPLICATIONS

Most complications occur as a result of the fracture-dislocation and not the reduction procedure. This includes neurologic damage, vascular damage, and compartment syndromes. A posttraumatic peroneal tendon dislocation can occur and may be initially unrecognized. The patient usually becomes symptomatic after the acute stage, when the tendon subluxes and dislocates. There is a low rate of subsequently developing avascular necrosis and degenerative joint disease with isolated ankle dislocations.

Complications associated with the reduction procedure, if they occur at all, are usually neurologic and vascular injuries. These structures may become impinged, or trapped, in the relocated joint or on a fracture fragment. **Emergently consult an Orthopedic Surgeon if there is any diminished or absent function of any nerve or artery.**

SUMMARY

Ankle dislocations without fractures are uncommon yet serious injuries. Closed ankle dislocations can be reduced emergently and successfully with the use of procedural sedation. Open ankle dislocations should be irrigated in the Emergency Department and reduced rapidly after consultation with an Orthopedic Surgeon. Reduction, irrigation, and debridement are all likely to occur in the Operating Room if an Orthopedic Surgeon is immediately available. Any ankle dislocation with evidence of distal neurovascular compromise should be reduced immediately. All patients with ankle dislocations should have an Orthopedic Surgery consultation. The majority of closed ankle dislocations are managed nonoperatively with good long-term results.

90 Common Fracture Reduction

Eric F. Reichman and Robert M. Zesut

INTRODUCTION

Extremity fractures are a common reason for Emergency Department (ED) visits. If there is no neurologic or vascular compromise, most closed fractures can be managed conservatively in the ED with splinting and Orthopedic Surgeon follow-up. This chapter addresses four common fractures of the upper extremity that may require reduction by the Emergency Physician (EP). These include clavicular fractures, Colles fractures, displaced surgical neck fractures of the humerus, and supracondylar fractures of the humerus. **The reduction of fractures in the ED should involve consultation with an Orthopedic Surgeon prior to performing the procedure. The only exception to this is if neurologic or vascular compromise exists in the extremity.**

CLAVICULAR FRACTURES

INTRODUCTION

Clavicular fractures are common and represent approximately 5% of all fractures.[1–3] Most of these occur at the junction of the middle and distal third of the clavicle, just medial to the coracoclavicular ligament. The clavicular fracture is the most common fracture encountered in childhood and occurs most often as a result of a fall. These fractures are usually detectable clinically, with plain radiographs helping to confirm the diagnosis. Although these fractures are relatively common, there is a small but definite risk of associated complications.

ANATOMY AND PATHOPHYSIOLOGY

The clavicle is the only bony attachment of the upper extremity to the axial skeleton. It serves as a strut to support the shoulder girdle. It provides support and stabilization of the upper limb while allowing a broad range of movements. The clavicle is securely attached at both the acromioclavicular and sternoclavicular joints by ligaments (**Figure 90-1**). The great vessels of the upper extremity and nerves of the brachial plexus pass posteriorly to the clavicle at its midportion where it overlies the first rib. The proximity of these neurovascular structures, as well as the underlying lung, accounts for most of the potential complications of clavicular fractures.

The most commonly used classification for clavicular fractures was proposed by Allman.[4] This simple classification is useful clinically and mechanistically to the EP. Group I fractures are midclavicular and account for approximately 80% of clavicular fractures. These most often result from a shearing force applied to the lateral aspect of the shoulder. Group II fractures involve the distal third of the clavicle and account for approximately 15% of all clavicular fractures. These most often result from a direct blow to the top of the shoulder. Several additional subclassifications have been proposed for these fractures based on the location of the fracture and associated ligamentous injury. Operative repair is suggested for some of these subtypes. All distal clavicular fractures should therefore be referred for follow-up within 24 hours to an Orthopedic Surgeon.[1,2] Group III fractures represent about 5% of clavicular fractures and involve the proximal third of the clavicle. They often result from a direct blow to the chest.

Patients with clavicular fractures are easily identified clinically. The clavicle is almost entirely subcutaneous, allowing most fractures to be palpated. Presenting signs and symptoms include localized pain, ecchymoses, and edema. Physical examination findings include superior and posterior displacement of the proximal portion of the clavicle due to traction from the sternocleidomastoid muscle (**Figure 90-2**). The shoulder is often displaced inferiorly by the weight of the upper extremity and the force of gravity. Medial displacement of the shoulder may be seen due to traction from the pectoral and the latissimus dorsi muscles.

Most fractures are readily identifiable on standard anteroposterior radiographs. Some group II and III fractures may not be readily identifiable.[1] Additional views at a 45° angle cephalad (apical

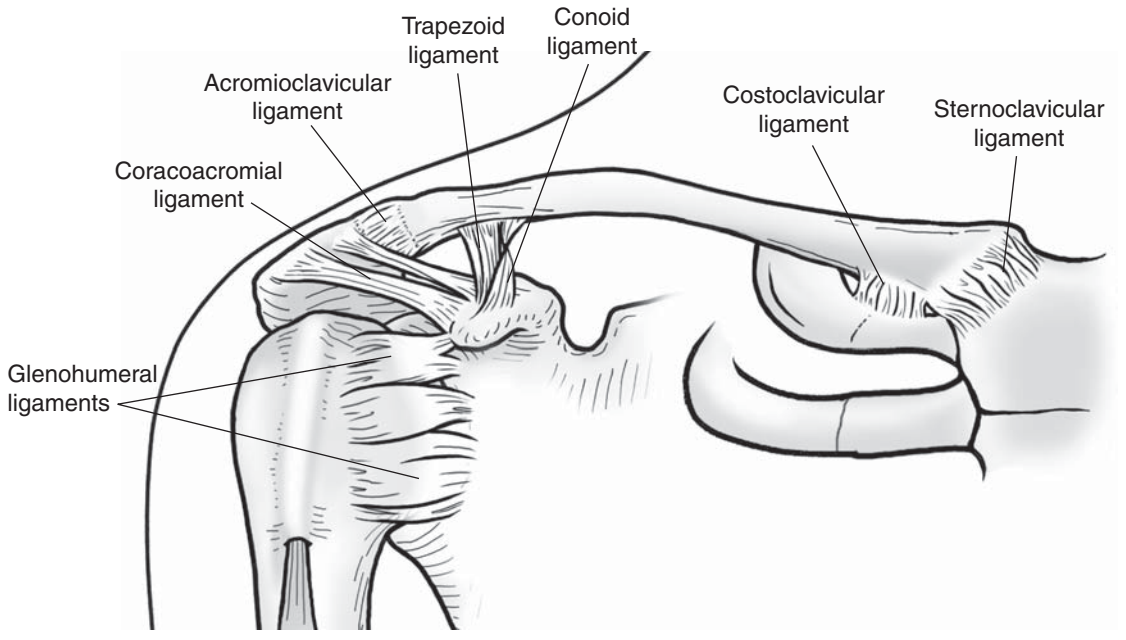

FIGURE 90-1. The clavicle serves as a strut between the torso and upper extremity; it is held firmly by the acromioclavicular and sternoclavicular ligaments. The brachial plexus and great vessels pass behind the middle third of the clavicle.

lordotic view) or 15° posteroanterior radiograph may be useful to assess displacement.[1,3,11] Evaluation of fracture union with spiral computed tomography may allow the best assessment of displacement. Computed tomography is usually required for adequate visualization of medial-end fractures, particularly those extending into the sternoclavicular joint.[12] Special views (e.g., cone views, tomograms, and upper rib films) may be required and are best determined in consultation with an Orthopedic Surgeon.

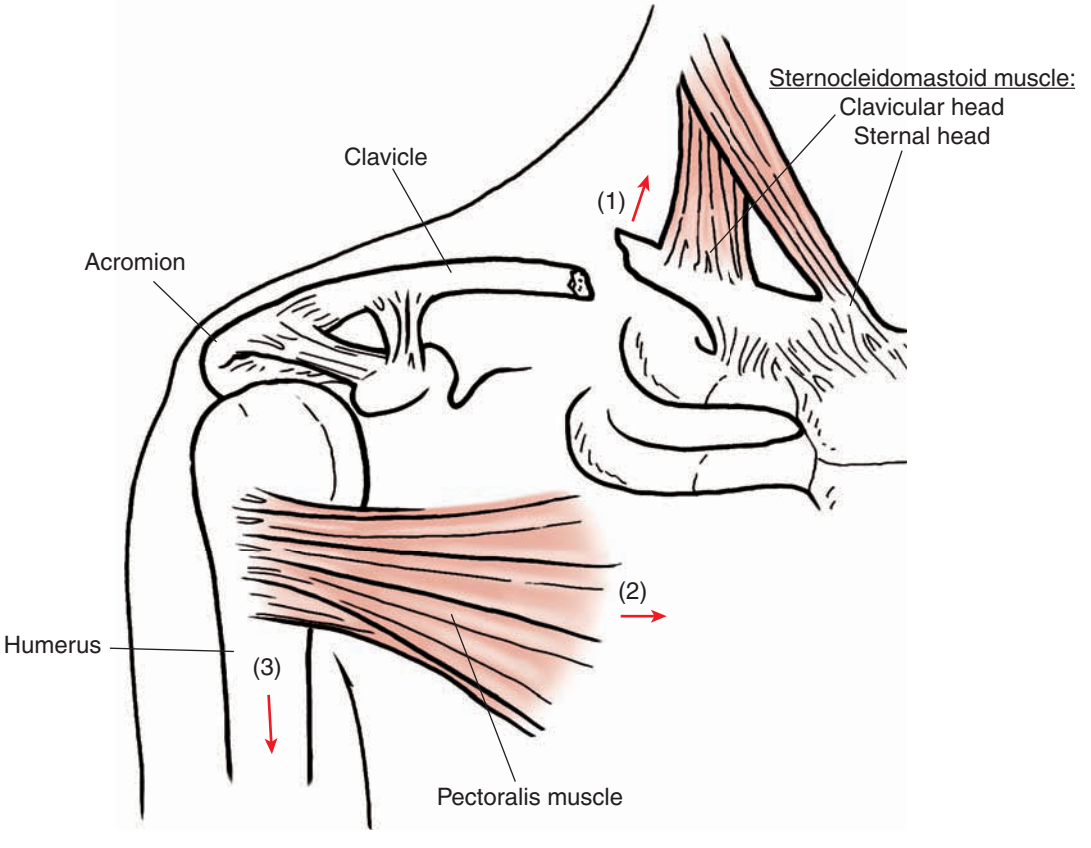

FIGURE 90-2. Displacement of the clavicle and shoulder after a clavicular fracture. The clavicular head of the sternocleidomastoid muscle displaces the proximal clavicular fragment superiorly and posteriorly (1). The pectoralis major and latissimus dorsi muscles pull the shoulder medially (2). The force of gravity displaces the distal clavicle and shoulder inferiorly (3).

Clavicular injury and pain in children present two concerns. First, nondisplaced greenstick fractures to the clavicle may not be radiographically visible for 7 to 10 days.[2,3] Clinical suspicion of a clavicular fracture with a negative radiograph should prompt conservative management. Follow-up should be arranged for 7 to 10 days after the injury to obtain repeat radiographs. Second, it may be unclear if the epiphyses are involved in some group II and III fractures.[2,3] **Any fracture through the epiphysis, or possibly through the epiphyses, requires an urgent referral to an Orthopedic Surgeon.**

INDICATIONS

Reduction of clavicular fractures is necessary in a few circumstances. **It is required if neurologic and/or vascular compromise is present in the affected extremity.** This includes medial fracture displacement producing superior mediastinal compromise. In these circumstances, an emergent attempt at closed reduction should be made.[11,13] Consider patients who are actively involved in athletics or have jobs that require overhead use of their arms (e.g., painters) for operative reduction by an Orthopedic Surgeon. Distal clavicular fractures that are displaced should be reduced. Otherwise, reduction is optional and at the discretion of the treating physician.

CONTRAINDICATIONS

Reduction of most clavicular fractures is not usually necessary in either the pediatric or adult patient.[1,2] A sling for simple arm support provides results comparable to the figure-of-eight reduction without the risk of brachial plexus injury or patient discomfort.[1–3] The sling may be additionally supported by a swath (**Figure 90-3A**) or a Velpeau wrap (**Figure 90-3B**). However, many physicians still prefer the use of a figure-of-eight strap (**Figures 90-3C & D**). The figure-of-eight splint still represents the treatment of choice in patients over the age of 10 years in the presence of greatly displaced fragments.[2,3] Despite this, there is no evidence that the figure-of-eight splint offers any advantage over a simple sling for midclavicular fractures. It is of note that the rates of compression of the neurovascular bundle, axillary pressure sores, and nonunion are higher in patients treated with the figure-of-eight splint.[11,12]

Contraindications to the reduction of a clavicular fracture include other injuries that represent a threat to life or limb. The patient's airway, breathing, and circulation must first be addressed and stabilized. Patients with open clavicular fractures require emergent consultation with an Orthopedic Surgeon, intravenous antibiotics, and hospital admission for possible open reduction and internal fixation. Reduction is also contraindicated if an expanding hematoma, indicative of a vascular injury, is observed. Finally, unfamiliarity with technique is a relative contraindication.

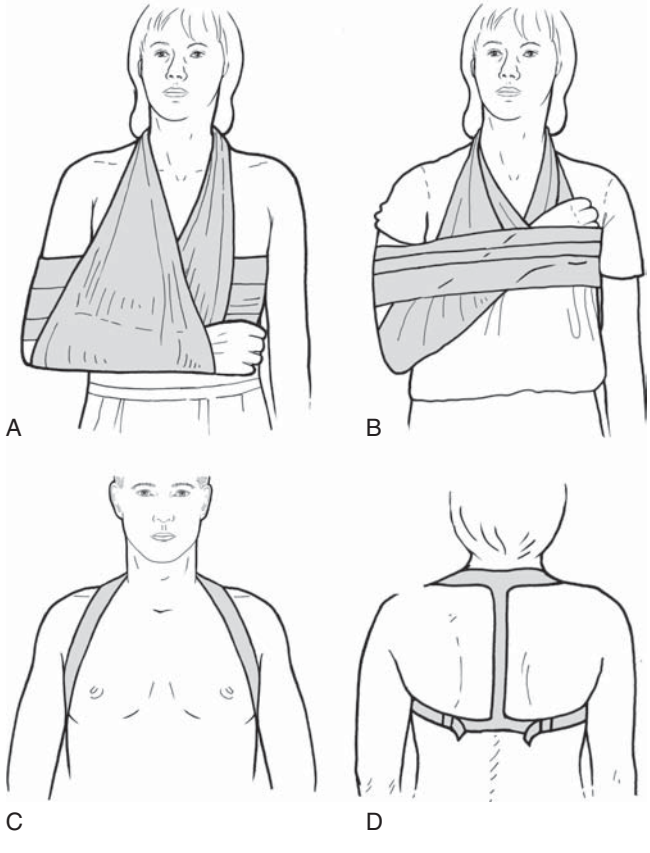

FIGURE 90-3. Treatment of clavicular fractures. **A.** Sling-over-swath immobilization. **B.** Velpeau sling immobilization. **C.** Anterior view of the figure-of-eight splint **D.** Posterior view of the figure-of-eight splint.

EQUIPMENT

- Figure-of-eight splint strap (commercially available)
- Sling
- Swath
- Kerlix rolls
- Elastic bandage

PATIENT PREPARATION

Explain the risks, and benefits of the reduction technique and aftercare to the patient and/or their representative. As with any procedure, informed consent should be obtained. Consider the administration of oral, intramuscular, or intravenous analgesics for patient comfort during the procedure. Procedural sedation is not needed or required for this fracture reduction.

TECHNIQUE

Sit the patient upright on the side of the stretcher with their feet on the floor. Alternatively, the patient may be standing upright. Stand behind the patient. Grasp and pull both of the patient's shoulders backward as if the patient were standing at attention. Instruct an assistant to apply the figure-of-eight splint while the patient is in this position. Apply the splint like a backpack and tighten the straps (**Figures 90-3C & D**). Reassess the neurologic and vascular integrity of the affected extremity after applying the splint.

ASSESSMENT

The neurologic and vascular integrity of the upper extremity should be assessed for all patients both initially, following any reduction attempts, and after the application of a figure-of-eight splint. Any neurologic and/or vascular compromise requires an emergent consultation with an Orthopedic Surgeon.

AFTERCARE

Patients with uncomplicated fractures should be referred to an Orthopedic Surgeon in 7 to 10 days. Patients with group II distal fractures and any fracture in a child potentially involving the epiphysis should have an urgent consultation with an Orthopedic Surgeon within 24 to 48 hours. Any patient with neurologic or vascular compromise, a pneumothorax, or signs of

vascular injury should be admitted to the hospital after an emergent consultation with an Orthopedic Surgeon.

Once the acute pain has subsided, the use of the sling can normally be discontinued and patients are encouraged to participate normal activities as pain allows. Most patients respond well to self-administered range-of-motion exercises. Recovery of the range of motion of the shoulder is usually swift, and supervised physiotherapy is very rarely required.[13]

General principles of orthopedic care are recommended. These include the application of ice, rest, nonsteroidal anti-inflammatory drugs, and narcotic analgesics as needed. Most patients find the figure-of-eight splint difficult to apply, extremely uncomfortable, and remove it shortly after its application. If the patient tolerates the splint, it should be tightened daily. The figure-of-eight splint should be worn until there is evidence of clinical union and the arm can be abducted without pain. This generally requires 3 to 5 weeks in children and 6 or more weeks in adults.[1,2] It may be more advantageous to apply a sling and swath or a sling and Velpeau wrap for patient comfort and compliance (**Figures 90-3A & B**). The outcomes of applying a figure-of-eight splint versus a sling are equivalent.[18,19] Alternatively, apply a shoulder immobilizer.

The sling is used to immobilize and elevate the elbow, forearm, and hand. It is also used to support the upper extremity. Slings are often used to support casts or splints of the upper extremity. These devices are simple, inexpensive, and effective. **It is imperative that the sling not be too short to allow the wrist and hand to hang over the sling.** This can result in an ulnar nerve neuropraxia.

The addition of a swath to a sling is used to immobilize dislocated shoulders that have been reduced and proximal humeral fractures (**Figure 90-3A**). The swath immobilizes the humerus against the torso to limit motion at the shoulder. A shoulder immobilizer may be substituted for a sling and swath.

The Velpeau wrap is a sling-and-swath technique that positions the forearm diagonally rather than horizontally (**Figure 90-3B**). The Velpeau wrap has no practical advantages over a sling and swath.

COMPLICATIONS

Complications of the reduction procedure include injuries to the brachial plexus, subclavian artery, and/or vein.[1,2] Commonly, these are the result of the initial injury and not the reduction procedure. **It is imperative to perform a neurologic and vascular examination prior to and after any attempt at reducing a clavicular fracture. Any neurologic or vascular deficit requires an immediate consultation with an Orthopedic Surgeon.**

SUMMARY

Clavicular fractures are common, easily diagnosed, and often treated in the ED. Fractures of the distal or medial third may be more challenging. Although the incidence of complications is low, a thorough search for resultant or concomitant injury is required. Any evidence of neurologic or vascular compromise requires an emergent consultation with an Orthopedic Surgeon.

COLLES FRACTURE

INTRODUCTION

A Colles fracture is a transverse fracture of the distal radial metaphysis with dorsal displacement and angulation of the distal fragment. The fracture usually occurs 2 cm from the distal end of the radius (**Figure 90-4**). The most common mechanism producing a Colles fracture is a fall on an outstretched hand.[5,6] The majority of fractures occur in patients 50 years of age and older.[5,6] This fracture is more commonly seen in women than in men.

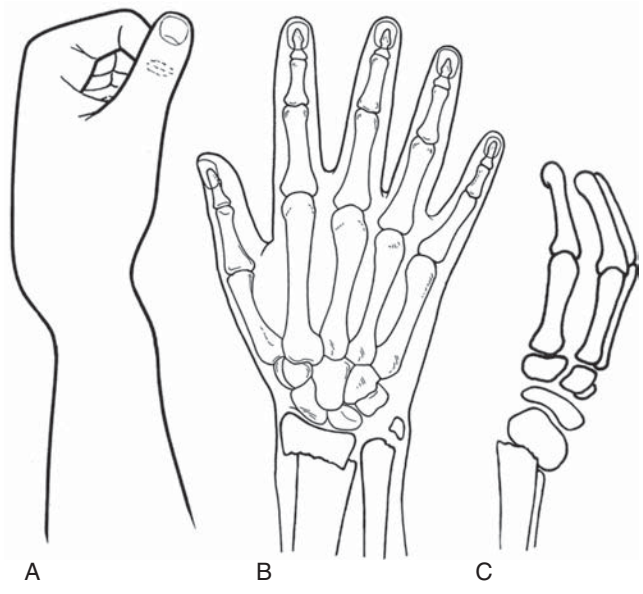

FIGURE 90-4. The Colles fracture. **A.** The dinner fork deformity, which is often seen. **B.** Anteroposterior view. **C.** Lateral view.

The Colles fracture is the most common fracture of the wrist.[5,6] Familiarity with its presentation, indications for reduction, and method of reduction are essential for the EP. Consult an Orthopedic Surgeon for the reduction of most fractures, due to the high incidence of long-term complications that may result, even when these fractures are appropriately managed and reduced.[5,6]

ANATOMY AND PATHOPHYSIOLOGY

The distal radius is involved in two important articulations. First is the distal radioulnar joint, which is responsible for pronation and supination of the forearm. The second is the wrist articulation. The distal radius normally displays approximately 15° to 30° of angulation relative to the ulna. It also has a volar tilt of up to 23°. It is important to maintain this anatomic position of the distal radius with the reduction of a Colles fracture so that the patient retains good function of the wrist and distal radioulnar joints.[6]

The Colles fracture can be associated with several other significant injuries. Up to 60% of patients have a fracture of the ulnar styloid process.[5,6] Other injuries include carpal fractures, distal radioulnar joint subluxations, flexor tendon injuries, median nerve injuries, ulnar neck fractures, and ulnar nerve injuries. A thorough physical examination and evaluation of the radiographs will uncover these injuries.

Standard radiographs include the anteroposterior and lateral views of the wrist. The Colles fracture is classically described as a "dinner fork" deformity when seen on lateral view (**Figure 90-4A**). Intraarticular involvement with the fracture is rare and should prompt an emergent consultation with an Orthopedic or Hand Surgeon in the ED for reduction.[6]

A variation of the Colles fracture is the Smith fracture (reversed Colles). The Smith fracture is similar to the Colles fracture except that the distal fracture fragment is displaced in a volar direction. This fracture most often results from a direct blow to the wrist while the hand is flexed. It is more commonly seen in young males. The management of these fractures is similar to that of the Colles fracture.

INDICATIONS

Nondisplaced Colles fractures can be placed in a splint or cast and the patient follow-up with an Orthopedic or Hand Surgeon on an outpatient basis. Displaced fractures should be reduced in the ED.[5,6] Simple Colles fractures may be reduced after consultation with an Orthopedic or Hand Surgeon. Many Orthopedic and Hand Surgeons prefer to reduce these fractures themselves, often prior to open reduction and internal fixation. **The fracture must be emergently reduced if the patient has any neurologic and/or vascular compromise.** The EP should reduce the fracture if the Orthopedic or Hand Surgeon is not immediately available. The goal is to relieve the neurologic and/or vascular compromise. Ideal positioning is not required as the Surgeon can later reduce the bony defect.

CONTRAINDICATIONS

Contraindications to the reduction of a Colles fracture include other injuries that represent a threat to life or limb. Airway, breathing, and circulation must first be addressed and stabilized. An Orthopedic or Hand Surgeon should reduce any fractures that involve the radioulnar or wrist joint. Complex, comminuted, or open fractures also require reduction by an Orthopedic or Hand Surgeon. Unfamiliarity with the reduction technique is a relative contraindication.

Any patient presenting with a Colles fracture should be evaluated for the presence of a compartment syndrome. **Any suspicion of a compartment syndrome necessitates having intracompartmental pressures measured. Elevated compartmental pressures require an emergent consultation with an Orthopedic, Hand, or General Surgeon.** Reduction and fasciotomies should be performed in the Operating Room. Refer to Chapters 74 and 75 for the details regarding a compartment syndrome and a fasciotomy, respectively.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Local anesthetic solution, 1% to 2% lidocaine
- 10 mL syringe
- 18 gauge needle
- Finger trap
- Compressive cotton bandage (Webril)
- Elastic wrap
- 8 to 10 pounds of weights
- Casting material (plaster, fiberglass, and prepackaged splints)
- Anesthesia and analgesia supplies

PATIENT PREPARATION

Obtain an informed consent for reduction of the fracture after explaining to the patient and/or their representative the indications, anticipated outcome, risks, benefits, and potential complications.

The patient should be given adequate anesthesia for the procedure. This can often be accomplished with a hematoma block. The procedure is briefly described here. Refer to Chapter 125 for a more complete discussion of this procedure. Clean the skin overlying the fracture of any dirt and debris. Apply povidone iodine or chlorhexidine solution to the skin and allow it to dry. Place a subcutaneous wheal of local anesthetic solution over the area of the hematoma. Insert an 18 gauge needle through the anesthetized skin and into the hematoma. Aspirate blood from the hematoma site to confirm proper needle placement. Inject 5 to 10 mL of the local anesthetic solution into the hematoma surrounding the fracture. Although a hematoma block will provide adequate anesthesia in most patients, it may be incomplete. Adjunctive or alternative anesthesia includes intramuscular analgesics, intravenous analgesics, regional nerve blocks (Chapter 126), intravenous regional anesthesia (Chapter 127), and procedural sedation (Chapter 129).

TECHNIQUE

Place the patient supine on a stretcher. Perform a hematoma block as described above. Provide supplemental analgesia to the patient if required. Position the patient as in **Figure 90-5A**. Abduct the arm 90° and allow it to hang over the edge of the bed. Flex the elbow 90° with the hand pointing upright. Insert the thumb, index finger, and long finger into the finger trap (**Figure 90-5B**). Suspend 8 to 10 pounds of weights from the distal humerus (**Figure 90-5C**). Allow the patient to remain in this position for 5 to 10 minutes to distract and disimpact the fracture fragments.

The fracture reduction involves traction followed by manipulation of the distal radial fragment to reverse the action that resulted in the fracture (Figure 90-6). Place both hands around the patient's wrist with the thumbs at the base of the fracture site (**Figure 90-6A**). Displace the fracture fragment distally with your thumbs while maintaining traction with the finger trap and the weights (**Figure 90-6A**). This maneuver allows the distal fragment to become free from any contacts with the proximal radius, which may prevent its movement. Continue to manipulate the fragment distally while simultaneously manipulating it in a volar direction until the fragment assumes the proper anatomic position. In the case of a volar angulation or Smith fracture, these manipulations would simply be reversed to reduce the displacement. Slight ulnar deviation of the fragment is often necessary (**Figure 90-6B**). Remove the weights. Palpation of a smooth surface at the radial and dorsal aspects of the radius indicates an appropriate reduction. Remove the finger trap and apply a splint.

Immobilize the forearm with a sugar tong splint. Place the forearm in a neutral position, halfway between pronation and supination. Place the wrist in 15° to 20° of flexion and 20° of ulnar deviation. Unstable fractures are best splinted immediately after the reduction while the hand is still maintained in the finger trap for traction (**Figure 90-6C**). If a long arm cast is applied, be sure to bivalve it to prevent complications. A short arm splint or cast may be used if the fracture is stable and impacted or is stable in an elderly person who needs to maintain mobility of the elbow.

ASSESSMENT

All patients should be assessed both initially and following any reduction attempts for neurologic and vascular integrity of the extremity. Postreduction radiographs should be obtained to confirm proper bony positioning. The procedure may be repeated if the radiographs show an incomplete reduction. Bedside ultrasound is a reliable and convenient method of assessing the reduction.[20] It is noninvasive, does not use ionizing radiation, involves minimal contact, and does not require the patient to remain motionless.[14]

The goal is the restoration of the normal relationships and angles of the radius with congruity of the radiocarpal and radioulnar joints. The lateral radiograph should reveal a 23° angle of the radiocarpal joint in a palmar direction with no dorsal angulation. The

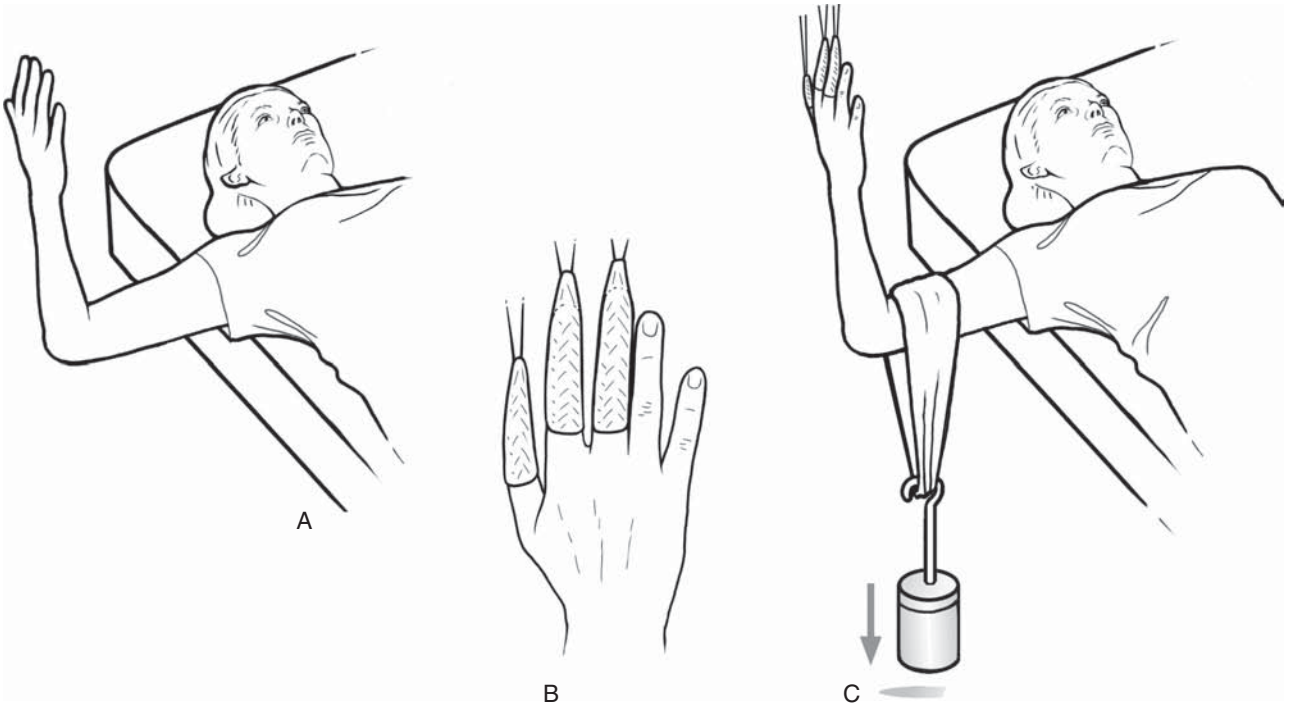

FIGURE 90-5. Patient positioning for the reduction of a Colles fracture. **A.** The arm is abducted 90° and the elbow is flexed 90°. **B.** The thumb, index finger, and long finger are placed in the finger trap. **C.** Weights are suspended from the distal humerus.

anteroposterior radiograph should reveal a radioulnar joint angle of 15° to 30° with the ulna in relation to the radiocarpal joint.

Positioning is not critical if the reduction was performed for neurologic and/or vascular compromise. The primary consideration is the relief of the compromised nerve and/or artery. The Orthopedic or Hand Surgeon can later reduce the bony defect that remains.

AFTERCARE

Patients with uncomplicated or nondisplaced fractures should be referred to an Orthopedic or Hand Surgeon in 24 to 48 hours. Patients with unstable fractures should be evaluated within 24 hours. **All patients should be given written instructions regarding the signs and symptoms of the splint or cast being**

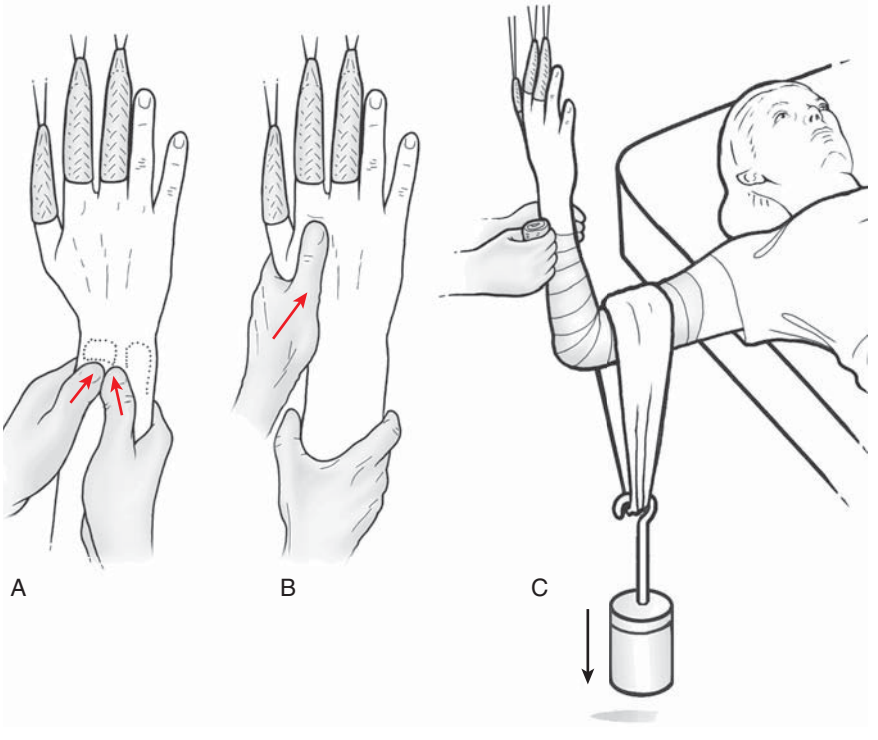

FIGURE 90-6. Reduction of a Colles fracture. **A.** Proper positioning of the EP hands. The arrows represent the application of a distally directed force. **B.** Application of an ulnar-directed force to reduce the radial deviation. **C.** The application of a splint to an unstable fracture. The finger trap and weights remain during the splinting.

too tight or a potential compartment syndrome. Any patient with an open fracture, evidence of neurologic and/or vascular compromise, or suspicion of a compartment syndrome should be admitted to the hospital after an emergent consultation with an Orthopedic or Hand Surgeon.

General principles of orthopedic care are recommended. These include rest, elevation of the arm, nonsteroidal anti-inflammatory drugs, and narcotic analgesics as needed. The patient should be instructed to exercise the fingers and shoulder to prevent weakness, muscular atrophy, and the ligaments surrounding these joints from becoming taut.

COMPLICATIONS

Complications of the reduction procedure include postreduction edema and bleeding into the forearm. These may contribute to the development of a compartment syndrome. Although infrequent, a neuropraxia of the median nerve is possible. Most complications result from the injury that produced the fracture and underlie the need for a good neurologic and vascular examination prior to any attempts at reduction. Any diminished or absent neurologic or vascular function requires an emergent consultation with an Orthopedic or Hand Surgeon. Incomplete reduction can result in future morbidity (i.e., pain, decreased range of motion, and deformity).

SUMMARY

The Colles fracture is the most common fracture of the wrist. Familiarity with its presentation and method of reduction are essential for the EP. Many Orthopedic and Hand Surgeons prefer to reduce these fractures. Consultation is advised prior to reduction unless the extremity has evidence of neurologic or vascular compromise. These fractures have a high incidence of long-term complications, even when appropriately managed and reduced.[5,6]

DISPLACED SURGICAL NECK FRACTURE OF THE HUMERUS

INTRODUCTION

Proximal humeral fractures are relatively common. Most patients presenting to the ED with a proximal humeral fracture are elderly and usually have osteoporosis. The most common mechanism of injury involves a fall on an outstretched hand with the elbow extended.[3,7] The EP can manage most of these fractures conservatively. However, the EP must have a basic knowledge of the types of proximal humeral fractures, those that should be managed by the Orthopedic Surgeon, and the indications for emergent reduction.

ANATOMY AND PATHOPHYSIOLOGY

The proximal humerus is composed of the articular segment, the greater and lesser tuberosities, and the proximal humeral shaft. This anatomic division is based on the epiphyseal lines and the development of the humerus.[2,3,7] The commonly used Neer classification utilizes the observation that proximal humeral fractures separate primarily along these epiphyseal lines.[2,3,7] Using this classification, it is the displacement of fragments, not the total number of fracture lines, that is important. Significant displacement is considered to be a separation of greater than 1 cm, angulation of more than 45°, or displacement of the greater tuberosity greater than 0.5 cm.[3,7] The classification separates fractures into one- to four-part fractures. The vast majority, approximately 80%, of proximal humeral fractures are one-part or minimally displaced fractures.[3,7] These fractures can be managed conservatively. Multiple-part fractures often require surgical intervention by an Orthopedic Surgeon. **A surgical neck fracture of the humerus is the only proximal humeral fracture that should be reduced by the EP.**

INDICATIONS

Surgical neck fractures of the humerus may be reduced in the ED after consultation with an Orthopedic Surgeon. **If the patient has neurologic and/or vascular compromise, the reduction should be undertaken emergently after consultation with the Orthopedic Surgeon.**

CONTRAINDICATIONS

Contraindications to the reduction of humeral fractures include other injuries that represent a threat to life or limb. Airway, breathing, and circulation must first be addressed and stabilized. An Orthopedic Surgeon should manage any open fracture, complex comminuted fracture, or multiple-part fracture as the patient often requires operative repair and reduction.[2,3,7] Unfamiliarity with the reduction technique is a relative contraindication. Children presenting with separation of the proximal humeral epiphyses require meticulous realignment. These fractures should be reduced by an Orthopedic Surgeon.[2]

EQUIPMENT

- Supplies and equipment for procedural sedation (Chapter 129)
- Compressive cotton bandage (Webril)
- Casting material (plaster, fiberglass, and prepackaged splints)
- Sling
- Elastic wrap

PATIENT PREPARATION

Obtain an informed consent for reduction of the fracture after explaining to the patient and/or their representative the indications, anticipated outcome, risks, benefits, and potential complications of the procedure. Adequate anesthesia for this procedure is best accomplished with procedural sedation. Obtain an informed consent for the procedural sedation procedure. Refer to Chapter 129 for complete details regarding procedural sedation.

TECHNIQUE

Place the patient supine. Apply procedural sedation. Completely flex the patient's elbow. Apply a distractive force along the long axis of the humerus by applying traction on the patient's elbow (**Figure 90-7A**). Simultaneously slightly adduct the arm across the chest (to allow relaxation of the pectoralis muscle), slightly flex the arm, and apply lateral pressure to the fracture site while distracting the humerus (**Figure 90-7B**). Slowly release the traction on the elbow as the fragments come into good reduction.

Apply a sugar tong splint from over the deltoid muscle, under the elbow, and up into the axilla (**Figure 90-8A**). Secure the splint in the usual manner with an elastic wrap. Apply a sling (**Figure 90-8B**). Place the arm slightly across the chest and apply a sling and swath in the event of an unstable proximal humeral fracture (**Figure 90-3A**). This can help to limit the pull of the pectoralis muscle on the fracture site.

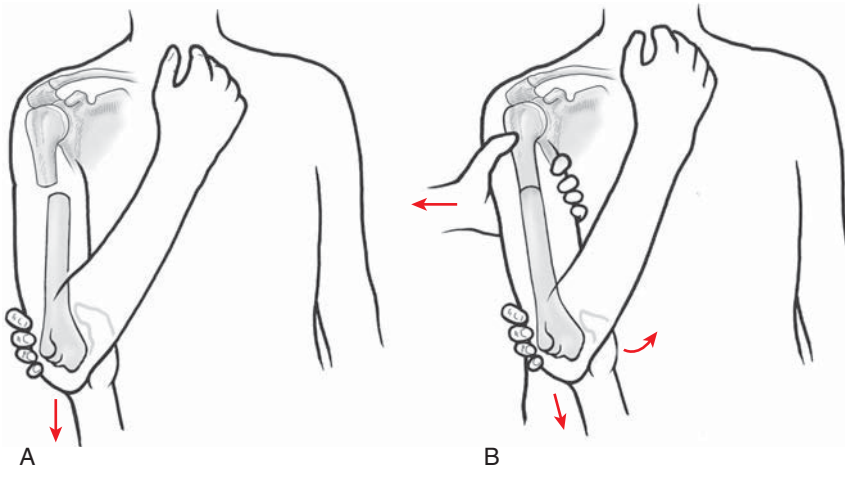

FIGURE 90-7. Reduction of a displaced surgical neck fracture of the humerus. **A.** The application of distal traction to the elbow. **B.** Lateral pressure is applied to reduce the fracture while maintaining distal traction, adducting the elbow, and slightly flexing the arm.

ASSESSMENT

All patients should be assessed both initially and following any reduction attempts for neurologic and vascular integrity of the extremity. Postreduction radiographs should be obtained to confirm proper bony positioning. The procedure may be repeated if the radiographs show incomplete reduction.

Positioning is not critical if the reduction was performed for neurologic or vascular compromise. The primary consideration is the relief of the compromised nerve and/or artery. The Orthopedic Surgeon can later reduce the bony defect that remains.

AFTERCARE

Patients with uncomplicated or nondisplaced fractures should be referred to an Orthopedic Surgeon in 24 to 48 hours. **All patients should receive written instructions on the signs and symptoms of the splint being too tight or a potential compartment syndrome.** Patients with unstable fractures should be evaluated within 24 hours. Any patient with an open fracture, evidence of neurologic and/or vascular compromise, or suspicion of a compartment syndrome should be admitted to the hospital after an emergent consultation with an Orthopedic Surgeon.

COMPLICATIONS

Complications of the reduction procedure include primarily neurologic and/or vascular compromise. However, most complications result from the injury that produced the fracture. This underlies the need for a good neurovascular examination prior to any reduction attempt.

SUMMARY

Proximal humeral fractures are common. While the EP can manage most of these conservatively, a displaced surgical neck fracture is the only proximal humeral fracture that should be reduced in the ED. Reduction is often reserved for patients who have evidence of neurologic and/or vascular compromise. Most of these injuries require open reduction and internal fixation in the Operating Room by an Orthopedic Surgeon. Close follow-up should be arranged for any patient discharged from the ED.

SUPRACONDYLAR FRACTURE OF THE HUMERUS

INTRODUCTION

Distal fractures of the humerus located within 2 cm or just proximal to the epicondyles are known as supracondylar fractures (**Figure 90-9**). Supracondylar fractures are classified as extension and flexion fractures.[8–10] These fractures are common in children under the age of 15 and are rare in people over the age of 20.[8–10] Supracondylar fractures are the most common elbow fractures seen in children.[15] The most common mechanism of injury involves a fall onto an outstretched hand with the elbow locked

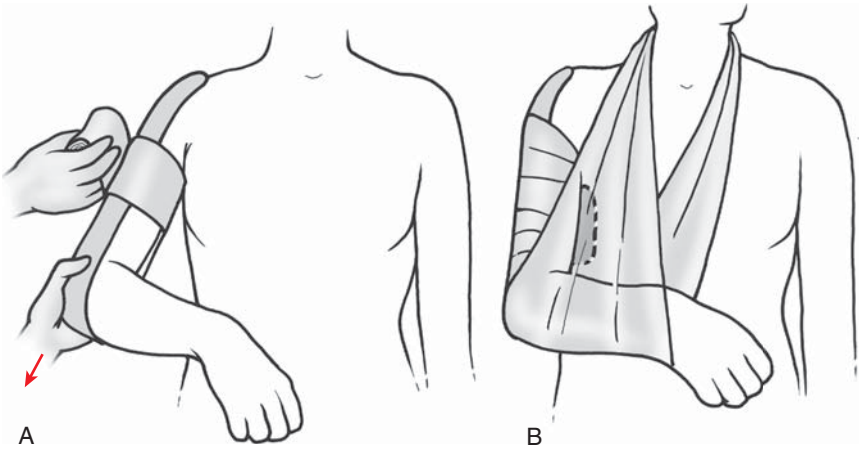

FIGURE 90-8. Immobilization of the reduced surgical neck fracture of the humerus. **A.** Application of a sugar tong splint. **B.** A sling is applied after padding is placed between the upper arm and the thorax.

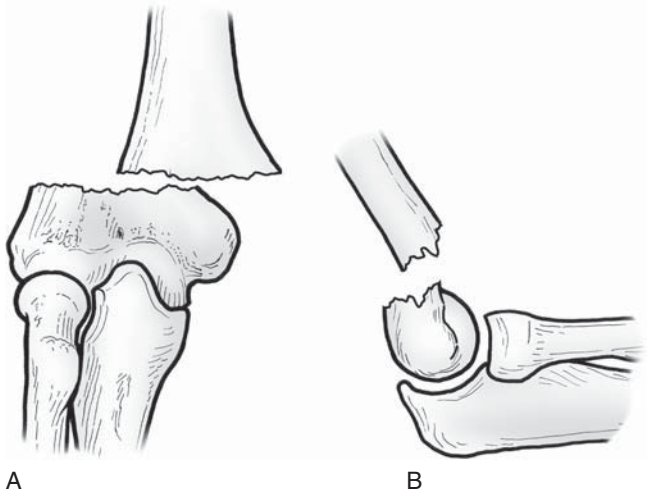

FIGURE 90-9. Supracondylar fracture of the humerus. **A.** Anteroposterior view. **B.** Lateral view.

in extension.[8–10] The same mechanism of injury in an adult often results in a posterior elbow dislocation. The bones of an adult are much stronger than those of a child, so that the ligaments rupture rather than the bone fracturing.[8,9] **These injuries have a significant incidence of associated neurologic and/or vascular injury. There is a significant incidence of a subsequent compartment syndrome.** All supracondylar fractures should be referred to an Orthopedic Surgeon for follow-up care.

ANATOMY AND PATHOPHYSIOLOGY

On presentation, the child will be holding the affected extremity with the elbow flexed 90° and the arm adducted.[8,10] Localized tenderness and swelling will be found upon examination. Extension fractures have posterior displacement of the distal fragment of the humerus that is aggravated by the pull of the triceps muscle.[8,10] The olecranon will be displaced posteriorly due to traction from the triceps muscle. The posterior displacement of the olecranon may mimic a posterior elbow dislocation. **Anterior angulation of the sharp proximal fragment (Figure 90-9B) may injure the brachial artery or median nerve (Figure 90-10). A thorough neurovascular examination is essential.** There will be loss of the normal olecranon prominence with flexion injuries. These fractures are frequently open and vascular injury is less frequent.[8,10]

The modified Gartland classification of supracondylar humeral fractures is the most commonly accepted and used system.[17] A Gartland type-I supracondylar fracture is nondisplaced or minimally displaced by <2 mm and is associated with an intact anterior humeral line. A type-II supracondylar fracture is displaced by >2 mm, and the posterior cortex is intact, but may be hinged. On a true lateral radiograph of the elbow, the anterior humeral line does not go through the middle third of the capitellum. Type-III fractures are displaced with no meaningful cortical contact. Gartland type-IV fractures are characterized by an incompetent periosteal hinge circumferentially and are defined by instability in both flexion and extension.[17] The EP's primary role in a supracondylar humeral fracture is to ascertain if there is any neurological and/or vascular compromise of the extremity distal to the fracture.

Radiological evaluation of supracondylar fractures is best appreciated on the lateral view. One-quarter of these fractures in children are of the greenstick variety.[8,10] The posterior fat pad sign and anterior humeral line should be closely examined. Initial radiographs may show no evidence of a fracture except for a posterior fat-pad sign.[15] Even without any radiologic signs, a child with localized tenderness in the supracondylar area should be treated conservatively with splinting and referral to an Orthopedic Surgeon.[8,10] The anteroposterior view allows an assessment of any displacement. Displaced fractures should be emergently referred to and reduced by an Orthopedic Surgeon.

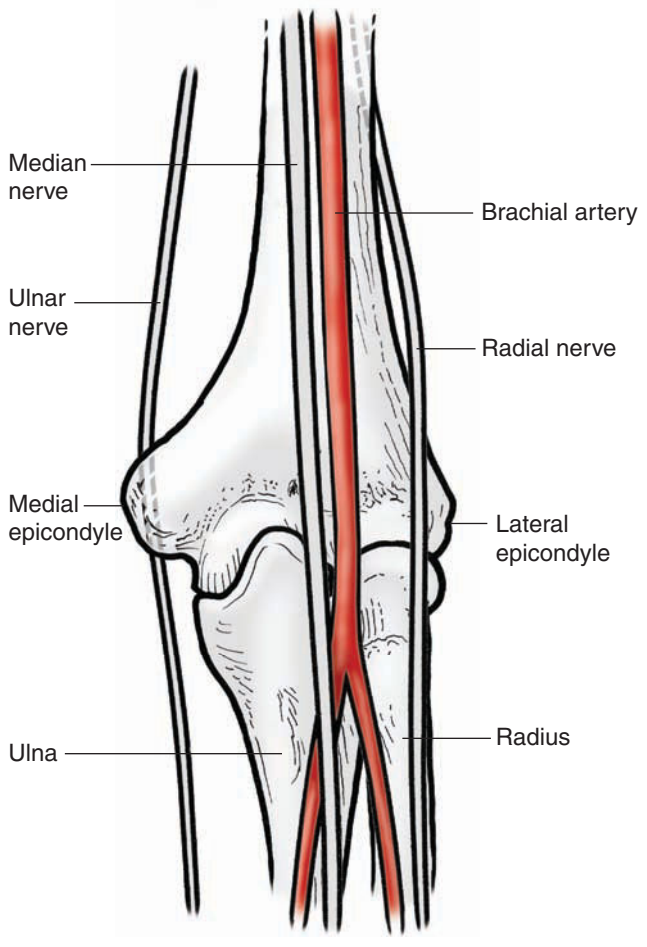

FIGURE 90-10. Major neurologic and vascular structures crossing the elbow.

INDICATIONS

The only indication for reducing a supracondylar fracture of the humerus emergently is neurologic and/or vascular compromise of the extremity distal to the fracture and an Orthopedic Surgeon is not immediately available.

CONTRAINDICATIONS

Contraindications to the reduction of a supracondylar fracture include other injuries that represent a threat to life or limb. The patient's airway, breathing, and circulation must first be addressed and stabilized. An Orthopedic Surgeon should manage any open or displaced fractures. Unfamiliarity with the reduction technique is a relative contraindication. If the EP is uncomfortable with the reduction procedure, simple traction on the extended elbow may be sufficient to restore neurologic and/or vascular integrity.

EQUIPMENT

- Supplies and equipment for procedural sedation (Chapter 129)
- Compressive cotton bandage (Webril)
- Elastic wraps
- Casting material (plaster, fiberglass, and prepackaged splints)
- Prepackaged splinting sheets
- Sling

PATIENT PREPARATION

Obtain an informed consent for the reduction of the fracture after explaining to the patient and/or their representative the indications, anticipated outcome, risks, benefits, and potential complications. Adequate anesthesia for this procedure is best accomplished with procedural sedation. Obtain an informed consent for this procedure in addition to the reduction procedure. Refer to Chapter 129 for the complete details regarding procedural sedation.

TECHNIQUE

Place the patient supine. Apply procedural sedation. Slightly abduct the affected extremity. Place the patient's hand in the midposition between pronation and supination with the thumb pointing upward (**Figure 90-11A**). Grasp the patient's elbow region with the dominant hand and grasp the wrist with the nondominant hand (**Figure 90-11A**). Instruct an assistant to stabilize the distal humerus (**Figure 90-11A**). Apply distal traction in line with the long axis of the arm by pulling on the wrist while simultaneously correcting any medial or lateral displacement at the elbow (**Figure 90-11A**). Supinate the patient's arm and correct any remaining medial or lateral displacement at the elbow while simultaneously distracting the wrist (**Figure 90-11B**). Place the thumb of the dominant hand across the joint line of the elbow with the fingers behind the olecranon process and slowly flex the elbow to just beyond 90° while distracting the elbow (**Figure 90-11C**). Splint the arm in this position. Avoid tight bandaging or splinting as significant swelling may occur up to 24 hours after the reduction. Excessive flexion or extension may compromise the limb's vascularity and increase compartment pressures.[16]

ASSESSMENT

All patients should be assessed both initially and following any reduction attempts for neurologic and vascular integrity of the extremity. Postprocedural swelling is common. Postreduction radiographs should be obtained to confirm proper bony positioning. The procedure may be repeated if the radiographs show incomplete reduction.

Positioning is not critical if the reduction was performed for neurologic or vascular compromise. The primary consideration is the relief of the compromised nerve and/or artery. The Orthopedic Surgeon can later reduce the bony defect that remains.

AFTERCARE

Patients with supracondylar fractures should be admitted to the hospital to be monitored for a delayed compartment syndrome, neurologic compromise, or vascular compromise. Any patient with an open fracture, evidence of neurologic or vascular compromise, or suspicion of a compartment syndrome should be admitted to the hospital after an emergent consultation with an Orthopedic Surgeon.

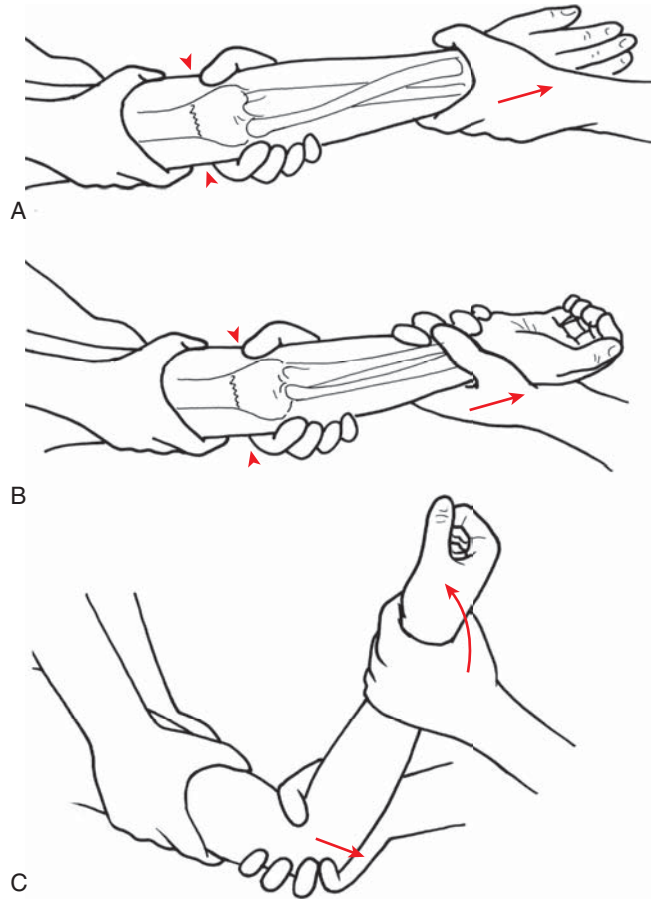

FIGURE 90-11. Reduction of a supracondylar fracture. **A.** Positioning of the hands of the EP and the assistant. Distal traction is applied (*arrow*) while reducing the medial or lateral displacement (*arrowheads*). **B.** The patient's hand is supinated while maintaining distal traction (*arrow*). Any remaining medial or lateral displacement is also corrected (*arrowheads*). **C.** The patient's elbow is flexed (*curved arrow*) just beyond 90° while maintaining distal traction (*straight arrow*).

COMPLICATIONS

Most complications result from the injury that produced the fracture and not the reduction. Complications of the reduction procedure include primarily neurologic and vascular compromise. This is most often a neuropraxia and may involve any of the three nerves crossing the fracture. The neurovascular structures crossing the fracture may become lacerated or entrapped during the reduction. **The necessity of an accurate and complete neurovascular examination prior to and after reduction cannot be overemphasized.**

SUMMARY

Supracondylar fractures of the humerus are common in children under the age of 15 and rare over the age of 20. The most common mechanism of injury involves a fall onto an outstretched hand with the elbow locked in extension. These injuries have a significant incidence of associated neurologic injury, vascular injury, and the subsequent development of a compartment syndrome. The only indication for the reduction of a supracondylar fracture of the humerus by the EP is neurologic and/or vascular compromise distal to the fracture.

91 Casts and Splints

Eric F. Reichman and Harold A. Sloas

INTRODUCTION

External immobilization of the extremities is the oldest form of fracture treatment. References to plaster use and various immobilization techniques are scattered throughout historical records. The use of plaster of paris (plaster) in fracture management dates back to the eighteenth century Turkish Empire. Plaster bandages became commercially available in 1931. Despite the development of plastic (i.e., fiberglass) casting products, the plaster bandage persists as the most economical and versatile material for immobilization techniques.[1]

Immobilization of an injured extremity begins at the scene of the accident. According to Advanced Trauma Life Support guidelines, the injured extremity must be aligned and immobilized after the appropriate management of any life-threatening problems.[2] Prehospital immobilization of fractures is invaluable for pain control, prevention of soft tissue injury, prevention of any new or further injury to neurovascular structures, and management of edema. External immobilization with splinting or casting is often the definitive management of injured extremities in the Emergency Department. Knowledge of and expertise in this therapeutic procedure is essential for any EP.

Splints are commonly used for the immobilization of upper and lower extremity injuries. A splint is a hard bandage that is not circumferential and prevents movement of the fracture site. Splinting may be the definitive management of certain injuries. Splints have the distinct advantage of being quick, easy to apply, and they are designed to accommodate postinjury swelling. The major disadvantages of splints are that they provide slightly less rigid immobilization than casting and require a Physician visit within a few days to be replaced with a cast.

Casts, which are generally circumferential, are better suited for the definitive treatment of fractures and ligamentous injuries. Casts provide superb immobilization and allow for the maintenance of a reduced fracture. The rigidity of a cast limits the amount of swelling and soft tissue edema in the first 24 to 48 hours after the injury and is therefore associated with an increased risk of developing a compartment syndrome. **Casts should be used with caution in the management of acute fractures. They are often split (i.e., bivalved) to allow swelling and prevent the development of a compartment syndrome before the patient is discharged from the Emergency Department.**

ANATOMY AND PATHOPHYSIOLOGY

Casts and splints rely on the principle of a three-point mold to maintain fracture reduction (**Figure 91-1**). **When applying a cast or splint, the application of directed force to the underlying bones should be uppermost in one's mind.** To obtain a three-point mold, place one point of contact over the convex side of the fracture site. The other two points of force are aimed in an opposite direction, proximal and distal to the fracture, and from the concave side. This is the classic teaching of Sir John Charnley, who noted that "a curved plaster is necessary in order to make a straight limb."[3] A skin-tight cast that closely follows the contours of the extremity will not maintain the fracture in alignment, as it does not apply appropriate pressure to the underlying bones.

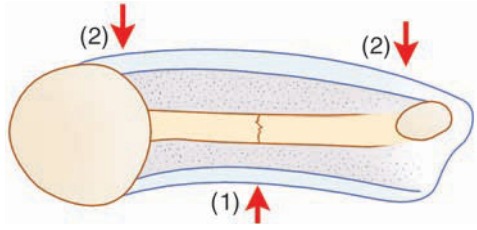

FIGURE 91-1. Three points of force are acting on the injured extremity in a well-applied cast or splint. One force is applied to the convex side of the fracture site (1). Two opposing forces are applied at sites proximal and distal to the fracture and on the concave side of the fracture (2).

Casts and splints also rely on hydraulic force to maintain limb length and alignment. One may think of the soft tissues surrounding the broken bones as constituting a flexible cylinder that contains the underlying fracture, hematoma, and edema. Axial loading of the bones will cause the soft tissue to expand and allow the limb to shorten. A well-applied cast or splint will resist the outward expansion from axial loading and provide additional support for the limb.[4]

Plaster is made of finely ground calcium sulfate that has been dehydrated by heat. The calcium sulfate is impregnated into muslin sheets containing dextrose or starch. The addition of various chemicals (e.g., alum, aluminum, copper, iron, magnesium, salicylic acid, or zinc) to the calcium sulfate alters the rate of hardening after the addition of water. Plaster grades include fast-setting and extra-fast-setting plaster, which are useful for different applications. Long cylindrical crystals form and interlock as the plaster sets to give strength to the cast. **For this reason, plaster should not be moved once it begins to set, as these crystals may fracture, causing the plaster to lose strength. Careful lamination of the plaster while it is still wet will add strength by enabling the formation of longer crystals.**

Crystal formation during the setting of plaster is an exothermic process that is initiated by the addition of water to the plaster. Using warm water will accelerate the chemical reaction, harden or set the plaster sooner, and decrease the setting time. Unfortunately, the use of very warm or hot water will also increase heat production while the plaster sets. The use of very thick splints or fast-setting plaster will also increase the heat produced during setting. Use cold water to activate the plaster, increase the setting time, and decrease the heat produced during setting. **Great care should be taken if warm water is used in applying a cast or splint to an anesthetized patient, unconscious or altered patient, or an insensate limb. The setting plaster may burn the skin in these cases as the patient will not notice the heat and pain associated with the exothermic reaction.** Rubbing and working with the plaster will also accelerate the setting process.[5]

The same principles described above regarding plaster apply to the use of fiberglass. The fiberglass splinting material consists of cloth impregnated with a plastic and spun glass resin and a water-activated catalyst.

INDICATIONS

SPLINTS

An injured extremity should be splinted as soon as possible after the injury. Splinting results in the reduction of pain, reduction of edema, relieves pressure on neurovascular structures, and the prevention of further soft tissue injury.[6] Any available material can be used to immobilize or realign the affected extremity in the

prehospital setting and in the Emergency Department. **A thorough neurologic and vascular examination of the extremity should be performed and documented before temporarily splinting the extremity. A thorough neurologic and vascular examination of the extremity should be performed and documented after temporarily splinting the extremity. The initial neurovascular examination, temporary splinting, and the postsplinting neurovascular examination should be performed before the patient undergoes radiographic studies.** Immobilize an extremity in the appropriate and definitive splint after diagnosing and stabilizing the fracture. **A thorough neurologic and vascular examination of the extremity should be performed and documented after the placement of the definitive splint.**

An extremity fracture is the most common reason for placement of a splint. A splint is also indicated following the reduction of a dislocated joint. The patient with ligamentous sprains or muscle strains will also receive significant pain relief with splint immobilization. Splints are placed following orthopedic or soft tissue surgery of the extremities.

CASTS

There are few reasons to immobilize an acutely injured extremity with a cast in the Emergency Department. Most injuries can be initially stabilized with a splint. Following reduction of certain fractures, placement of a cast will secure the bones in their proper alignment and allow for a primary union (e.g., distal radius, tibial shaft).[6,7] **Placement of a cast instead of a splint should be performed only if the patient has access to close follow-up or can return to the Emergency Department for a cast check within 24 hours.**

Patients with casts may present to the Emergency Department with various cast-associated problems. The cast may have become wet and lost its strength and integrity. The cast may no longer fit properly if the affected extremity has decreased in size from reduction of swelling. The cast must be removed and the affected area examined if the patient complains of persistent pain.[6,7] All these patients may safely be placed back in a cast. They may also be placed in an appropriate splint and follow-up arranged with an Orthopedic Surgeon for casting.

CONTRAINDICATIONS

SPLINTS

There are no absolute contraindications for the placement of a splint. Relative contraindications include soft tissue injuries or wounds that need regular care and evaluation. In this setting, the wounds should be appropriately dressed and padded and the splint constructed so that it can easily be removed and replaced. A "window" may also be cut in the splint as it is being applied to facilitate access to the wound. The splint should not place pressure over the wound.

CASTS

Do not cast an extremity that has the potential for significant edema or that may develop a compartment syndrome. An injured extremity with significant edema or soft tissue injuries should not be constrained by a cast. Similarly, infections of joint spaces or soft tissues must remain exposed for frequent evaluations. Any fracture that is not adequately reduced by closed manipulation should not be placed in a cast.[3,7] A cast should not be applied by someone unfamiliar with the technique and unable to manage the associated complications.

EQUIPMENT

- Bucket or basin to hold water
- Source of cool or tepid water
- Cotton cast padding (e.g., Webril), various widths
- Plaster strips or rolls, various widths
- Fiberglass strips or rolls, various widths
- Prefabricated splinting material, various widths
- Bias stockinette, various widths
- Cloth tape, 1 in. wide
- Bias stockinette, optional
- Elastic bandages (e.g., Ace wraps), various widths
- Slings, various sizes

The width of the cotton cast padding, plaster, and bias stockinette required will vary by the site of application. In general, 1 to 3 in. material can be used for the hands and digits, 3 to 4 in. wide material can be used for the upper extremity, and 4 to 5 in. wide material can be used for the lower extremity. Alternative materials include fiberglass strips and rolls instead of plaster strips. Elastic bandages (e.g., Ace wraps) can be substituted for bias stockinette. Prefabricated splinting material is also available, with the padding and fiberglass (or plaster) already assembled and covered with cotton material (e.g., Parker Splints or Orthoglass). **It is important to remember that all of the casts and splints described in this chapter can be constructed using plaster or fiberglass splinting material.**

Fiberglass rolls must be cut to the appropriate length with scissors while plaster can easily be torn by hand. The fibers are too strong to be torn by hand. Gloves should always be worn when handling fiberglass because the resin will stick to skin and is exceedingly difficult to remove.[4–6] Otherwise, the same principles described for plaster apply to fiberglass.

PATIENT PREPARATION

Whether reducing a fracture or simply manipulating the extremity to place a cast or splint, make sure that the patient has received appropriate analgesia. Conduct a thorough examination of the skin overlying the site of injury. **It is inexcusable to miss the diagnosis of an open fracture. All skin wounds must be inspected and explored.** Exploration of the wound is undertaken cautiously with a sterile probe or gloved finger according to wound size. Fractures may puncture the skin from the "inside-out," resulting in an innocuous appearing pinhole in the skin. These are grade I open fractures and carry with them a 5% risk of infection.[8] Cover any open fractures with sterile saline-soaked gauze until formal irrigation and debridement can be undertaken in the Operating Room. Do not examine open wounds repeatedly due to the risk of increased contamination. Administer tetanus prophylaxis as indicated. Administer the appropriate intravenous broad spectrum antibiotics for an open fracture if present.

Document a thorough neurologic and vascular examination of the injured extremity before and after any splinting or casting. A change in the neurologic or vascular status of an extremity may be the result of the fracture reduction, the splint or cast application, or a compartment syndrome. The fracture may have to be reduced and held in position while a splint or a cast is applied. If no reduction is needed, splint the affected extremity in a position of stability. Techniques for achieving and maintaining fracture reduction are beyond the scope of this chapter.

GENERAL SPLINTING CONSIDERATIONS

The general considerations and techniques common to the application of all splints are discussed in this section.[14,15] It describes the techniques for splints utilizing cotton cast padding, plaster, and bias stockinette. Many alternative materials are available and may be substituted, such as fiberglass for plaster or elastic wraps for stockinette. Prefabricated splint materials that incorporate padding may also be used. The techniques described in these chapters are applicable for all splinting materials. Where alterations in technique are required, they are so noted.

Splints are constructed of cotton padding overlaid by splinting material (i.e., strips of plaster or fiberglass) and subsequently held in position by an overwrap of bias stockinette or an elastic bandage. Splint padding should be thick enough to provide protection for the skin from the plaster. **The splint or cast will be unable to provide sufficient immobilization of the fracture to maintain a reduction if the padding is too thick.** One to two layers of cotton cast padding are sufficient over the fracture site. Three to four layers of cotton cast padding are required at the proximal and distal extents of the splint to distribute the stresses. Thinner padding can be used when maintenance of fracture reduction is a priority (e.g., with a fracture of the distal radius).

Plaster strips are available in precut slabs measuring either 4 by 15 or 5 by 30 in. The precut strips have the advantage of speed and ease of application. Alternatively, plaster and fiberglass are available in rolls of various widths ranging from 2 to 8 in. The rolls of splinting material may be rolled out to the precise length desired and cut appropriately. The rolls of splinting material are useful for splints requiring long strips, such as coaptation splints. **The ideal thickness for most upper extremity splints is 10 sheets or layers of plaster or five to six layers of fiberglass. The use of 15 sheets or layers of plaster or 8 to 10 sheets of fiberglass is preferable for lower extremity splints.** The strength of the splint depends on the number of layers as well as the lamination of the layers during their application.

A piece of cotton cast padding may be used as a template for the length of the required splinting material. Roll a piece of cotton cast padding over the desired location of the splint to determine the length of the splinting material required (**Figure 91-2A**). Roll out the splinting material to the appropriate lengths and cut them slightly shorter than the template.

An alternative is to cut the splinting material approximately 1 to 2 in. longer than necessary so that the ends may be folded back on themselves. This will prevent any contact of the sharp splint ends with the patient's skin. Prefabricated splinting material covered with padding has jagged ends and once it has been cut it begins to harden immediately; even prior to the addition of water. These sharp ends will rub against the patients exposed skin, even through cotton cast padding or bias, and for that reason should be folded back. To avoid premature hardening of the prefabricated splinting material, keep it inside of the protective foil and seal it with tape or the manufacturer provided clips.

Bias stockinette may be applied to the extremity for extra padding and comfort. This may also be omitted depending on EP preference. Prepare strips of cotton cast padding. **The strips of cotton cast padding should always be longer and wider than the plaster.** This prevents the plaster from touching the skin and causing a pressure sore, abrasion, or burn. Padding is especially important at the proximal and distal edges, as this is where significant pressure originates. Apply additional pieces of padding over pressure points and bony prominences (e.g., the olecranon). **Additional padding may also be created by folding a loose piece of cotton cast padding back on itself several times and placing it over the individual prominences.** Alternatively, cotton cast padding may be applied directly by wrapping the pressure point or bony prominence circumferentially as is done in cast application.

Begin applying the splint once the padding and splinting material have been cut to the appropriate lengths. Be sure that all required materials have been collected before dipping the splinting material in water to activate it. Only a limited amount of time, less than 10 minutes, is available for splint application and molding once the splinting material is wet. Completely immerse all of the splinting material in a bucket of tepid, clean tap water. Keep the splinting material submersed until no more bubbles arise from under the water (**Figures 91-2B & C**). At this point, the splinting material can absorb no more water. Suspend the splinting material over the bucket and lightly squeeze out the excess water by running your fingers down its length (**Figure 91-2D**). **It should only take two or three passes of the fingers to remove the excess water. Do not wring the plaster strips like a dish rag, as that will cause loss of plaster into the bucket!** Lay the splinting material on a clean flat surface. Run your hands over the splinting material to laminate the individual strips into one slab. Laminating the strips together adds significant strength. Lay the splinting material onto the cotton cast padding (**Figure 91-2E**). Fold the edges of the cotton cast padding over the splinting material to cover all the edges completely. Apply the splint to the extremity.

An alternative and more commonly used method that is preferred by many is to apply the cotton cast padding circumferentially over the extremity, overlapping each layer by 50%, and then applying the wet splinting material. In this fashion, the splinting material will "stick" to the cotton cast padding. **Smooth the splinting material with the broad aspect of your hand and not your fingers to help minimize irregular indentations.**

The cotton cast padding should be facing the patient and no splinting material should directly contact the skin regardless of the method used. Secure the splint with a wrap of bias stockinette or an elastic bandage. The wrap must be applied under minimal tension when you are using an elastic wrap to affix the splint. The elastic may cause increasing pressure over time. Gently apply strips of tape to the end of the wrap to secure the bias stockinette or the elastic bandage. **Tape should never be applied circumferentially, as this can impede expansion of the splint due to underlying swelling and create a tourniquet effect. Application of the tape under tension before the splint is completely hard will cause indentations in the splinting material and result in pressure points on the underlying skin.**

The splinting material may be molded at this point to achieve greater conformity to the extremity or better reduction of the fracture. **It is paramount to use only the palms and not the fingertips when molding the finished splint. Finger pressure induces deformity in the splint that will result in skin breakdown under those defects. All molding must stop once the splinting material begins to harden.** The plaster is quite fragile, and cracks that weaken the splint may be propagated. Apply 1 in. wide tape in a spiral fashion to secure the bias or elastic wrap after the plaster has hardened.

If using prefabricated splinting materials, cut it to length, remove it from the sealed foil, and wet it to activate the splinting materials. Briefly pass the prefabricated splinting material under cool water. Place the wet prefabricated splinting material on a towel and roll it up. This will remove any excess water. **The splinting material should not be soaked or placed in a bucket of water. It requires only one pass under the running water.** The prefabricated splinting material should not be squeezed dry as

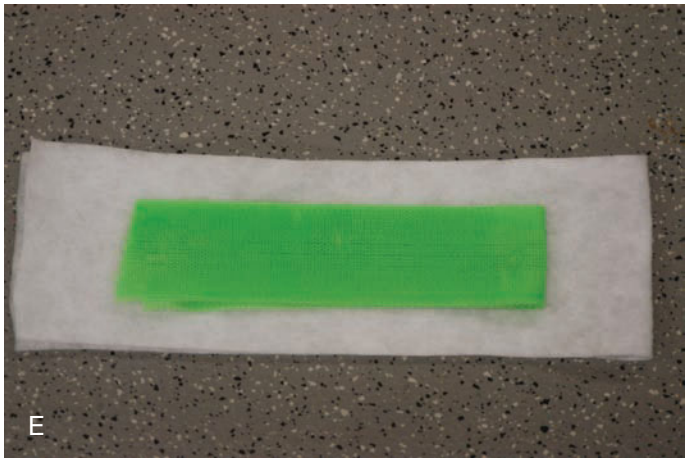

FIGURE 91-2. Preparing the splint. **A.** Cotton cast padding to measure the length of material needed. **B.** Plaster is submersed in tepid water and air bubbles arising from it. **C.** Fiberglass is submerged in tepid water and air bubbles arising from it. **D.** Suspend the lengths of wet splinting material over the bucket and gently squeeze out the excess water. **E.** The splinting material is placed on the cotton cast padding.

this tends to deform the splinting material and result in a poorly molded final product.

Apply the splint and mold it to the extremity. **It is paramount to use only the palms and not the fingertips when molding the finished splint. Finger pressure induces deformity in the splint that will result in skin breakdown under those defects.** Any excess length of splinting material should be folded back on itself so that the cut ends do not come in contact with the patient's skin. The distal part of any extremity should always be left visible so that the EP may recheck a neurovascular exam. The patient will also be able to visualize any changes in color that may occur latter. It is held in place by circumferentially wrapping the splinting material with an elastic bandage. **The elastic bandage should be applied relatively loosely so it will not induce increased compartment pressures.**

GENERAL CASTING CONSIDERATIONS

The general considerations and techniques common to the application of all casts are discussed in this section.[3,5,6,10] **Casting requires careful circumferential turns of material instead of longitudinal layers of material, as for splints.** Casts are constructed of cotton cast padding overlaid with either fiberglass or plaster bandages (i.e., casting materials). The four areas that require particular attention and are discussed in this section are the application of padding, padding pressure points, application of casting material, and molding the cast.

Begin by organizing the required supplies. Cast application requires the same material as that used in splinting (i.e., water, cotton cast padding, stockinette, and casting material). The width of the padding and casting material depends on the size of the

FIGURE 91-3. Preparing to place a cast. **A.** Apply an initial layer of tubular stockinette. **B.** The stockinette has been unrolled over the extremity. **C.** Begin and end the layering of the cotton cast padding at a site distal and proximal to where the casting material will end. Unroll the cotton cast padding in a circumferential manner, covering each preceding layer by one-third to one-half of its width. **D.** The cotton cast padding tears easily to provide additional layers of padding over bony prominences.

extremity. Generally, the 4 to 6 in. wide rolls of casting material are used for lower extremity casts while 3 or 4 in. wide rolls are used for the upper extremity. **Use the widest casting material available and possible in order to limit the number of turns of the fiberglass or plaster roll over joints and other curved surfaces.** Place all materials on a tray near the bedside, including a bucket of tepid water. An assistant designated to dip and drain the casting material and help with patient positioning is immensely helpful.

Prepare the patient. Position the extremity and the patient appropriately for cast placement. The patient is frequently able to assist in the process. Cover the patient with gowns or towels to keep casting material off their clothes.

Apply tubular stockinette to the extremity (**Figures 91-3A & B**). The stockinette is not a necessary component of casting, but many EP use it as a first layer.[5] It provides a smooth covering over the skin that wraps neatly over both ends of the cast. Roll up the stockinette. Place it over the distal extremity as if you were putting on a sock (**Figure 91-3A**). Unroll the stockinette up the leg (**Figure 91-3B**). Care must be taken to apply the stockinette gently. **Do not create tension in the stockinette by pulling it tightly. Eliminate any creases or redundancy of material by trimming any overlapping folds with a scissors.** For upper extremity injuries, cut a small hole one-third of the way from the end of one side of the stockinette to allow the thumb to pass through.

The primary layer of padding is provided by the cotton cast padding. **Casts and cast padding should be applied from distal to proximal.** Begin wrapping the cotton cast padding at a point that will be distal to the start of the plaster (**Figure 91-3C**). This initial band of padding is essential for protection against the cast edge. Keep the roll of padding in contact with the skin so that the material conforms easily to the contours of the extremity as it unrolls. Unroll the padding in a circumferential manner around the extremity. **The cotton cast padding must be laid down neatly and cleanly with no kinks or creases.** Each turn should overlap one-third to one-half of the previous turn. Tear off the extra cotton cast padding to eliminate excess material as you turn angles (e.g., ankle, heel, elbow, or thumb). **Lay the torn edges down by rubbing the padding smoothly.** Continue applying the padding, ensuring that it extends beyond the proximal end of where the cast edge will be to ensure skin protection at the cast edge. Excess length can easily be torn away after the cast is applied and hardened. Typically, two layers of cotton cast padding are adequate for protection between the skin and the casting material.

Pressure points occur over bony prominences or where excess padding has created an unnatural prominence. Palpate the obvious bony prominences to get a sense of whether or not there is adequate padding after the application of the two layers of padding. If the area feels vulnerable, place torn off pieces of cotton cast padding onto the exposed areas (**Figure 91-3D**). **Do not over-pad bony prominences, as excess layering can also lead to excess pressure.** Two to three layers of padding are adequate for most pressure points and bony prominences. Rub the torn edges of the padding so that they fuse smoothly to the underlying padding.

Place the rolls of casting material in a bucket of tepid water so that they are standing on end. Let the casting material remain submersed as long as air bubbles rise out from the center of the roll (**Figures 91-2B & C**). Remove the rolls of casting material when all bubbles stop rising. Hold the casting material in both hands and squeeze some of the water out (**Figure 91-4**). **Do not wring the roll. Do not eliminate all the water from the roll.** Squeeze it gently. The remaining water in the roll is necessary for smoothing and molding the casting material into one solid unit. In general, casts should be applied with "wetter" material and splints with "drier" material as less time is required to apply a splint.

FIGURE 91-4. Hold the casting material roll in both hands and gently twist each end to squeeze out the excess water. Keeping the free end of the casting material folded over will facilitate access after it has been removed from the water.

Apply the casting material (**Figure 91-5**). Place the roll of casting material on the extremity (**Figure 91-5A**). Unroll the casting material in a circumferential fashion around the extremity. **Never lift the roll of casting material off the extremity!** Continue each consecutive wrap around the extremity by overlapping the casting material by approximately 50%. The free border of the casting material will have excess material in it as the extremity changes in size. Grasp this excess casting material with the thumb and index finger of the nondominant hand (**Figure 91-5B**). Pull it outward to create a tuck or a fold. Wrap this fold around the extremity (**Figure 91-5C**) and smooth the fold down against the extremity. This fold will barely be noticeable in the final product. As one roll of casting material ends, another should begin with a small amount of end-to-end overlap. Do not make consecutive folds at the same site as this will create bumps and add bulk to the cast.

Continuously mold and smooth the casting material with wet hands as each layer is applied. **This action ensures continuity of casting material throughout the cast and forms a smooth cast that conforms to the contours of the extremity. Use only the palmar surface of the hands and proximal digits to mold and smooth the casting material (Figure 91-5D). Excessive use of the fingertips will produce irregular indentations and pressure points.** Molding around irregular bony areas is best accomplished with two hands simultaneously rubbing the casting material. **Do not allow excessive time to pass between applying each layer of the casting material, as lamination between layers may not occur. This will weaken the cast considerably.**

A cast thickness of 1/4 in. is felt to be adequate. This usually requires four to five layers of plaster or three to four layers of fiberglass. Allow the cast to set and dry with no further manipulations by the EP or the patient. The time for drying is variable depending upon the casting material used, the water temperature, and the thickness of the cast. Typically, let the casting material set over a period of 10 to 15 minutes. Fold the free ends of the cotton cast padding and the stockinette over the edges of the cast as it sets (**Figure 91-6**). This prevents the rough edges of the casting material from irritating and abrading the skin. Secure the edges of the cotton cast padding neatly with tape or thin strips of casting material.

It is a common practice to bivalve the cast with a cast saw if the potential for increased swelling of the extremity is a concern (**Figure 91-7**). Cut completely through the length of the cast in two

FIGURE 91-5. Apply the casting material to form the cast. **A.** Lay the roll of casting material on the extremity and unroll it. **B.** As the limb changes in girth, there will be excess plaster. Use the nondominant hand to pull on the excess material. **C.** Fold the excess material back onto the extremity in a neat tuck. Each tuck should be laid down smoothly with a molding of the hand. **D.** The casting material is laminated smooth with a continuous motion of the palmar surface of the hand and the proximal fingers.

FIGURE 91-6. Fold the free ends of the cotton cast padding and the stockinette over the edges of the casting material to finish the cast.

FIGURE 91-7. Splitting of the cast can be achieved with a cast saw that cuts through the thickness of the fiberglass or plaster. Cut the underlying protective material with a scissors.

spots 180° apart (i.e., medial and lateral or anterior and posterior). This simple maneuver provides some room for edema without compromising the integrity of the reduction or the strength of the cast. **The underlying cast padding must also be split. Splitting the plaster alone will not reduce the pressure sufficiently.**

UPPER EXTREMITY CASTS AND SPLINTS

COAPTATION SPLINT

A coaptation ("to bring together") splint is used primarily in the acute setting for humeral shaft fractures that are nondisplaced or minimally displaced. This splinting technique allows for motion of the hand and wrist while limiting shoulder and elbow mobility. The cotton cast padding should extend from the nape of the neck to the axilla to avoid skin breakdown. The patient should then be placed in a sitting position to minimize splint displacement during the actual application process. The length of the splint extends from the axilla, around the 90° flexed elbow, along the outer arm, over the deltoid muscle, and over the acromion process (**Figure 91-8**). **It is critical that the splinting material extend over the deltoid muscle and the acromion process.** The shoulder portion can be held down by applying 3 in. wide tape over the portion of the splint that covers the acromion. Secure the splint with an elastic bandage that covers the entire splint. The major pitfall is making the splint too short and having it fall off! A splint that is too long will not provide proper immobilization. Always leave plenty of length over the shoulder. Padding is required to minimize axillary irritation. The disadvantages of this splint include the possibility of fracture displacement and extremity shortening. The splint should be replaced with a functional brace or cast after a short period of immobilization for pain control.[4]

FIGURE 91-8. The coaptation splint. The overwrap has been omitted for easier visualization of the splint.

FIGURE 91-9. The sugar tong splint. Leave the metacarpal joints free for flexion and extension. The overwrap has been omitted for easier visualization of the splint.

SUGAR TONG SPLINT

Sugar tong splints may be used for mid-forearm fractures, distal forearm fractures, and some wrist fractures. They are most commonly recommended for minimally displaced and distal ulnar and radial fractures (i.e., Colles and Smiths fractures). This splint immobilizes the elbow and wrist joints to prevent supination and pronation of the forearm (**Figure 91-9**). The splint begins at the palm, just proximal to the metacarpophalangeal (MCP) joints. It has the distinct advantage of allowing the MCPs to remain free preventing stiffness in those joints. Measure the required length of splinting material along the volar surface of the hand (starting just proximal to the MCP joints) and forearm, around the elbow, and back on the dorsal surface of the forearm ending just proximal to the MCP joints. **The MCP joints should be left completely free to prevent stiffness.** Early mobilization of the fingers will help to reduce swelling. Apply cotton cast padding from the MCP joints to just proximal to the elbow. The ulnar styloid process and the olecranon process are two bony prominences that need extra padding for comfort and prevention of pressure sores. The free ends of the splint also need added protection to minimize hand discomfort. Apply the splint. **Mold the splinting material with great caution to prevent closure of the sides of the splint, thus forming a closed cast.** Fold and/or cut the volar and dorsal splinting material to ensure that the finger MCP joints are freely mobile (**Figure 91-9**).

POSTERIOR LONG ARM SPLINT

Distal humeral fractures and proximal forearm fractures can be immobilized in a posterior long arm splint (**Figure 91-10**). It is also useful for fractures of the radial head and neck, olecranon fractures, and severe ligamentous injuries to the elbow. The posterior long arm splint extends from the axillary crease area, behind the elbow, distally to incorporate the wrist joint, and ending at the MCP shafts (**Figure 91-10**). This splint immobilizes the elbow in a range of 45° to 90° with the forearm in supination, pronation, or neutral

FIGURE 91-10. The posterior long arm splint. The forearm and wrist are in a neutral position. The padding and overwrap have been omitted for easier visualization of the splint.

FIGURE 91-11. The radial gutter splint with the hand in the "safe" position.[9]

positioning depending upon the type of injury. The wrist can also be in a flexed, extended, or neutral position. **The metacarpals should not be immobilized in this splint unless the distal forearm or wrist fracture is comminuted.** Despite the many possibilities, the posterior long arm splint is usually applied with the elbow flexed 90°, the forearm neutral, and the wrist neutral (**Figure 91-10**).

RADIAL GUTTER SPLINT

The radial gutter splint is used for the treatment of stable phalangeal and metacarpal fractures of the index or middle fingers. The splinting material extends from the pulp of the distal fingers to the proximal forearm (**Figure 91-11**). It is helpful to measure and cut a hole in the middle of the splinting material to allow for the insertion of the thumb prior to wetting the splinting material. Place cotton cast padding between the index and middle fingers prior to applying the splint to prevent skin maceration. Mold the width of the splinting material around the radial aspect of the index finger, middle finger, hand, and forearm to create a stabilizing force. The ulnar aspect of the hand and forearm is left entirely free. The hand is immobilized in what is considered a "safe" position with the wrist dorsiflexed 20°, the MCP joints flexed 60° to 90°, and the interphalangeal (IP) joints extended or slightly flexed at 10°[9] (**Figure 91-11**). This is also known as the "position of comfort." It can be described as if the patient were holding a can of soda. The fingertips should be visible to allow for repeat neurovascular examinations.

ULNAR GUTTER SPLINT

This splint is used for the treatment of stable metacarpal and phalangeal fractures of the ring and small fingers (**Figure 91-12**). The long axis of the plaster extends from the pulp of the distal fingers to the proximal forearm. Place cotton cast padding between the ring and little fingers to prevent any maceration (**Figure 91-12A**). The width of the plaster must wrap around the ulnar aspect of the hand and forearm. Mold the splint around the forearm, hand, fourth finger, and fifth finger. The radial side of the hand is left entirely free. The hand is immobilized in the "safe" position with the wrist dorsiflexed 20°, the MCP joints flexed 60° to 70°, and the IP joints extended or slightly flexed at 10°[9] (**Figure 91-12B**). The fingertips should remain visible to allow for repeat neurovascular examinations.

VOLAR SPLINT

The volar splint can be used for the treatment of wrist fractures, radial styloid fractures, ulnar styloid fractures, metacarpal fractures, middle phalangeal fractures, and proximal phalangeal fractures. This splint remains only on the volar surface of the hand and forearm, as the name suggests. The splint begins at the proximal forearm and ends just proximal to the MCP joints (**Figure 91-13**). The splint can be modified and extended to include the fingers

FIGURE 91-12. The ulnar gutter splint. **A.** Padding is necessary between any fingers that are immobilized together. **B.** The final product with the hand in the "safe" position.[9]

FIGURE 91-13. The volar splint. The overwrap has been omitted for easier visualization of the splint.

for phalangeal fractures with the wrist dorsiflexed 20°, the MCP joints flexed 60° to 90°, and the IP joints extended or slightly flexed at 10°.

DORSAL ("CLAM DIGGER") SPLINT

The dorsal splint can be used in place of a volar splint for injuries of the distal forearm, wrist, or hand. The splint runs along the dorsal surface of the forearm and hand, from the proximal forearm to the ends of the digits. As with the volar splint, the wrist is extended 15° to 20°, the MCP joints are flexed 60° to 90°, and the IP joints are extended or slightly flexed to a maximum of 10°.

The dorsal splint maintains better control of the MCP and IP joints, assuring that the hand remains in the "safe position," when compared to the volar splint. Pad the splint adequately to prevent pressure sores, since the dorsal surface of the hand lacks the intrinsic fat pads of the palm.

THUMB SPICA SPLINT

Scaphoid fractures, navicular fractures, carpometacarpal subluxations and dislocations of the thumb, and collateral ligament injuries of the thumb can all be immobilized in a thumb spica splint (**Figure 91-14**). This splint extends to the proximal forearm. It can be extended proximally to include the elbow joint if required. It is positioned on the forearm, like a radial gutter splint, but only the thumb is immobilized. There are several methods to forming a thumb spica splint. One can simply lay the plaster over the radial aspect of the forearm and thumb. It is useful to cut one side of the splint into a shape that conforms to the thumb to facilitate the placement of the splint material around the thumb (**Figure 91-14A**). Cutting a wedge out of one side of the plaster will allow for easier splinting of the thumb without excess material

FIGURE 91-14. The thumb spica splint. **A.** One technique of thumb spica application with the splinting material cut to conform to the thumb. **B.** Cutting the splinting material facilitates this different technique of thumb spica application. **C.** The final product with the wrist dorsiflexed 20° and the thumb positioned as if a glass were being held in the hand.

collecting in the first web space (**Figure 91-14B**). Position the thumb as if a glass were being held in the hand with the wrist in 20° of dorsiflexion (**Figure 91-14C**).

FINGER SPLINTS

Immobilization of the finger lends itself to great creativity in the field of splinting. Finger splints may be adequate for immobilization of stable finger fractures, reduced dislocated joints, or ligamentous strains. Splint the finger in full extension if it involves an extraarticular fracture of the distal phalanx. Splint the finger in slight flexion if it involves the strain of a joint or ligament. The finger can be splinted in isolation, or it can be immobilized with the adjacent finger for additional stability. Applying a single-digit or two-digit splint allows neighboring joints to remain mobile. Splinting material is rarely used for finger splints in the modern Emergency Department setting. The creation of foam-padded metal or plastic splints has facilitated immobilization of the affected digit. Nonetheless, small strips of cut splinting material can still be used to stabilize any finger injuries. **The juxtaposition of the affected finger with its neighboring finger requires padding between the digits to prevent skin maceration and breakdown.**

FIGURE 91-15. The short arm cast. **A.** Flex the elbow 90°. The patient can help position the wrist and fingers in a position of function. **B.** Tubular stockinette is applied to the entire arm in anticipation of a long arm cast. **C.** Cotton cast padding is applied to the forearm. Adequate padding is also needed at the thumb, as it will remain exposed and mobile. **D.** Cut one side of the casting material as it is wrapped around the thumb. Less bunching of excess material occurs with quick cuts of the casting material. **E.** An additional length of casting material (four to five layers) can be applied along the ulnar length of the cast. This serves as reinforcement if additional strength is necessary. **F.** Mold the cast with the palmar aspect of the hands.

FIGURE 91-15. (*continued*) **G.** The wet casting material and underlying padding are cut and folded back to fully expose the thumb. **H.** The "okay" sign of a properly exposed thumb.

SHORT ARM CAST

The short arm cast is used for stable fractures of the metacarpals, the carpal bones, the distal radius, and the radial or ulnar styloid processes (**Figure 91-15**). The short arm cast begins at the proximal forearm and extends to include the palm and the dorsum of the hand. The metacarpophalangeal and elbow joints are left exposed to allow for full motion at these joints. Flex the patient's elbow 90° (**Figure 91-15A**). Place the wrist in the desired position. The extent of flexion and ulnar-radial deviation of the wrist is determined by the underlying injury. The forearm can be in a neutral, pronated, or supinated position. Apply bias stockinette (**Figure 91-15B**). Apply cotton cast padding (**Figure 91-15C**). Ensure that extra padding is applied to the bony prominences of the base of the thumb and the ulnar styloid.

Apply the casting material. Roll the casting material over the padding from the hand to the forearm. A quick trim of the casting material will allow for a better fit as it passes around the thumb (**Figure 91-15D**). **Provide adequate space for the thumb so that its motion is not limited.** The application of additional layers to the anteromedial surface will strengthen the cast (**Figure 91-15E**). Mold the cast with an anterior–posterior force applied to the forearm and not up and down strokes (**Figure 91-15F**). Use smooth, rapid, and repetitive motions to mold and laminate the casting material. Trim the casting material while it is still wet to even out the thumb opening and the cast ends (**Figure 91-15G**). Ensure that all protective padding is pulled out from under the casting material to protect the skin from the sharp edges (**Figure 91-15G**). The patient should be able to touch the tips of the thumb and index fingers when the cast is properly applied (**Figure 91-15H**).

LONG ARM CAST

A short arm cast can easily be extended into a long arm cast if needed. Simply extend the cast proximally with the elbow in 90° of flexion. Extend the padding and the casting material to the proximal humerus, ending two or three finger breadths distal to the axilla (**Figure 91-16**). Be careful to provide adequate padding around the axilla or the patient will complain about the sharp cast edge.

LOWER EXTREMITY SPLINTS AND CASTS

ANKLE (SHORT LEG) SPLINT

The ankle splint helps to immobilize isolated ankle injuries with the joint at a 90° angle (**Figure 91-17**). This splint is commonly used for ankle fractures and sprains. It can also be helpful for certain stable fractures of the foot. This splint can be applied as a posterior splint or a lateral to medial stirrup splint.[13] Combining the two techniques can provide additional support for the ankle and is known as a trilaminar splint. The first part (posterior splint) provides posterior support to the foot and ankle. The second part creates a medial-to-lateral stirrup-like splint around the sides of the ankle for additional stability.

Place the patient prone with their knee flexed 90° and the foot pointing upward (**Figure 91-17A**). Place the posterior support of splint material from the proximal posterior calf, passing under the heel, and along the plantar surface of the foot (**Figure 91-17B**). It

FIGURE 91-16. The short arm cast is extended into a long arm cast. The axilla needs adequate padding for protection of its sensitive skin.

FIGURE 91-17. The ankle splint. **A.** Stockinette is applied and the leg is positioned. **B.** The splinting material is applied posteriorly. **C.** A stirrup splint is applied around the medial to lateral ankle. **D.** Fold the corners and smooth out the splint. **E.** An elastic wrap is applied over the splint after folding back the stockinette. The foot is maintained in this position until the plaster sets.

can be extended distal to the toes to provide protection. Place the foot 90° to the tibia and in neutral rotation.

For a "stirrup" support of the ankle, begin by applying splinting material onto the length of the medial aspect of the proximal calf, over the medial malleolus, under the heel, and up the lateral aspect of the ankle and calf (**Figure 91-17C**). The stirrup portion should be long enough to go from mid-tibia to mid-fibula when wrapped under the affected foot. Fold and smooth the edges of the stirrup around the heel (**Figure 91-17D**). Keep the ankle flexed 90° with the foot neutral while the splint material sets (**Figure 91-17E**).

LONG LEG SPLINT

This splint is commonly used for knee and tibial injuries prior to and after surgical fixation. It is basically a longer extension of the short leg splint described above. Posterior, medial, and lateral lengths of splinting material are used to stabilize the leg while the anterior aspect of the leg is left exposed. Measure the extremity from the gluteal crease distally to the tips of the toes. It is important to add an additional 1 to 2 in. to the measured length so that the splinting material can be folded back on itself to protect the patient from the sharp ends. The application of medial and lateral splinting material begins at the upper thigh just below the level of the gluteal crease and travels down the knee, calf, and under the ankle. The posterior portion of splinting material begins at this same level and travels down the posterior aspect of the leg, behind the knee, curving around the heel, and ending just beyond the ends of the toes. Flex the foot 90° to the tibia, flex the knee 10° to 30°, and mold the splint. Failure to keep the ankle at 90° will allow the Achilles tendon to shorten and stiffen. A pillow may be placed under the knee to maintain 20° to 30° of flexion while the splint hardens.

FIGURE 91-18. Positioning and splinting of the patient with an Achilles tendon injury.

SPLINT FOR ACHILLES TENDON RUPTURE

Rupture of the Achilles tendon can be managed surgically or conservatively with immobilization. Surgery is often delayed and the patient will require immobilization. Position the patient as if placing an ankle splint or have the patient sit up with the affected extremity hanging over the gurney's edge. Position the foot in 20° to 30° of plantarflexion (**Figure 91-18**). This is a position that the foot will naturally relax into. Place a posterior splint on the lower extremity extending from the proximal calf to the distal aspect of the toes. Cut out wedges of plaster in order to minimize buckling at the malleoli as the splint material wraps around the heel.

SHORT LEG CAST

The short leg cast is used for stable ankle fractures and stable fractures of the hindfoot, midfoot, and forefoot (**Figure 91-19**). Place the patient either supine or sitting on the edge of the gurney. Place a padded block under the distal thigh if the patient is supine. Instruct an assistant to hold the patient's toes to help keep the lower extremity in a good position. Holding the leg by the toes may allow the force of gravity to disrupt fracture alignment. Care must be taken to prevent this outcome. The patient can sit upright on the edge of the gurney with the affected leg hanging down freely if no assistant is available.

FIGURE 91-19. The short leg cast leaves the knee and tibial tuberosity exposed. The finger is pointing to the tibial tuberosity.

The short leg cast begins at the proximal calf, below the knee, and extends down to the toes (**Figure 91-19**). The knee and tibial tuberosity are left entirely free to allow for full flexion and extension. The toes can be left entirely exposed or the cast can provide a hard sole of support and protection beneath the toes. Apply cotton cast padding with extra attention to the areas of bony prominence such as the fibular head, the lateral malleolus, and the medial malleolus. Apply the casting material from the calf to the toes as if applying a short arm cast. Mold the casting material around the Achilles tendon, away from the malleoli and to conform to the plantar arch. Cut the wet casting material under the metatarsal heads to expose the toes or leave it long to support the entire toes.

Converting a short leg non-weight bearing cast to a walking cast requires small adjustments to the existing cast. Supplement the arched foot of the short leg cast with additional casting material to form a flat surface. **Apply a preformed heel after the cast has completely dried to prevent any indentation.** Place the walking heel in the midsagittal plane of the foot with the center aspect lining up with the anterior calf. Secure the heel in place with copious casting material wrapped around the foot and ankle (**Figure 91-20**).

FIGURE 91-20. Converting the short leg cast into a walking cast. A walking heel is secured with an additional casting material over-wrappings.

FIGURE 91-21. The long leg cast.

LONG LEG CAST

The long leg cast can be used for immobilization of distal femoral or proximal tibial fractures (**Figure 91-21**). The cast extends from the metatarsal heads to several finger breadths below the groin. The leg is immobilized with the knee in slight flexion and the foot 90° to the tibia with no internal or external rotation (**Figure 91-21**). Extending the short leg cast up to the groin is a safe and stepwise technique of forming a long leg cast. Be sure to provide sufficient overlap of casting material at the junction between the two casts. Inadequate overlap will weaken the integrity of the cast. Support the knee in slight flexion while the casting material sets. Make sure that there is adequate padding around the proximal free edge of the cast to protect the groin.

KNEE IMMOBILIZERS

Knee immobilizers can be made using splinting material and are indicated for ligamentous injuries. Measure the extremity starting 10 in. above the patella to 10 in. below the patella. Double that length and cut the splinting material. Fold the splinting material end-to-end. Make a cut in the folded side extending from one edge to the middle of the folded side to create a hinge. Apply cotton cast padding starting 10 in. above the patella to 10 in. below the patella. Place the hinged portion of the splinting material 10 in. below the anterior patella with the cut ends extending proximally up both the medial and lateral leg. Secure the splinting material with a loose fitting elastic bandage.

AFTERCARE

The most feared complication of a splint or cast application is the development of a compartment syndrome. The aftercare is geared toward edema reduction and patient education. Instruct the patient regarding the early signs of a compartment syndrome. This includes increased pain, pain with passive motion, paresthesias, pallor, decreased or altered sensation, as well as delayed capillary refill. The patient should return to the Emergency Department immediately if they develop any of these symptoms, if the digits become cold or blue, or if the patient has other concerns. The extremity should be maintained above the level of the heart for the first 48 to 72 hours after the injury. Ice should be applied to the surface of the cast or splint for at least 15 minutes three times a day. The cold therapy will be transmitted through the cast or splint and result in significant reduction of edema. Active motion of the fingers and toes should be encouraged to help reduce edema in the extremity. **The cast or splint must be kept completely dry.** Should bathing be desired, instruct the patient to place two plastic bags over the extremity and tape the proximal edge to the skin of the extremity. Sufficient pain medication should be supplied to last the patient until their follow-up visit with an Orthopedic Surgeon. This should include nonsteroidal anti-inflammatory drugs supplemented with narcotic analgesics. A sling may facilitate mobilization for some upper extremity injuries.

COMPLICATIONS

The most common complications associated with the application of a cast or splint include plaster sores, compartment syndrome, joint stiffness, thermal injury, infection, and allergic reactions. The following section focuses on the prevention of these complications.[4,6,10]

PLASTER SORES

Plaster sores result from ischemic necrosis of the skin underneath a cast or splint. The skin begins to exhibit necrosis after only 2 hours of continuous pressure. **Great care should be taken in applying a cast or splint and only molding it with the broad surfaces of the hands. Molding with the fingers can result in indentations and localized areas of pressure. The cast or splint should never be allowed to rest on a hard or pointed surface until it is completely dry.** Points of contact on the hard surfaces may cause impressions that result in increased pressure. Extra padding over bony prominences may decrease the incidence of plaster sores.

Complaints of pain should be taken very seriously. The cast or splint should be split or removed immediately and the skin examined. If the pressure point is not addressed rapidly, the pain will often subside as the skin becomes necrotic. This oversight often results in a foul smelling pressure sore under the cast or splint when the patient returns for follow-up. Cast and splint treatment may be rife with complications for patients with limited sensation from underlying medical conditions (i.e., diabetes, paraplegia, and myelomeningocele). **Great care should be taken and extra padding used when casting or splinting these individuals.**

Common areas of pressure necrosis also include the proximal and distal ends of the cast or splint. These are areas of stress concentration. **Great care should be taken in padding the ends of the cast or splint during the application. No plaster or fiberglass should ever touch the skin directly. If the edges of the splint are sharp or too long, they should be folded out and away from the patient.**

COMPARTMENT SYNDROME

A compartment syndrome is a significant complication from the application of a cast or, less commonly, a splint. The rigid immobilization prevents soft tissue expansion from edema and decreases the amount of fluid needed to raise compartment pressures.[11] In cases of acute fractures, casts should be used with caution and always split in the direction perpendicular to the force needed to maintain the reduction. **For example, after casting a distal radius fracture where a dorsal mold is needed to maintain the reduction, split the cast longitudinally on the volar and dorsal surfaces (i.e., bivalved) to allow for mediolateral spread of the plaster.** Splinting greatly reduces the chance of iatrogenic-induced compartment syndromes because unlike casting, splints do not harden circumferentially.

It is not sufficient to split only the plaster. The plaster and underlying cotton cast padding must be split to visualize the skin underneath. Making a single longitudinal cut (i.e., univalving) in

the cast can also decrease the compartment pressure. Univalving the cast can decrease intracompartmental pressures by 30%.[12] Spreading the cast 1 cm after cutting it can lower the pressure 60%.[12] Splitting the cotton cast padding will decrease the pressure by 70%.[12]

JOINT STIFFNESS

Joint stiffness is a significant complication of joint immobilization with casts and splints. Sometimes the immobilization is unavoidable, as the incorporation of the ankle and the knee in a long leg cast. **Every effort should be made to decrease adjacent joint immobilization as soon as it is safe and practical.** For example, by converting a long leg cast into a short leg cast.

Immobilize the extremity in a position of function as long as this does not interfere with the maintenance of fracture reduction. For example, take great care not to immobilize the ankle in plantarflexion when applying a lower extremity splint or cast. This mistake is commonly seen when a long leg cast is placed. This pitfall may be avoided by the stepwise application of the cast. First apply the cast to the foot and ankle with the ankle held 90° to the tibia. Second, extend the cast proximally to become a short leg cast and mold the reduction. Finally, extend the cast up the thigh as needed. An additional benefit is the reduction of anterior compartment pressures of the leg when the foot is held in 0° to 37° of dorsiflexion.

Great care should also be taken in splinting the upper extremity. **Every effort should be made to leave the fingers mobile at the metacarpophalangeal joints.** Immobilization of the metacarpophalangeal joints in extension results in shortening of the collateral ligaments and thus limits flexion. **Immobilize the metacarpophalangeal joints in 90° of flexion if they must be immobilized.** This position keeps the collateral ligaments in a lengthened position and allows a rapid return to function.

THERMAL INJURY

Thermal injury may result from the exothermic reaction of plaster or fiberglass as it sets (i.e., dries). The heat generated during the setting increases as the number of layers (i.e., thickness) increases as well as the temperature of the water increases. Also important is the ability to dissipate the heat generated by the drying plaster or fiberglass. Placing a cast or splint on a plastic pillow as it dries will result in reflection of the heat and an increased temperature within the cast or splint. The use of cloth pillows or towels under the cast or splint allows for some dissipation of the heat. Optimal heat dissipation occurs by exposing the cast or splint to circulating air.

Sufficient cotton cast padding must be used to protect the skin. Plaster and fiberglass must never touch the skin directly. The incidence of thermal injury can be decreased by using cool water and as thin a layer of plaster or fiberglass as possible to accomplish stable immobilization of the extremity. Great care should be used in the application of a cast or splint to anesthetized patients, insensate limbs, or confused patients.

INFECTION

Infection secondary to a cast or splint is uncommon and is usually related to open wounds or exposed surgical pins underneath the plaster. Fresh water should be used to wet the plaster. Do not use standing or previously used water, as it is an excellent culture medium. All wounds should be dressed with sterile gauze and cotton cast padding prior to applying the cast or splint. Windows can be created over wound sites to allow for regular care and evaluation. Patients should be instructed to keep casts and splints clean and dry so as to prevent skin maceration.

ALLERGIC REACTIONS

Allergic reactions to cotton, fiberglass, and plaster have been reported but are exceedingly rare. Orthopedists and orthopedic technicians may develop a contact dermatitis from continued exposure to plaster over many years. Gloves should be worn for plaster and fiberglass application.

SUMMARY

The initial management of orthopedic trauma is a fundamental aspect of Emergency Medicine. Fractures and dislocations of the extremities are routinely handled in the Emergency Department with prompt Orthopedic follow-up or consultation. The application of external immobilization can be the definitive or temporizing management of the injured extremity. The application of splints accounts for the majority of immobilization of injured extremities. Cast application plays a role in maintaining bony alignment following closed reductions of fractures.

Clear benefits of external immobilization include pain relief and the reduction of further soft tissue injury from bony fragments. Immobilization of the fracture decreases motion and traction on the nerve-rich periosteum.[4,7] The immobilization of fracture ends protects adjacent neurovascular structures from injury and helps prevent bony fragments from penetrating the skin. External immobilization also reduces the area available for hemorrhage and decreases bone bleeding.[4] Early immobilization leading to fracture stabilization is also important in reducing the morbidity associated with long bone fractures.[12] Finally, the closed treatment of fractures facilitates the body's natural processes of repair. External periosteal and internal intramedullary callus formation is optimized in the setting of bony alignment that has been secured by casting or splinting.

The application of splints is an essential skill for any Emergency Physician. The application of a cast in the Emergency Department is appropriate in some select situations. The casting or splinting of an extremity is simple, easy to perform, and relatively quick.

SECTION 7

Skin and Soft Tissue Procedures

92 General Principles of Wound Management

Lisa Freeman Grossheim

INTRODUCTION

An acute wound can be defined as an unplanned disruption in the integrity of the skin, including the epidermis and dermis. **The goals of wound management are to restore tissue continuity and function, minimize infection, repair with minimal cosmetic deformity, and be able to distinguish wounds that require special care.** The principles of wound management should be emphasized over the repair technique. Appropriate wound management prior to approximating the wound will allow it to heal with minimal complications. This includes wound cleansing, debridement of the wound edges, wound approximation, and prevention of secondary injury.

HEALING OF WOUNDED TISSUE

PHASES OF WOUND HEALING

The response of tissue to an injury is described in three phases. The first phase is coagulation and inflammation. The second phase is the proliferative phase. The final phase is the reepithelialization or remodeling phase.

Phase I consists of coagulation and inflammation. It occurs in the first 5 days. This phase is also known as the vascular phase. A fibrin clot forms a transitional matrix that allows for the migration of cells into the wound site over a period of 72 hours. Inflammatory cells (i.e., neutrophils, monocytes, and macrophages) kill microbes, prevent microbial colonization, break down soluble wound debris, and secrete cytokines. The cytokines signal synthetic cells, such as fibroblasts, to initiate phase II. Most sutured wounds develop an epithelial covering that is impermeable to water within 24 to 28 hours.

Phase II is the proliferative phase. It occurs during days 5 to 14 after the injury. Fibroblasts proliferate and synthesize a new connective tissue matrix that replaces the transitional fibrin matrix. Granulation tissue consisting of fibroblasts, immature connective tissue, epidermal cells that have migrated, and abundant capillaries forms within the wound. Fibroblasts release collagen, a protein substance that is the chief constituent of connective tissue. **At 5 days, the tensile strength of the wound itself is 5% that of normal skin. Collagen formation peaks at day 7.**

Phase III is known as the remodeling, reepithelialization, or maturation phase. It occurs from day 14 and lasts until there is complete healing of the wound. The new granulation tissue is being converted into a scar. The scar consists of a rich matrix with decreasing cell density, decreasing vascular density, and increasing thickness of collagen fiber bundles packed in parallel arrays.[1] **The wound will have 15% to 20% of its full strength at 3 weeks and 60% of its full strength at 4 months.** Tensile strength continues to increase up to 1 year after wounding. The skin will eventually regain only 70% to 90% of its original tensile strength.

FACTORS AFFECTING NORMAL REPAIR

The most common causes of improper wound healing are tension on the wound edges, necrosis and/or ischemia of the tissues from local conditions (e.g., crush injuries and contusions decrease blood flow and lymphatic drainage, which alters local defense mechanisms), or shock. Hypovolemia is the major deterrent to wound healing in patients with hemorrhage and shock, hemorrhage from inadequate hemostasis, infection, or retention of foreign bodies. Systemic conditions such as malnutrition, immunosuppression, shock, diabetes secondary to microangiopathy, decreased oxygen and nutrient delivery to the wound, renal insufficiency, cytotoxic drugs, vitamin deficiency, trace metal deficiency, and collagen vascular disease can result in poor wound healing. Polymorphonuclear leukocyte function is known to be impaired from hyperglycemia, jaundice, uremia, cancer, or chronic infections.

Drugs and medications can contribute to good wound healing or affect it adversely. Malnutrition, lack of protein, and lack of vitamins (e.g., vitamins A and C) may inhibit or prolong healing. Zinc deficiency, which is reversible, may play a role in retarding the healing process.[3] Anti-inflammatory drugs (e.g., colchicine, aspirin, and glucocorticoids) disrupt macrophage function, collagen synthesis, and polymorphonuclear neutrophil concentrations. Pretreatment or early introduction of glucocorticoids results in retarded wound repair by slowing cell proliferation.[4]

SCAR FORMATION

Some 6 to 12 months are required to form a mature scar. This explains why scars should not be revised until 12 months have passed. A wider scar, inadequate wound closure, or a wound dehiscence may occur in areas with increased skin tension or if the wound is in an area of excessive motion (e.g., over joints). **Adequate immobilization of the approximated wound (but not necessarily the entire anatomic part) is mandatory after wound closure for efficient healing and minimal scar formation.** Contractures can develop when a scar crosses perpendicular to a joint crease. These patients may require physical therapy to prevent the loss of range of motion secondary to contractures.

Hypertrophic scars result from full-thickness injuries. **Hypertrophic scars are characterized by a thick and raised scar that remains within the boundaries of the original injury.** They must often be corrected by surgical intervention.[1]

Keloids are hypertrophic scars (i.e., thick and raised) that exceed the boundaries of the initial injury. They can develop from superficial injuries and appear to have a genetic basis. Surgical intervention rarely resolves keloids. They may be prevented or minimized by the local application of pressure dressings, Silastic dressings, glucocorticoids, and calcium channel blockers.[1]

The repair procedure may result in more scar tissue. Absorbable suture materials contribute to the formation of suture marks because of their increased reactivity, whereas nonabsorbable materials do

not. Wounds that are approximated too tightly can result in tissue ischemia and more scar tissue formation.

WOUND CLOSURE TECHNIQUES

PRIMARY INTENTION

Primary intention involves surgically approximating the wound edges shortly after the time of injury. The skin's greatest strength is in the dermal layer. The best repair results when the entire depth of the dermis is accurately approximated to the entire depth of the opposite dermis. **Accurate approximation of the epidermis gives a cosmetically appealing effect to the repair but does not contribute to its strength. Wound eversion and the use of buried sutures can greatly improve healing by primary intention.**

SECONDARY INTENTION

Secondary intention involves allowing the wound to heal without any surgical intervention. The wound is left open and allowed to heal from the inner layer to the outer surface. It is a more complicated and prolonged healing process than primary intention. Infection, excessive trauma, tissue loss, or imprecise approximation of tissue can result due to healing by secondary intention. Wound contraction by granulation tissue containing myofibroblasts is the major influence on this type of healing. Wound contraction becomes more significant when the dermis is lost.

Concave skin wounds heal with the best results. These areas often heal better by secondary intention than by primary intention. Such concave areas include the inner ear, the nasal alar crease, the nasolabial fold, the temple, and the concave areas of the pinna. Flat surfaces can also heal well by secondary intention, although surgical intervention may be best. Some examples include the forehead, the side of the nose, and periorbital areas. Wounds on convex surfaces are not optimal for healing by secondary intention. Convex surfaces include the malar cheek, the tip of the nose, and the vermilion border of the lip.[2]

TERTIARY INTENTION

Tertiary intention, or delayed primary closure, can often decrease infection rates. Wound closure by tertiary intention is accomplished 3 to 5 days following the initial injury. It is a combination of allowing the wound to heal secondarily for 3 to 5 days and then primarily closing the wound. It is the safest method of repair for wounds that are contaminated, dirty, infected, traumatic, associated with extensive tissue loss, at high risk for infection, and for wounds that are "too old" to close. The ultimate cosmetic result is the same as that of primary wound closure. This method may not be suitable for young children, having to return a second time for an uncomfortable procedure.

During the interim period, instruct the patient to apply wet-to-dry dressing changes twice a day. Upon the patients return, assess the wound for any signs of infection. Anesthetize and clean the wound. Scrub the wound base and edges with saline-moistened gauze and irrigate the wound to remove any dirt, debris, and granulation tissue. Suture the wound to approximate and evert the wound edges. The postprocedural wound care is the same as if the wound was closed primarily.

WOUND INFECTION

Wound infections occur as a result of the patient's resident flora and the environment. It is related to wound age, the amount of devitalized tissue, and the tissue concentration of pyogenic bacteria. A wound infection exists when there are bacterial densities of more than 10,000 organisms per gram of tissue.[5] Bacteria slow wound healing by secreting proteases that directly injure the tissue in the wound.[2] They also secrete other factors that lead to excess inflammatory cells in the wound, which also injures the tissue.[2]

PATIENT EVALUATION AND ASSESSMENT

HOST HISTORY

A thorough and accurate history and physical examination are essential for optimum wound management. Documentation of the patient's age, prior tetanus immunization history, systemic illnesses, medications, allergies (such as to latex or local anesthetics), and the circumstances of the injury are essential to good wound management. These principles are emphasized because the presence of disease processes (such as diabetes mellitus, chronic malnutrition, alcoholism, hepatic or renal insufficiency, asplenism, malignancies, and extremes of age) may impair host defenses or complicate wound healing.[6,7] **Second, the wound itself is often less important than an associated injury to an adjacent structure or cavity. Associated injuries can easily be missed without a specific directed search for their presence.**

TETANUS PROPHYLAXIS

A thorough history must be obtained concerning the patient's tetanus immunization status. Important factors to consider in assessing the risk of developing tetanus include prior immunization history, the type of wound, the degree of wound contamination, the time from injury to treatment, and the presence of underlying medical disease.

Wounds may or may not be prone to tetanus (**Table 92-1**). The administration of tetanus prophylaxis is based upon the patient's immunization history and the risk of developing tetanus (**Table 92-2**). Current guidelines state that tetanus toxoid (Td) may be deferred in patients with "clean, minor" wounds who have completed a primary series or received a booster dose (Td 0.5 mL IM) within 10 years. Consider tetanus immune globulin (TIG 250 to 500 U IM) in addition to Td for patients at risk of developing tetanus. Elderly patients without documentation of a primary series, patients from nonindustrialized nations, and those from rural or

TABLE 92-1 Characteristics of Tetanus-Prone and Non-Tetanus-Prone Wounds

Clinical feature	Tetanus-prone wounds	Non-tetanus-prone wounds
Contaminants (feces, foreign body saliva, and soil)	Present	Absent
Devitalized tissue	Present	Absent
Infection	Present	Absent
Ischemic or denervated tissue	Present	Absent
Mechanism of injury	Burn, crush, bullet	Sharp and smooth (knife or glass)
Wound age	>6 h	<6 h
Wound depth	>1 cm	<1 cm
Wound type	Abrasion, avulsion, crush, irregular, stellate	Linear or straight

TABLE 92-2 Tetanus Prophylaxis

Immunization history	Tetanus-prone wounds	Non-tetanus-prone wounds
History of adsorbed Td	Td and TIG	Td and TIG
Unknown or less than three doses	Td, TIG, and complete the series	Td and complete the series
Fully immunized, >5 years and <10 years since last dose	Td	None needed
Fully immunized; ≤5 years since last dose	None needed	None needed
Fully immunized, ≥10 years since last dose	Td and TIG	Td

Td, tetanus and diphtheria toxoids; TIG, tetanus immune globulin.

inner-city areas may never have received tetanus immunization and should be considered for TIG.

MECHANISM OF INJURY

Severity of injury as well as associated injuries can be anticipated by determining the precise mechanism of injury. This will often indicate additional soft tissue injury, the presence of a foreign body, or the amount of contamination present.

Soft tissue injuries are rarely surgical emergencies. The patient's general condition should be attended to, with priority given to observing the ABCs (airway, breathing, and circulation) of Emergency Medicine. The skin margins of a laceration can be tacked together with well-placed atraumatic sutures and the wound covered with a moist pressure dressing until the time is more opportune for definitive repair.

Important questions and answers that must be documented are exactly how the injury occurred, when and where the injury occurred, and what contaminants were present or involved. If the injury involves the hand, what position was the hand in at the time of the injury, what kind of work does the patient do, and which is the patient's dominant hand? Complicated wounds, such as those caused by animal or human bites, chemical exposure, or high-pressure injection may require a more extensive evaluation and consultation with the appropriate specialist.

CLASSIFICATION OF WOUNDS

Wounds are described and classified based upon their cause and the type of injury. Abrasions are the result of grinding or abrading forces on the skin. The epidermis and/or dermis is disrupted but not removed in its entirety. Crush injuries are due to compressive forces. The patient sustains a large amount of kinetic energy that results in microvascular disruption, edema, and devitalized tissue. Crush wounds are 100-fold more likely to become infected than lacerations because of the much lower bacterial loads required for infection.[8]

Lacerations are wounds that are caused by shear forces that result in a tearing of the tissue. They are subclassified as avulsion, shear, or tension lacerations. Avulsion lacerations are injuries where there is sharp trauma at an angle that removes the epidermal and possibly also the dermal layer of skin. The injury creates a skin flap. Shear lacerations are produced by a sharp force, usually perpendicular to the skin surface, that results in a tidy or clean wound. These wounds are usually caused by knives, glass, or sharp metal objects. There is little tissue damage, and this type of wound is not prone to infection. Tension or tensile lacerations are injuries with jagged or contused edges that are created by a compressive force. These wounds pose a greater risk for infection than shear lacerations.[8]

Punctures result in a wound that is deeper than it is wide. The skin opening is small and the depth of the wound is often unknown. Such wounds are made by discrete and thin objects, and they carry a high risk for infection. Irrigation is mandatory for puncture wounds; however, the pressure must not be so high as to drive contaminants deeper into the wound.

The wound may also be clinically classified based upon an estimate of microbial contamination and the subsequent risk of infection. Clean wounds are those that occur under aseptic technique. These are usually surgical incisions that are elective in nature and preceded by a thorough skin cleansing and decontamination process. Clean-contaminated wounds are those associated with the usual and normal flora of the region. There is no contamination from foreign bodies or pus. Contaminated wounds are those that are traumatic (e.g., lacerations, open fractures), less than 12 hours old, or associated with a break in aseptic technique. Most wounds seen in the Emergency Department are of the contaminated type. They may be associated with the introduction of "dirt" or foreign bodies into the wound. Dirty wounds are those that are heavily contaminated (e.g., soil or feces), occur through infected tissue, are over 12 hours old, are associated with retained foreign bodies, or associated with devitalized tissue.

TIME OF INJURY

This is probably the most pertinent factor of the history. After 3 to 6 hours, the bacterial count in a wound increases dramatically. Few studies have been conducted to determine the maximal time in which lacerations can be closed without resulting in infectious complications. One study performed in an underdeveloped country indicated that wounds might be closed up to 18 hours postinjury.[9] Lacerations of the face and scalp that are reasonably clean may be closed primarily up to 12 to 24 (or even 48) hours postinjury with little risk of infection because of the excellent circulation in these areas. Other lacerations may generally be closed primarily if they are less than 6 to 12 hours old provided that they are not heavily contaminated or located in high-risk areas (i.e., hand or foot). The infection rate rises rapidly after 12 hours.

WOUND ASSESSMENT

A complete examination and documentation of the laceration is necessary. This includes noting the location and depth of the laceration, the presence of any gross contamination, the presence of an obvious foreign body, and any associated injuries.

Assessment of soft tissue wounds involves an examination of the surrounding tendons as well as the vascular and neurologic structures; bony injuries and foreign bodies should also be sought. Emergency Physicians must possess a working knowledge of functional anatomy, particularly of the face and distal upper extremity.

Hemostasis can be achieved by direct pressure with a gauze sponge or gloved finger for simple lacerations. Suturing the wound best controls bleeding of the scalp. Extremity wounds, particularly of the wrist and hand, should have a pneumatic tourniquet applied after the extremity is elevated for 1 minute to promote venous drainage. Inflate the cuff above the patient's systolic blood pressure for 20 to 30 minutes at a time. A blood pressure cuff may be substituted if a pneumatic tourniquet is not available. For more severe bleeding, there are several commercial tourniquets available, as well as new hemostatic agents such as Quick Clot.[37–39] **Vascular**

structures (with the exception of small arterioles, small venules, and vessels within muscles) should not be clamped and may require special techniques for hemostasis.

Wounds may cross tissue planes, opening them and creating potential pockets or dead spaces. Elimination of the dead space has been advocated in the past to decrease the probability of this area becoming a nidus for infection. This once traditional practice of obliteration of dead space to avoid infection of a nonvascularized space or to prevent hematoma formation is now considered controversial. Studies in animal models have found the incidence of infected wounds to be consistently proportional to the number of suture layers.[10,11] Leaving dead space open resulted in lower rates of infection than obliterating it with sutures.[10,11] Studies in 1994 and 1996 concluded that buried absorbable sutures increase the infection rate and the degree of inflammation in contaminated wounds and do not significantly increase the degree of inflammation in noncontaminated wounds.[12] Sutures placed in fat contribute no strength to the repair and fail to prevent hematoma formation and infection. **Deep absorbable sutures may be placed to repair the periosteum, muscles, or fascia or to minimize tension on skin sutures. Use only enough subcutaneous sutures to restore anatomic and functional integrity.** In most wounds, however, leaving potential space may be preferable to attempting to obliterate it.

It is important to explore the deep structures through a full range of motion in order to detect partial tendon lacerations or joint capsule disruption. **Tendons can be evaluated by inspection, but individual muscles must also be tested for full range of motion and full strength.**

A distal neurologic and vascular examination should be performed on extremity injuries. Capillary refill should be checked distally and take less than 2 seconds. Neurologic assessment involves checking distal muscle strength and sensation. **Check two-point discrimination prior to the administration of anesthesia for hand and finger lacerations.** Two-point discrimination at 5 mm on the radial and ulnar aspects of the finger pads is the most efficient method of assessing median and ulnar nerve function. Two-point discrimination should be less than 1 cm at the fingertips. A crush injury may be associated with decreased two-point discrimination and may take several months for recovery. Numbness may also be the first sign of a developing compartment syndrome. Nerve lacerations can be repaired immediately or the wound can be loosely approximated and repair of the lacerated nerve delayed.

Obvious as well as questionable fractures should receive a radiograph of the area. Bone injuries require checking the overlying skin to exclude an open fracture. An open fracture is an indication for surgical debridement and repair except in the case of a distal phalanx fracture, which can be treated with copious irrigation, oral antibiotics, and detailed discharge instructions.

WOUND FOREIGN BODIES

Failure to identify foreign bodies in wounds may lead to complications such as an increased risk of infection, delayed wound healing, and loss of function.[36] Foreign bodies and foreign matter greatly enhance the infectivity of a given bacterial inoculum.[13] Retained foreign bodies are a common complication of simple wound repair. **Perform a thorough inspection to attempt to diagnose the presence of a foreign body.** Missed foreign bodies are the second leading cause (14%) of lawsuits brought against Emergency Physicians.[14] Some foreign bodies cause an inflammatory reaction (e.g., wood, thorns, splinters, cloth, teeth, and rubber from shoes or foam insoles), while others do not (e.g., metal, glass, most plastics, and pencil graphite).

Wound exploration, irrigation, and radiography may be needed when the clinical setting suggests a possible foreign body. **Spread the tissue during exploration. Do not cut tissue and risk neurovascular injury.** Puncture wounds have not been proven to benefit by coring or probing to determine the depth of the wound. Imaging may be required to detect retained foreign bodies. Retained wood, thorns, and plastic are often detectable only by wound exploration and may not be visible on plain radiographs. Radiographs will identify retained metallic fragments and more than 90% of glass foreign bodies if the glass does not have a low lead content and the fragments are at least 2 mm long.[15,16] Wound markers can be used during radiography. Radiographs obtained in two planes can help localize the object for recovery. Glass may penetrate at an angle and be buried deeper than it appears. The use of ultrasound is controversial because of its lack of specificity, lack of sensitivity, and operator dependency.

Foreign bodies that do not cause an inflammatory reaction are often not removed from lacerations. This is especially true if there are multiple fragments or if excessive tissue disruption will result with attempted removal. **The patient should be made aware of any retained foreign bodies at the time of discharge, their benign presence, why removal was not attempted, the possibility of later infection, and the fact that they may eventually self-extrude. This must also be documented in the medical record.** If the wound is in a complex area, such as the palm, it may be necessary to gain consultation for immediate or delayed removal. The wound can be approximated loosely and immobilized for comfort and to avoid further tissue disruption, antibiotics prescribed, and arrangements made for appropriate out-patient follow-up in 24 to 48 hours.

Soils have varied levels of contamination potential. Sandy soils present a low risk of wound contamination. Clay-containing soils are pyogenic because they impair host defense mechanisms and promote inflammation. Organic soils contain *Clostridium tetani* and a more concentrated bacterial inocula. Soil contaminants, when present, can be removed by copious irrigation. These contaminated wounds should be left open and allowed to heal by secondary or tertiary intention.

HIGH-RISK WOUNDS

Many wounds require special consideration in deciding upon the method of closure, the type of suture to use, and the use of antibiotic prophylaxis. These include wounds contaminated by saliva, feces, vaginal secretions, soil, and organic material. **Wounds in immunocompromised patients or patients taking immunosuppressive drugs may require antibiotics and longer times for the sutures to remain before removal.** Hand wounds, including bite wounds, and foot wounds require special care. Wounds greater than 6 to 12 hours old, other than wounds on the face, may require delayed closure. Puncture wounds may require radiographs, incision and exploration, and antibiotic prophylaxis. Wounds accompanied by excessive tissue damage and devitalization or crush injuries are prone to infection. Wounds with retained foreign bodies may require radiographs, exploration, and removal. Major tissue defects may be closed with advanced wound closure techniques. Wounds overlying sites of active infection require antibiotics and delayed closure. These topics are covered further on in this chapter and in other chapters of this book (see Chapters 95 through 98 for details).

SKIN AND WOUND PREPARATION

ANESTHESIA

Wounds must be anesthetized with either local or regional techniques prior to cleansing and repair. Local anesthesia distorts wound edges; therefore regional nerve blocks should be used where appropriate (e.g., the hand, face, ear, nasal cartilage, palm, sole). Refer to Chapters 123 through 129 for a complete discussion of local

anesthetic agents, regional anesthesia, topical anesthesia, nitrous oxide anesthesia, and procedural sedation.

Lidocaine (Xylocaine) in a dose not to exceed 4.5 mg/kg is an effective and standard local anesthetic agent. Lidocaine anesthesia lasts approximately 60 to 90 minutes. If a longer period of anesthesia is required, bupivacaine may be used. It provides approximately 120 to 180 minutes of anesthesia. The addition of a 1:100,000 dilution of epinephrine to lidocaine or bupivacaine will prolong the duration of anesthesia, promote hemostasis, allow a larger dose to be used, and reduce systemic absorption of locally infiltrated local anesthetic solution. Epinephrine is a potent vasoconstrictor and should not be used near end organs such as the fingers or toes. It may decrease blood flow and induce ischemia. Epinephrine should also be avoided near the tip of the nose, the ear, and the penis.

Animal model studies have consistently shown that epinephrine increases the incidence of infection in contaminated wounds. This may be due to vasospasm-induced local ischemia. Epinephrine should not be used to enhance local anesthesia in contaminated wounds. Consider the use of regional anesthesia or procedural sedation in these patients.

The pain of local anesthetic injection can be reduced. The use of a 27 or 30 gauge needle, slower and deeper infiltration (into the dermis), warming the local anesthetic solution, and the addition of bicarbonate to lidocaine (9 mL lidocaine to 1 mL of bicarbonate) may decrease the pain of anesthetic injection.[21–26] Other strategies involve anesthetizing as much tissue as possible through a single site, starting proximally on the extremity and moving distally. Infiltration of the local anesthetic solution through the wound edges is less painful than through intact skin.

Most "allergic" reactions are actually vasovagal or other adverse responses. Allergies to "caines" are attributed to what is often a vasovagal or other side effect. True allergies to local anesthetics are rare and are generally seen only with the ester class of local anesthetics. If an allergy to lidocaine (an amide class of local anesthetic) is suspected, the use of an ester class of local anesthetic is suggested. An alternative is the use of cardiac lidocaine, the prefilled syringes used in codes and cardiac arrests, which contains no preservative. It is felt that the preservative in lidocaine is responsible for the allergic effect. Another alternative is to use a 1% to 2% solution of diphenhydramine (Benadryl). This provides adequate but not ideal anesthesia. The most common complication of local anesthesia infiltration is hypotension and bradycardia as a result of a vasovagal reaction.

Topical anesthesia is an attractive alternative to injection, particularly in the management of pediatric patients with simple wounds. Lidocaine, epinephrine, and tetracaine (LET) gel or tetracaine, adrenaline, and cocaine (TAC) are two agents that can be used as effective local anesthesia.[27] Both of these agents contain epinephrine and should not be used on areas involving an end artery or contaminated wounds. TAC involves expense and incorporates problems with the use and maintenance of a controlled substance. TAC also has the potential for toxicity, especially when applied to mucosal surfaces. EMLA (eutectic mixture of local anesthetics) cream, also used for local anesthesia, has been found to provide effective anesthesia for extremity lacerations. EMLA is a combination of 2.5% lidocaine and 2.5% prilocaine suspended in an oil-in-water emulsion. Studies have found that it takes longer to obtain optimal anesthesia with EMLA than with TAC.[28]

SKIN CLEANSING

Meticulous preparation of the skin surrounding the wound and the actual wound, irrigation, and wound debridement are tantamount to good wound healing. The goal is to remove bacteria, foreign matter, and tissue debris. Wounds should be adequately anesthetized prior to cleansing and/or local exploration. Adequate light, anesthesia, and equipment are a must in order to avoid inadequate debridement, a retained foreign body, or a wound hematoma that can result in a necrotizing soft tissue infection.

Disinfecting the intact skin surrounding the wound and ridding it of foreign bodies, debris, and particulate matter is the initial step in wound preparation. This technique can be accomplished by scrubbing the skin with povidone iodine, chlorhexidine, or poloxamer 188 (Shur Clens) skin-prep solutions. **Do not expose the wound itself to these solutions.** Povidone iodine and chlorhexidine solution are bactericidal and work as it dries. Its toxicity to wound tissue is controversial. Shur Clens has no tissue toxicity but also has no antibacterial activity. A wide area surrounding the wound should be prepped with an antimicrobial agent, preferably povidone iodine or chlorhexidine solution.

HAIR REMOVAL

Hair removal is often unnecessary prior to closing wounds, can be embarrassing for the patient after discharge from the Emergency Department, and may increase the risk of wound infection. Shaving can cause minimal soft tissue trauma and wound infections.[17] **Eyebrows should never be shaved, as they can grow back unpredictably or not at all.** Simple scalp lacerations can be exposed by using antibiotic ointment (or lubricating gel) to move the hair away from the wound margins prior to placing sutures.

WOUND IRRIGATION

Wound cleansing and preparation have been proven to be the foundations of proper wound management and the prevention of wound infections. Irrigation removes contaminants, reduces infection, and improves visualization. There are two concerns regarding wound irrigation: the pressure required for adequate cleansing of the wound and the means to irrigate the wound safely while protecting the healthcare worker from the threat of human immunodeficiency virus and hepatitis B (by contamination of their own skin surfaces, mucosal surfaces [eyes, nose, or mouth], or minor open skin wounds).

Irrigation pressures of 5 to 8 pounds per square inch (psi) are felt to be adequate to cleanse a wound that is not heavily contaminated. This surface pressure can be generated by the combination of a 35 mL syringe and a 19 gauge angiocatheter held 2 cm from the wound surface.[18,40–42] Unfortunately, this process can be quite messy (**Figure 92-1**). High-pressure irrigation, which generates

FIGURE 92-1. Wound irrigation with an angiocatheter on a syringe. This process is quite messy and can result in an occupational exposure. (Photo courtesy of Zerowet Incorporated.)

peak pressures of 25 to 40 psi, has been a controversial issue in the Emergency Medicine literature. The theory is that high pressures may cause tissue disruption and increase infection rates. High-pressure irrigation should be reserved for highly contaminated wounds. High-pressure irrigation may drive contaminants deeper into puncture wounds and should be avoided.

Though there are a variety of irrigation fluids, the optimal type is unknown. Normal saline is the most commonly used irrigant. The volume of irrigation fluid to be used has not been well established. The use of 100 to 300 mL has been suggested in the literature. Heavily contaminated wounds require larger amounts of irrigant. Anecdotal recommendations suggest using 50 mL/cm for clean wounds and 100 mL/cm for dirty wounds. Heavily contaminated wounds may have to be scrubbed (after adequate anesthesia) with fine-mesh gauze or a micropore sponge using a 1% solution of povidone iodine or poloxamer 188. Tap water can be used for irrigation with no increased incidence of infection, especially when a large volume of irrigant is required.[43–47] Soaking of wounds is discouraged as a poor substitute for the preparation of contaminated or clean wounds. **Do not soak wounds in any fluid.** Soaking does not reduce bacterial contamination or decrease infection rates. It may actually increase infection rates. **Do not use undiluted povidone-iodine, hydrogen peroxide, or detergents in the wound as they cause tissue toxicity.**[48]

Numerous commercially available devices are available to irrigate a wound (**Figure 92-2**). The Combiport (Moog Medical Devices, Salt Lake City, UT) is a wound irrigation device that inserts directly into the port of an intravenous fluid bag (**Figure 92-2A**). Squeeze the bag of saline and direct the stream of fluid through the device and into the wound. Wound Wash Saline (Church & Dwight, East Princeton, NJ) is sterile normal saline within a pressurized can (**Figure 92-2B**). Direct the tip of the can toward the wound, press the button, and direct the saline stream into the wound. This is also available at retail stores for patients to use at home for wound care. The company offers a convenient chart that uses wound depth and base characteristics to determine how much saline to use to irrigate the wound. The can controls the pressure (6 to 13 psi), so that tissue is not devitalized during the irrigation. Unfortunately, using this method is quite messy as the saline and wound materials (e.g., tissue fluid, blood, and debris) splash all over.

The Emergency Physician should use barrier protection to shield their face, eyes, skin, and submucosal surfaces during the irrigation process. There are several barrier devices on the market that decrease the splatter of irrigation fluid[19] (**Figure 92-2**). Some of these devices are preattached to a wound irrigation device. Others can be attached to a wound irrigation device. The Zerowet Supershield (Zerowet Inc., Palos Verdes Peninsula, CA) is a dome-shaped device that attaches to a syringe (**Figure 92-2C**). The Combiguard Irrigation Splash Guard (Moog Medical Devices, Salt Lake City, UT) is similar in function to the Zerowet Splashield and has a slightly different shape. The Combiguard can attach to a syringe or the Combiport Wound Irrigation Device (**Figure 92-2D**). The Igloo Wound Irrigation System (Bionix Medical Technologies, Toledo, OH) is a similar device that provides a multiport shower effect to deliver the irrigation solution (**Figure 92-2E**). The Irrijet (Cooper Surgical, Trumbull, CT) is a spring-loaded, self-refilling system that

is operated with one hand (**Figure 92-2F**). A Splashield or Splash Guard can be attached to the Irrijet. The Canyons Wound Irrigation System (Wolfe Tory Medical Inc., Salt Lake City, UT) is a similar device with the exception of using the built-in Zerowet Splashield (**Figure 92-2G**). The Squirt Wound Irrigation Kit (Merit Medical Systems Inc., South Jordan, UT) is a manually operated system that may be used alone or attached to the Splashield, Combiguard, or an angiocatheter (**Figure 92-2H**). The Klenzalac (Zerowet Inc., Palos Verdes Peninsula, CA) is a similar device with the exception of using the built-in Zerowet Splashield (**Figure 92-2I**). The Splashcap (Splash Medical Devices, Atlanta, GA) attaches to a bottle of sterile saline (**Figure 92-2J**). The Irrisept (Irrisept, Gainesville, FL) attaches to a proprietary bottle containing a saline and chlorhexidine mixture (**Figure 92-2K**).

WOUND DEBRIDEMENT

Debridement creates straight and clean wound edges that are easier to repair by removing tissue that is devitalized, contaminated by bacteria, or contaminated by foreign matter and may impair the ability of the tissue to resist infection. Successful wound closure may require the transformation of a ragged laceration, the removal of devitalized tissue, or the removal of contaminated tissue in order to convert a traumatic wound into a surgical wound. Devitalized and necrotic tissue must be removed in order to remove a nidus for bacterial growth and wound infection.[20]

Close approximation of the wound requires that debridement of jagged edges not be too vigorous in order to avoid widening the scar and making it difficult to close. Wounds of the face or areas that are devoid of redundant tissue require conservative debridement. Debridement to simplify wound closure is not always the answer for a superior cosmetic result in the repair of irregular wound edges. The meticulous repair of complex wound edges can often provide a superior cosmetic result.

Debridement can be accomplished mechanically, hydrodynamically, or with a combination of both methods. Tissue must be removed mechanically with a #11 or #15 scalpel blade or a scissors (**Figure 92-3**). Superficial debris and contaminants can be removed with a pulsatile stream of normal saline solution during the irrigation process. **Debridement must be performed using aseptic technique. Scrubbing is not a substitute for debridement of heavily contaminated tissue. Wound edges should be handled delicately or gingerly in order to avoid further soft tissue damage and devitalization of injured tissue.**

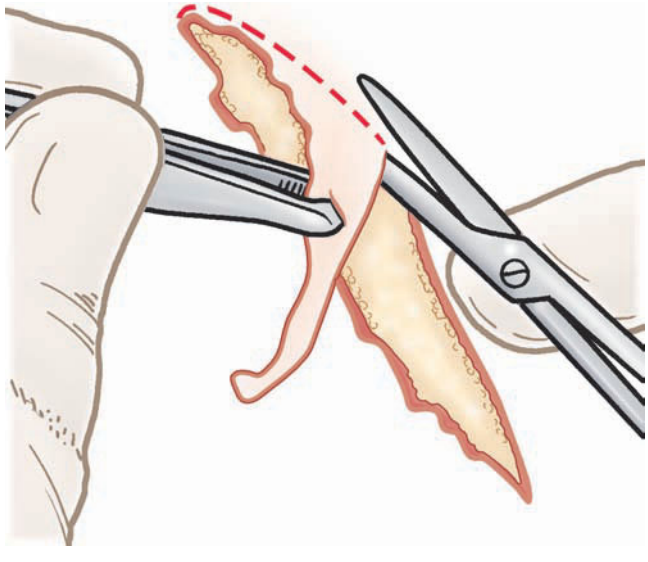

FIGURE 92-3. Wound debridement. Removal of the wound edges with a scissors (or a scalpel).

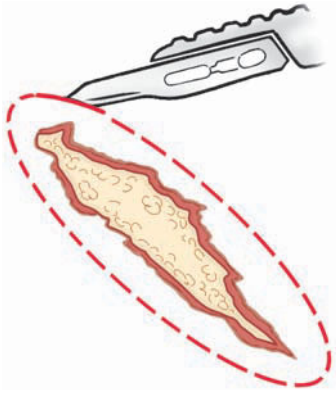

FIGURE 92-4. Wound excision. Removal of an ellipse of tissue that contains the wound results in smooth, clean edges that can be approximated.

WOUND EXCISION

The entire wound may be excised in areas of excess tissue or tissue laxity if no blood vessels, nerves, tendons, or joints lie within or at the base of the wound (**Figure 92-4**). The excision of a wound creates smooth, clean edges that may be approximated with sutures. This is especially useful in wounds that are heavily contaminated. Most wounds are excised with an elliptical incision (**Figure 92-4**). Other types of wound excision are discussed in Chapters 95 and 96.

Carefully plan the excision before removing any tissue. Mark the edges of the proposed incision with a marking pen. The long axis of the ellipse should be two-and-a-half to four times as long as the greatest width of the ellipse. Removal of too much tissue will produce a large defect that may not be possible to close primarily. Remove the tissue using aseptic technique, preventing any contamination of the new wound edges.

WOUND UNDERMINING

The undermining of tissue creates a "flap" that involves the separation of the skin and superficial subcutaneous tissue from the deeper subcutaneous tissue and fascia (**Figure 92-5**). The process of undermining tissue minimizes skin tension, allows for eversion of the approximated skin edges, and relieves the extrinsic tension from sutures. **Undermining is performed when the wound cannot be closed due to a tissue defect or if a wound is under tension.** This procedure requires the Emergency Physician to be familiar with the local anatomy so that no blood vessels, nerves, or tendons are injured in the process. **Do not undermine contaminated wounds.** Undermining large areas can separate the skin from its underlying blood supply and result in a diminished blood flow that predisposes the area to infection and necrosis. Undermining may be useful on the forehead, scalp, arm, forearm, thigh, calf, and torso. **Never undermine wounds on the palms, soles, and face.**

Undermine tissue at the dermal-epidermal junction or within the subcutaneous adipose tissue. The amount of undermining necessary to close a laceration is approximately double the width of the gap of the laceration at its widest point. A 1 cm wide laceration should be undermined for 1 cm on both sides of the wound, including the ends (**Figure 92-5**). The use of a Mayo scissors versus a #15 scalpel blade to undermine tissue is based on physician experience

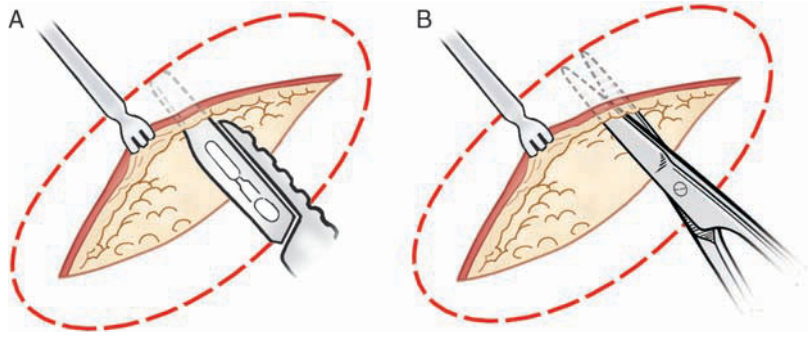

FIGURE 92-5. Wound undermining. **A.** Sharp undermining with a #15 scalpel blade. **B.** Blunt undermining with a Mayo scissors.

and preference. A Mayo scissors is recommended as it may cause less secondary injury, especially in experienced hands.

EMERGENCY DEPARTMENT VERSUS OPERATING ROOM MANAGEMENT OF WOUNDS

Laceration repair may sometimes have to be performed in the operating room. Indications for operating room repair of lacerations include those associated with open fractures, major or complex wounds involving devitalized tissue, heavily contaminated wounds, wounds with associated injuries (e.g., visceral, neurovascular, fracture, and tendon), perineal wounds, large or complicated soft tissue injuries, compartment syndromes, wounds with extensive amounts of necrotic or ischemic tissue, the total local anesthetic solution required would exceed toxic tissue levels, and high-pressure injection injuries.

ANTIBIOTIC PROPHYLAXIS

Despite the best wound care and management, the rate of infection has been determined to be approximately 1% to 12%. Not all wounds result in infection. Most uncomplicated wounds heal without the need for antibiotics. Wounds associated with an increased risk for infection are those of the extremities (especially the lower), complex wounds, or wounds over 3 to 5 cm in length. The use of antibiotics for traumatic wounds is controversial. Prophylactic antibiotics are not indicated for uncomplicated minor wounds with a low chance of becoming infected. It has not been proven that oral antibiotic administration following injury actually reduces the probability of infection. However, the use of topical antibiotics can decrease the rate of wound infection.[34] Useful preparations include bacitracin, triple antibiotic ointment, or silver sulfadiazine.

It is necessary to identify those patients who may benefit from early antibiotics. Antibiotic therapy should be considered in the following situations: where wounds are heavily contaminated or associated with major soft tissue injury; open fractures, intraoral lacerations, wounds associated with active infection; when there is a delay in care that results in a prolonged time from debridement or treatment (>3 hours); when the patient is immunocompromised or has cardiac valvular disease; when there are bites to the hand or face, deep puncture wounds, or lacerations to lymphedematous tissue; or when the patient has prosthetic joints (**Table 92-3**).

SUTURES

SUTURE TYPES

Proper size suture material can be summarized as the smallest suture needed to approximate the edges of a wound. This will reduce tissue damage caused by the suture, and the resulting scar will be minimized. The tensile strength of the suture should never exceed the tensile strength of the tissue, or it can pull through and damage the tissue. The sutures should be at least as strong as the normal tissue through which they are being placed.

The size of the suture material is related to the diameter of the suture. As the number of 0s in the suture size increases, the diameter of the strand decreases. For example, size 5-0, or 00000, is smaller in diameter than size 4-0, or 0000. The smaller the size, the less tensile strength the suture will have.

Suture description entails numerous characteristics. Sutures can be classified into two major groups based upon the number of strands of which they are composed. Monofilament sutures are made of a single strand of material. They encounter less resistance passing through tissue and resist harboring organisms that may cause suture-line infections. Multifilament sutures consist of several filaments, or strands, that are twisted or braided together. This affords greater tensile strength, pliability, and flexibility. Unfortunately, bacteria can migrate between the filaments and into the wound.

Another classification is based on the ability of the body to break down and absorb the suture material. Absorbable sutures are digested by body enzymes or hydrolyzed in body tissue. Nonabsorbable sutures are not digested by body enzymes or hydrolyzed.

Absorbable suture can be made of natural or synthetic material. Natural absorbable suture is classified as surgical gut (plain or chromic). Plain surgical gut is composed of collagen from bovine or sheep intestine. It is rapidly absorbed, maintaining its tensile

TABLE 92-3 Antibiotic Prophylaxis for High-Risk Wounds[35]

Situation	Antibiotic of choice	Days of treatment
Open fractures	First Generation Cephalosporin Add an aminoglycoside for more extensive injuries	1–3
Intraoral injuries	Penicillin VK or Clindamycin	5
Human bites	First dose: parenteral ampicillin sulbactam or Ertapenem, then Augmentin Or Clindamycin plus fluoroquinolone (Bactrim in children) Or Augmentin	3–5
Dog/cat bites	First dose: parenteral ampicillin sulbactam or carbapenem or clindamycin, then clindamycin plus fluoroquinolone Or Augmentin	3–5

strength for only 7 to 10 days, and is completely absorbed within 70 days. Chromic gut is treated with a chromium salt solution to resist body enzymes. It retains its tensile strength for 10 to 14 days and is absorbed over 90 days.

Synthetic absorbable sutures include polyglactin 910 (Vicryl, Ethicon) and polyglycolic acid (Dexon). They were developed because of the tissue reaction, suture antigenicity, and unpredictable rates of absorption of natural absorbable sutures. These sutures are braided synthetic materials that retain 50% of their initial strength at 4 weeks. The synthetic absorbable sutures retain their tensile strength long enough to ensure the security of the subcutaneous layers after the removal of percutaneous sutures.

Nonabsorbable sutures are made of silk, nylon, polypropylene, cotton, linen, or metal. They can be monofilament or multifilament in construction. Nylon is the most commonly used suture in the Emergency Department. It is used to approximate lacerations at the skin surface. Silk may occasionally be used in the mouth. It causes significant tissue reactions that result in inflammation and granuloma formation as the body "fights off" this natural fiber. The other types of nonabsorbable sutures are generally not utilized in the Emergency Department.

Several factors must be considered in choosing suture material. Choose sutures that match the healing properties of the tissues. Approximate slow-healing tissues (e.g., fascia and tendons) with nonabsorbable sutures or a long-lasting absorbable suture. Foreign bodies in potentially contaminated tissues may result in an infection. Multifilament sutures can act as a foreign body and may convert a contaminated wound into an infected one. Multifilament sutures should generally be avoided. Use monofilament sutures or absorbable sutures that resist harboring infection. Use the smallest inert monofilament suture materials (such as nylon or polypropylene), avoid using skin sutures alone (use subcuticular closure whenever possible), and use sterile skin closure strips for apposition when possible. **Use the smallest possible size of the chosen suture type that is capable of closing the wound to help minimize scarring.**

NEEDLES

Needles are generally of two types, tapered and cutting (**Figure 92-6**). Cutting needles have sharp ends and sharp edges that act as a cutting instrument (**Figure 92-6A**). The cutting needle is commonly used for tougher tissues such as subcutaneous, intradermal, and cutaneous (skin) closure. In addition to the two cutting edges, conventional cutting needles have a third cutting edge on the inside concave curvature of the needle. This needle type may be prone to "cutout" of tissue because the inside cutting edge cuts toward the edges of the incision or wound.

Reverse cutting needles are as sharp as the conventional cutting needle except that the third cutting edge is located on the outer convex curvature of the needle (**Figure 92-6B**). Reverse cutting needles have more strength than similar-sized conventional cutting needles. The danger of tissue "cutout" is greatly reduced. The hole left by the needle leaves a wide wall of tissue against which the suture is to be tied.

Taper point needles have a pointed end (**Figure 92-6C**). The rest of the needle is a smooth, rounded tube with no cutting edges. This type of needle is commonly used in surgery to close tissues with minimal trauma. It is used for all tissues except skin.

Two other types of needles are often available but not used in the Emergency Department. The blunt point needle has a smooth tip and tapered body (**Figure 92-6D**). It is used for suturing friable tissue and blunt dissection. The taper cut needle has a cutting tip and a tapered body (**Figure 92-6E**). It is a combination of the tapered point and cutting needle. It is used to place sutures through tough tissues. Numerous other needles are available, as are modifications of the five basic needle types. These needles are used by Surgeons for specialized tissues.

Always keep some general principles in mind when suturing. **Needles should be pulled through tissue using a needle driver and never a hemostat.** A hemostat or other clamp can damage the needle. Avoid injury to yourself and others. **Keep all open needles in a place so that they will not injure you or your assistant.** Account for and discard all suture needles in a "sharps" container. Following these two steps will dramatically decrease the chance for a needle-stick injury.

NEEDLE DRIVERS AND HANDLING SUTURES

Always use a needle driver when suturing. The use of a hemostat or other type of "clamp" can damage the needle and cause it to bend or break in the tissue. Needle drivers are generally made of steel with a jaw designed to hold the needle securely without damaging it. They come in numerous sizes and shapes. Choose a needle driver that is an appropriate size for the needle that is to be grasped. A 4.5 to 6 in. long needle driver is appropriate for Emergency Department use. Grasp and remove a clean needle from its package with your hands,

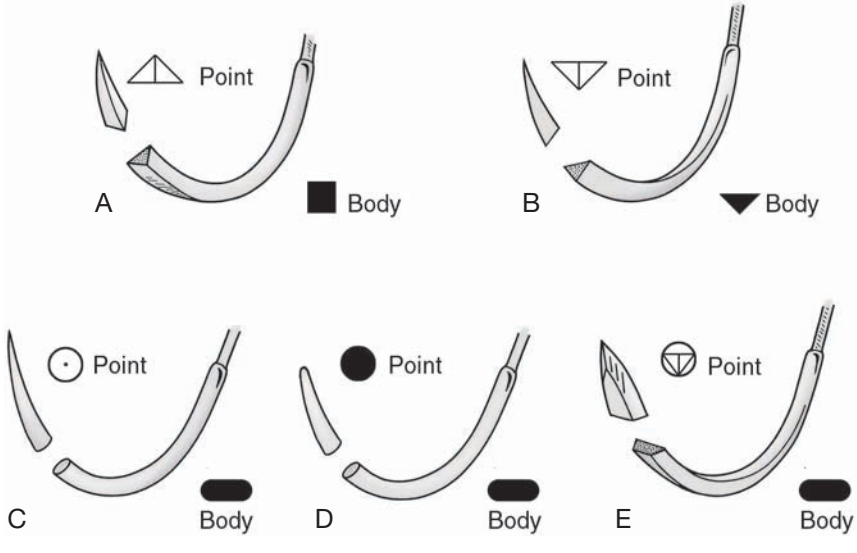

FIGURE 92-6. Common types of suture needles. **A.** The cutting needle. **B.** The reverse cutting needle. **C.** The taper point needle. **D.** The blunt point needle. **E.** The taper cut needle.

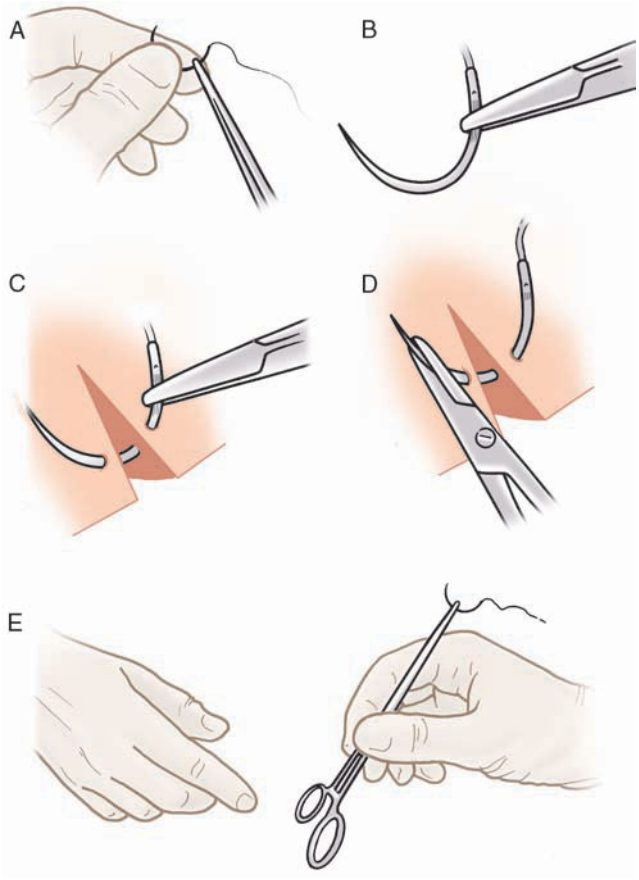

FIGURE 92-7. Using a needle driver. **A.** Grasp the proximal one-third to one-half of the needle. **B.** Always use the tips of the jaws to grasp the needle. **C.** Drive the needle through the tissue following the natural curve of the needle. **D.** Grasp the distal needle proximal to the cutting edges. **E.** Correct method to pass a needle driver armed with a needle.

forceps, or a needle driver. Securely grasp the proximal one-third to one-half of the needle with the needle driver (**Figure 92-7A**). **Do not grasp the distal one-third of the needle.** This can damage its cutting surfaces. **Always use the tips of the needle driver to grasp the needle (Figure 92-7B).** Grasping a needle with the base of the jaws may damage the needle.

Use the needle driver when pushing the needle through the tissue to place a suture (**Figure 92-7C**). **Apply the force in a direction following the curve of the needle. Do not twist or force the needle to push the point through the tissue and out the other side.** Use a larger needle if the first one is too short or too small. **Do not use a needle that has become dull and difficult to pass through the tissue.** Obtain a new needle and continue the procedure. Grasp the distal tip of the needle with a needle driver when it emerges from the tissues (**Figure 92-7D**). **Always grasp the needle proximal to its distal third to prevent damage to the cutting edges.**

Always use caution when handing a needle driver armed with a needle to another person. Grasp the needle driver between the thumb, index, and middle fingers (**Figure 92-7E**). Hand the base of the needle driver to another person. **Do not blindly pass the needle driver. Do not pass the needle driver over a third party without their knowledge of the transfer. Never grasp the distal end of an armed needle driver.**

Typical needle drivers contained within most disposable, commercially available laceration repair trays are not ideal. The suture often snags on the jaws or hinge when performing an instrument tie.

FIGURE 92-8. Examples of snag-free needle drivers. From left to right: The Centurion SnagFree (Centurion Healthcare Products, Howell, MI), the SutureCut needle driver (SutureCut LLC, Lexington, KY), and the Olsen-Hegar needle driver (Henry Schein Inc., Port Washington, NY).

Some needle drivers are designed to be snag-free (**Figure 92-8**). Two of these, the Centurion SnagFree (Centurion Healthcare Products, Howell, MI) and the SutureCut (SutureCut LLC, Lexington, KY) needle drivers, are available both as individual disposable instruments and in disposable laceration repair trays.

Suturing lacerations can take a significant amount of time. Much of this time is spent tying knots or switching between instruments (i.e., the needle driver and scissors). Two needle drivers are designed to also cut suture. This decreases the total time required to repair a laceration as well as avoiding the constant switching between instruments. The SutureCut (SutureCut LLC, Lexington, KY) and the Olsen-Hagar (Henry Schein Inc., Port Washington, NY) needle drivers cut the suture in their specially designed joint located at the base of the jaws.

We are all not fortunate to have suture-cutting needle drivers in our laceration repair trays. A needle driver and scissors can be simultaneously held in the same hand to improve efficiency (**Figure 92-9**). While awkward at first, this technique is easy to learn. Grasp a scissors with the tip pointing ulnarly (**Figure 92-9A**). Insert your middle finger through the adjacent ring on the handle. Grasp a needle driver in the same hand with the tip pointing radially (**Figure 92-9A**). Insert your thumb and ring finger through the rings on the handle of the needle driver. Grasp a suture needle with the needle driver. Place a stitch and tie it. Remove your thumb from the ring of the needle driver and place it in the open ring of the scissors. Use the thumb to open and close the scissors. Cut off the excess suture (**Figure 92-9B**). Place your thumb back into the ring of the needle driver and place the next stitch. Repeat this process until the laceration is closed.

WOUND CLOSURE

The goal of wound closure is approximation of the skin under minimal tension while achieving eversion of the wound edges (Chapter 93). Wound eversion slightly raises the wound edges to keep the epidermal cells from migrating into the dermal layers, therefore leaving a flat scar (**Figure 92-10**). Sutures should be placed closely enough to approximate wound edges, but not so tight as to cause tissue necrosis. The time from the injury to the

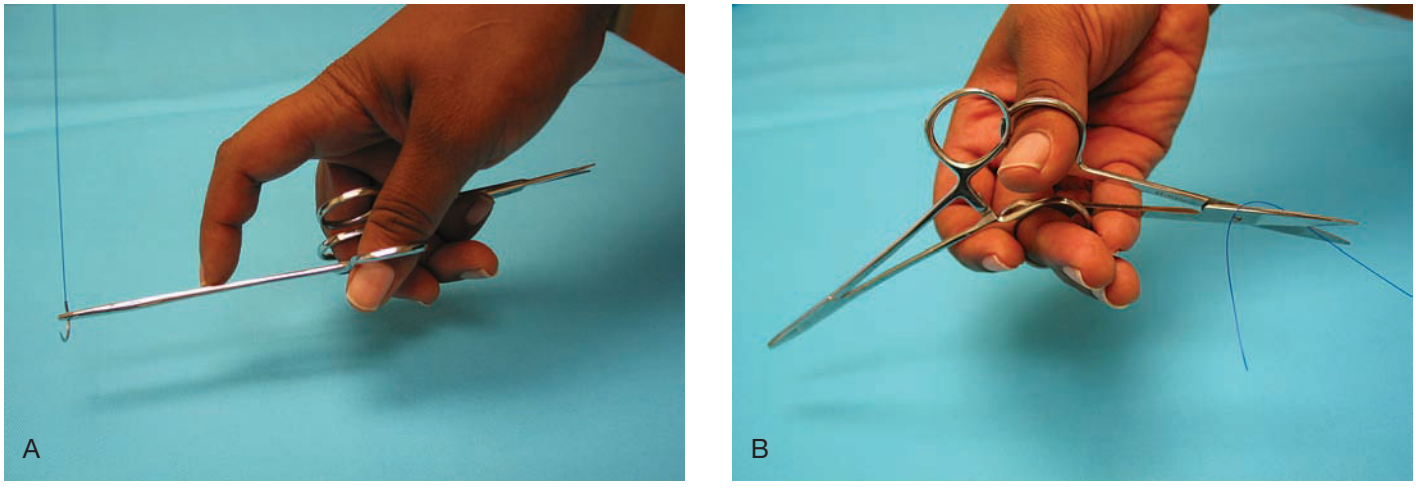

FIGURE 92-9. A one-handed method to simultaneously hold a needle driver and scissors. **A.** Placing a stitch. **B.** Cutting the suture.

presentation and the mechanism of injury will indicate whether the laceration mandates delayed closure instead of primary closure and whether tetanus prophylaxis is required. With the exception of patients who are immunocompromised or taking immunosuppressive therapy, those with high-risk wounds should be considered for delayed closure.

SINGLE-LAYER VERSUS MULTILAYER CLOSURE

The greatest strength of the skin (and of the wound) is contained within the dermis. The better the coaptation of the dermal edges, the narrower the scar will be. The best results occur when the entire depth of the dermis is accurately approximated to the entire depth of the opposite dermis. Dermal closure is best performed with synthetic monofilament absorbable suture that requires enzymatic degradation (e.g., Vicryl). Chromic or plain catgut suture dissolves much more rapidly by means of hydrolysis.

Close the wound in multiple layers if the goal is cosmesis. Close the wound with a minimal number of sutures in a single layer if the goal is a functional result. Do not suture through fat and muscle. Fat has no tensile strength. Sutures placed tightly in fat can cause ischemia and necrosis in the wound and increase the risk of a wound infection. Muscle fibers do not support sutures. Muscle is best treated by repair of the overlying fascia and immobilization to prevent motion and to allow coaptation of the muscle fibers.

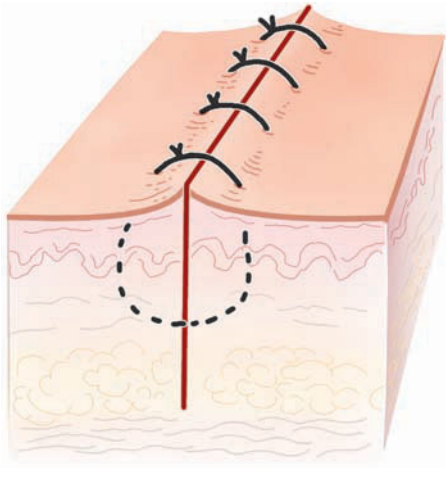

FIGURE 92-10. Eversion of the wound edge signifies proper suture placement and knot tension.

STERILE GLOVES

It is a common practice to wear sterile gloves when repairing a laceration. The advantages of sterile gloves include a better fit, improved tactile sensitivity, and improved dexterity. The use of sterile gloves for laceration repair costs significantly more than using nonsterile, clean gloves from a box. Clean, nonsterile, powder-free, boxed examination gloves can be used for uncomplicated wound repair in the Emergency Department. No clinically important differences in infection rates has been found when comparing sterile gloves to clean gloves.[49,50]

The use of clean gloves from a box is not always ideal. Clean gloves come in a limited number of sizes (i.e., extra small, small, medium, large, and extra large). The fit and feel of clean gloves may not be as comfortable for the Emergency Physician. Clean gloves may have more manufacturing defects when compared to sterile gloves.[51] These defects can result in the loss of personnel protection and the potential to contaminate the wound. Others have shown clean gloves to have comparable quality to sterile gloves.[52–54] A box of clean gloves that has become wet can harbor mold.[55] While the use of clean gloves in uncomplicated wound repair is acceptable, the decision is physician dependent.

WOUND CLOSURE PROCEDURE

Clean any dirt and debris from the skin. Scrub the skin surrounding the wound with an antiseptic skin cleanser (e.g., povidone iodine or chlorhexidine). Anesthetize the wound with a 27 to 30 gauge hypodermic needle and local anesthetic solution. Irrigate the wound with normal saline. Use a mask with a face shield to prevent exposure to the patient's blood and tissue fluid. Debride and undermine the wound as necessary. Irrigate the wound again to remove exposed debris and devitalized tissue. Repair the wound with sutures or pack it with saline-soaked fine-mesh gauze for delayed closure. Clean the repaired wound with normal saline and apply a dressing for comfort and protection. Consider the application of a splint for wounds across joints or muscle lacerations.

Write a procedure note describing the sterile preparation of the wound, the type and volume of anesthesia administered, the type of suture(s) used in the repair, the layers repaired, the type of repair

(interrupted vs. continuous), and how the procedure was tolerated by the patient. Any complications should also be noted.

AFTERCARE

Wound care has become a specialty involving sophisticated research in many areas, including dressings and the environment in which wounds heal best. Clean the area surrounding the repaired wound with normal saline to remove any antimicrobial agents and blood. It has been demonstrated that optimal growth of fibroblasts in tissue culture occurs at low partial pressures of oxygen (5 to 10 mmHg). Epidermal cell growth is inhibited at oxygen levels higher than that in surrounding air. It has been shown clinically that hydrocolloid dressings are capable of maintaining low oxygen tension independent of the underlying disease process.[29] The application of an occlusive dressing has been shown to increase the rate of wound healing by approximately 40%, as well as preventing environmental trauma and keeping bacteria out of the wound.

Dressings, regardless of the type used, should produce a moist but not macerated wound that is free of infection, toxic chemicals, and foreign material while maintaining an optimum temperature and pH. Layered dressings of nonadherent gauze, such as Xeroform, covered with dry gauze can be used for large sutured lacerations and abrasions. This dressing draws exudate into a layer that can be replaced without disturbing the underlying wound. Shear wounds or hematomas may require gauze that is fluffed and formed into a pressure dressing. Dressings of antibiotic ointment with a standard adhesive bandage (e.g., Band-Aid) provide adequate healing and protection for smaller repaired lacerations. The topical application of topical antibiotics to the suture line after wound closure may help to protect against exogenous bacterial contamination. No studies have shown that topical antibiotic ointments have an effect on the final outcome of a wound. Despite this, their use is still recommended because they keep the wound surface moist and their use has not been shown to have any negative effects. The use of paper gauze and Telfa pads is not advisable.

DISCHARGE INSTRUCTIONS

High-risk wounds such as animal and/or human bites, hand wounds, heavily contaminated wounds, and wounds that require prophylactic antibiotic coverage should be reevaluated within 24 hours.

Patients should be made aware, orally and in writing, that up to one in 10 persons develops a wound infection that can be treated with an oral antibiotic. Puncture wounds are considered high-risk injuries that can result in bone infections. Patients should immediately return to the Emergency Department or their primary physician if a wound becomes red or has a discharge, if redness or red streaks are emanating from the wound, or if they develop a fever.

Explain briefly the progression of healing. The new scar's appearance is usually worst at 3 to 5 weeks. Most scars remodel within 6 to 12 months. Any revision of the wound should be postponed for at least 6 to 12 months from the time of injury.

SUTURE REMOVAL

The length of time that the sutures remain in place depends upon the location of the wound, the amount of tension on the wound, and the healing time of the involved tissue. Some general guidelines are listed in **Table 92-4**. Appropriate and timely removal of sutures minimizes scarring. Full-thickness sutures can be left in place for 2 or more weeks without risk of suture-track formation in areas where sebaceous glands and other adnexal structures are not present, such as the plantar and palmar surfaces. Leaving sutures in place too long results in epithelialization of the suture tracts, larger scars, and possibly infections. Suture removal kits are commercially available. They typically contain a metal or plastic forceps, a scissors, and a few gauze squares. These kits are inexpensive, disposable, and intended for single-patient use.

TABLE 92-4 Suture Removal Recommendations

Location	Days
Face	3–4 (child), 3–5 (adult)
Neck	2–3 (child), 3–4 (adult)
Upper extremity	7–10
Hand	10–14
Chest	7–10
Back	10–14
Buttocks	10–14
Legs	8–10
Foot	10–14
Delayed closure	8–12
Retention sutures	14–30
Overlying joints	10–14

Sutures should be removed using aseptic and sterile techniques. Clean the wound with saline. Apply hydrogen peroxide to remove any dried blood and serum encrusted around the sutures. Grasp the suture at the knot with forceps (**Figure 92-11**). Lift the knot off the skin. Cut the suture as close to the skin as possible with a scissors and where the suture enters the skin (**Figure 92-11**). This will avoid drawing contaminated suture through the depth of the wound. Sutures that are close together, small, or tight may require a #11 scalpel blade to cut them rather than a scissors. Gently pull the suture strand out of the tissue with the forceps and across the wound. Pulling a suture out away from the wound may result in the wound edges opening (dehiscing). Remove one to three sutures and ensure that the wound edges do not dehisce. Remove the remaining sutures. Apply skin adhesive strips (e.g., Steri-strips) across the wound to provide support.

MANAGEMENT OF PUNCTURE WOUNDS

Puncture wounds are considered to be at higher risk for infection than simple lacerations. They should be allowed to heal by delayed intention, particularly if they penetrate into the subcutaneous tissues. Local cleansing is the initial step in management. High-pressure irrigation, coring, and probing are generally not recommended.

Infection is most frequently due to *Staphylococcus aureus, Staphylococcus epidermidis*, or streptococcal species. Treatment should be reserved for compromised hosts, dirty wounds, or actual infected wounds.[30] Puncture wounds of the foot are of special concern due to the risk of *Pseudomonas aeruginosa* infection, particularly with wounds through athletic shoes. A tender wound that is not infected usually indicates that there may be a retained foreign body. Persistent infection from a plantar wound suggests an

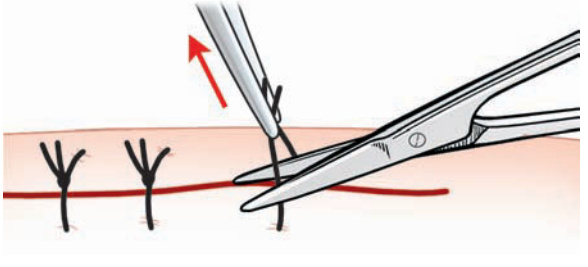

FIGURE 92-11. Suture removal.

underlying osteomyelitis that requires radiographs and treatment with a fluoroquinolone.[31]

PEDIATRIC ISSUES OF WOUND HEALING

Pediatric patients less than 15 years of age experience infection rates of less than 1% for clean surgical wounds.[7] This is less than that seen in adults. Young children, despite the ultimate in the way of gentle reassurance, will sometimes require sedation in order to make painful or difficult procedures possible. Safe and effective procedural sedation for patient comfort or cooperation to facilitate or expedite medical care is described in Chapter 129. Undermining is not useful in most pediatric wounds as they do not usually require advancement of skin over a significant tissue defect. Scalp lacerations account for 30% of pediatric lacerations. Scalp lacerations are well suited for single-layer repair with staples. Cosmetic results are comparable with those of sutured repairs, with no differences in complication and infection rates. Staples are six times faster, less expensive in cost of supplies and physician time than standard sutures, and can be implanted rapidly and accurately, even in a moving child.

ALTERNATIVE CLOSURES

Alternative methods of wound closure include skin closure tapes, tissue adhesives, and staples. These are mentioned briefly below. A more complete discussion can be found in Chapters 93 and 94.

SKIN CLOSURE TAPES

Skin closure tapes are adhesive strips that are used when skin tension and wound contamination are not concerning factors. Adhesive-backed long and narrow strips are used for approximating the edges of lacerations (with or without staples or sutures) and for closing the skin following many operative procedures. The most common type is the Steri-strip. Skin closure tapes are felt to develop and increase wound tensile strength faster than sutured wounds because uniformly orienting collagen fibers apply equal stress across the wound. Skin closure tapes are porous, which allows for good air inflow and the escape of water vapor from the wound during the healing process. Strips are placed perpendicular to the wound in conjunction with an adhesive such as tincture of benzoin, taking care not to get benzoin in the wound.

TISSUE ADHESIVES

Tissue adhesives such as the older and weaker butyl cyanoacrylates focused on small linear lacerations. Newer and stronger medical-grade octyl cyanoacrylate formulations have been approved by the US Food and Drug Administration. It has been clinically proven that there is no difference 1 year after treatment in the cosmetic outcome of wounds repaired with suture versus those closed with octyl cyanoacrylate tissue adhesive.[32]

STAPLES

Staple closure is time-efficient compared to the suture repair of lacerations.[33] It is primarily used for large wounds that are not on the face, neck, hands, or feet. Stapling is especially useful for closure of incisions in hair-bearing skin (i.e., scalp) areas as well as the trunk and extremities. The wound edges require manual eversion with forceps prior to placing the staples.

SUMMARY

Expert wound management consists of attention to the details surrounding the wound, gleaning important information concerning the host's history, as well as meticulous wound preparation. Aggressive attention to the presence of foreign bodies, underlying injury to anatomic structures of significance, and the possibility of subsequent wound infection should be kept in mind at all times. An effort should be made to educate the patient about the possible outcomes of wounds and lacerations and to encourage expedited follow-up.

93 Basic Wound Closure Techniques

Eric F. Reichman and Candace Powell

INTRODUCTION

Wound management is crucial to the practice of Emergency Medicine. Emergency Physicians routinely care for wounds ranging from simple lacerations to complex injuries in the trauma patient.[1–6] Wound repair is always secondary to the evaluation and stabilization of any life-threatening and limb-threatening emergencies. However, patients are often legitimately concerned about the outcome of wounds and lacerations. There are several basic suture principles that will help to provide optimal wound healing and ensure a more than acceptable cosmetic result. The previous chapter outlines the essential principles of wound management. This chapter describes the basic methods used to close wounds.

SUTURES

The choice of suture materials is important in wound closure. Sutures are made of a wide variety of materials, both natural and synthetic. Natural substances include gut (sheep and beef), cotton, and silk. **Natural substance sutures cause more tissue reactions and scarring, which limits their use.** Cotton sutures are not discussed, as they are no longer used in clinical practice. Synthetic sutures can be made of nylon, polyethylene (Dacron), polyglactin (Vicryl), polypropylene (Surgilene, Prolene), polyglycolic acid (Dexon), poliglecaprone (Monocryl), polydiaxanone (PDS), polyglyconate (Maxon), and metal.[6] Metal sutures are used in the Operating Room and not in the Emergency Department as they are difficult to handle, prone to breakage, and indicated in only a few situations. Synthetic sutures tend to have a problem with "memory." That is, they tend to retain the shape of their packaging. This can make it difficult to manipulate the suture during wound closure.

Sutures are constructed as monofilaments or polyfilaments. Polyfilament fibers consist of multiple filaments braided together to form one suture. They are easier to handle than monofilament sutures, as they tend to be more pliable. Polyfilament sutures have better knot security and therefore reduce the incidence of knot slippage. However, they can be associated with a higher incidence of infection than monofilament sutures. They allow bacteria to migrate (or wick) between the strands of the suture located at the skin surface and into the wound.

Select the smallest diameter suture that can adequately hold the tissue edges together in order to reduce tissue damage and scarring. The largest suture material available is size #5. The suture sizes decrease to zero (#4, #3, #2, #1, #0) and then are followed by #00 (2-0), #000 (3-0), and #0000 (4-0), in decreasing size. The smallest suture commonly used in the Emergency Department is 6-0 for facial lacerations, nail bed lacerations, as well as lacerations in cosmetically sensitive areas. The tensile strength of sutures is related

TABLE 93-1 Absorbable Suture Materials

Suture type	Source	Tensile strength	Tissue reaction	Knot security	Absorption
Plain surgical gut	Beef or sheep collagen	Poor	Moderate	Poor	1–2 weeks
Chromic surgical gut	Beef or sheep collagen	Poor	Moderate	Fair	2–3 weeks
Monocryl	Poliglecaprone 25	20% remains by 3 weeks	Minimal	Good	3 months
Coated Vicryl	Polyglycolic 910, polyglactin 370, and calcium stearate	65% remains at 2 weeks; 40% at 3 weeks	Minimal	Fair	3–6 months
Dexon	Polyglycolic acid	50% remains at 4 weeks	Minimal	Good	3–4 months
Vicryl Rapide	Polyglactin 910	50% remains in 5–6 days	Minimal	Good	42 days
PDS polydioxanone	Polyester polymer	70% remains at 2 weeks; 50% at 4 weeks	Slight	Poor	6 months
Maxon	Polyglyconate	50% remains at 7 weeks	Slight	Fair	6 months

to their size. The tensile strength of suture increases as the size increases. For example, 4-0 is stronger than 5-0.

The other main category of suture classification is absorbable versus nonabsorbable. In the past, absorbable sutures were primarily used to close the subcutaneous layers of a wound. More recently, absorbable sutures have also been used for skin closure. Nonabsorbable sutures are primarily used for skin closure.

ABSORBABLE SUTURE MATERIALS

Absorbable sutures are degraded by the body and do not require removal. They usually do not maintain their tensile strength for longer than 60 days. Body enzymes dissolve the absorbable sutures with the aid of an inflammatory reaction. The rate of absorption of the sutures varies based upon the tissue where it is placed, the composition of the suture, and the size of the suture. Absorbable sutures placed in mucous membranes absorb faster than those placed in muscle tissue or fascia. Smaller sizes of suture dissolve faster than larger sizes.

There are several types of absorbable sutures, both natural and synthetic (**Table 93-1**). The most commonly used absorbable sutures in the Emergency Department are plain gut, chromic gut, polyglycolic acid (Dexon), polyglactin (Vicryl), and Vicryl Rapide. Plain gut and chromic gut are both natural forms of absorbable sutures. They are made from the intestines of sheep and cattle. Gut is a tissue irritant and can cause a substantial tissue reaction while it is being absorbed and degraded by the body. Chromic gut is plain gut that has been soaked in chromic acid salts. This process helps to extend the half-life of the suture and allows it to maintain its tensile strength longer than plain gut. Chromic gut may retain its tensile strength for 2 to 3 weeks, while plain gut retains its tensile strength for 1 to 2 weeks. Both types of gut are packaged wet in order to keep them from drying out and becoming too stiff.

Synthetic absorbable sutures, such as Dexon and Vicryl, are typically used more often than natural absorbable sutures in the Emergency Department. They are degraded by the body more slowly than natural fibers and can therefore help maintain the strength of the wound longer. Vicryl and Dexon maintain their tensile strength at 80 days and 120 days, respectively. They cause less reaction in the tissues as they break down when compared to natural absorbable sutures.

Recently, absorbable sutures have gained some popularity for use in skin closure.[7–10] Absorbable sutures have been shown to yield equal results in their rate of dehiscence, rate of infection, and cosmesis when compared to nonabsorbable sutures.[7] Absorbable sutures have the added benefit for the patient of not having to return to have their sutures removed. Vicryl Rapide is a newer form of Vicryl that is especially suited for this purpose. This type of suture is rapidly absorbed. They begin to fall off in 7 to 10 days as the wound heals. This can be especially useful for children in whom suture removal can be difficult, under casts, or if a patient will not be able to follow up due to travel.

NONABSORBABLE SUTURE MATERIALS

Nonabsorbable sutures are not degraded by the body and must be removed. They maintain their tensile strength for longer than 60 days. They are composed of monofilament or polyfilament strands of organic, synthetic, or metal fibers (**Table 93-2**). Nonabsorbable sutures generally have greater tensile strength and lower tissue reactivity than absorbable sutures. They are used in a variety of applications including skin closure. Nonabsorbable sutures can be used within a body cavity and subcutaneously, where they will eventually become encapsulated in connective tissue.

Nonabsorbable sutures can be classified as organic, synthetic, and wire. Organic sutures include those made of cotton or silk. Cotton

TABLE 93-2 Nonabsorbable Suture Materials

Suture type	Source	Tensile strength	Tissue reaction	Knot security	Absorption
Silk (braided)	Organic protein	Gradual loss by progressive degradation	High	Good	Gradual encapsulation by connective tissue
Ethilon	Polyamide (nylon)	Progressive hydrolysis may result in gradual loss of tensile strength	Minimal	Fair	Gradual encapsulation by connective tissue
Nurolon	Polyamide (nylon)	Progressive hydrolysis may result in gradual loss of tensile strength	Minimal	Fair	Gradual encapsulation by connective tissue
Prolene	Polyamide (nylon)	Not subject to degradation	Minimal	Poor	Nonabsorbable
Mersilene	Polyester	No significant change occurs	Minimal	Good	Gradual encapsulation by connective tissue
Ethibond	Coated polyester	No significant change occurs	Minimal	Good	Gradual encapsulation by connective tissue
Stainless steel	Stainless steel	Indefinite	Minimal	Good	Nonabsorbable

is the oldest of the nonabsorbable sutures. It is not discussed here as cotton sutures are no longer used in general medical practice. Silk is a polyfilament suture that has limited use in the practice of Emergency Medicine. There are several advantages to silk suture material. Its pliability makes it very easy to handle. It holds knots better than other types of suture. However, as with all natural and/or polyfilament sutures, it has a greater tendency to cause wound infections. The polyfilament braids can provide a place for bacteria to lodge. Silk suture may actually protect the bacteria from attack by the body's defenses if the wound becomes infected. The primary use of silk sutures is for the repair of lip, oral cavity, and tongue lacerations.

Synthetic nonabsorbable sutures are available in monofilament and polyfilament forms. Commonly used synthetic sutures include nylon, polypropylene, polybutester, and Dacron. Nylon, polypropylene, and polybutester are monofilament synthetic sutures. Dacron is a polyfilament synthetic suture. The synthetic nonabsorbable sutures have several advantages over the natural nonabsorbable sutures. They are less reactive in tissues, generally stronger than the natural sutures, and retain their tensile strength over many years.

Nylon (Ethilon, Dermalon) is the most common nonabsorbable suture used in the Emergency Department. It is a monofilament suture, it is inert, and it does not tend to harbor bacteria. It is primarily used for skin closure. Nylon has good tensile strength and minimal tissue reactivity. However, nylon is difficult to handle and difficult to tie. It requires more knots to achieve good knot security than other types of suture. This is primarily due to the tendency of the suture to return to its packaged shape. This tendency is also known as "memory." Because the knot can unravel or slip, it is important to place at least four or five knots when using nylon suture.

Polypropylene and polybutester are less commonly used synthetic nonabsorbable sutures. Polypropylene (Prolene) is stronger but more difficult to work with than nylon because it has greater memory. Polybutester (Novafil) is a newer suture in this category. It is stronger than the other monofilaments and does not have significant memory. Therefore, it is easier to work with than the other monofilament synthetic sutures.

EQUIPMENT

- Needle drivers, 4.5 and 6.0 in.
- Skin hooks
- Scalpel blades (#10, #11, and #15)
- Scalpel handles
- Iris scissors, straight 4 in. and curved 4 in.
- Suture scissors, 6 in.
- Forceps, toothed Adson
- Metzenbaum scissors, curved 6 in.
- Hemostats, straight 6 in., and curved mosquitoes
- Suture material
- Skin closure tapes
- Benzoin solution, swabs, or spray
- Gum mastic (e.g., Mastisol)
- Tissue adhesive
- Tissue adhesive forceps
- Skin stapler
- Staple remover
- Gauze, 4 × 4 squares

Much of the above equipment can be purchased in single-use, sterile, and disposable suture kits from several commercial manufacturers (**Figure 93-1A**). These kits tend to be expensive and occasionally have a limited amount of equipment. Many hospitals package and sterilize their own wound repair kits (**Figure 93-1B**). This decreases the cost, as the equipment can be repeatedly sterilized and reused. It also allows the kits to contain a wide variety of instruments for multiple situations (e.g., minor laceration, large laceration, and plastics closure).

FIGURE 93-1. The equipment required for basic wound closure techniques. **A.** The contents of a disposable and commercially available wound closure kit. **B.** A hospital packaged kit with reusable instruments.

Needle drivers come in a variety of sizes. A 4.5 in. needle driver can be used comfortably with most types of needles. A 6 in. needle driver may be required if large needles are used to close a wound. Hold the needle driver with the fingertips to provide greater flexibility. The fingers can also be placed through the finger holes, but this is not as efficient when closing a wound. Grasp the needle one-third of the way from the swag (distal) end with the tip of the needle driver.

The skin must be grasped and manipulated during wound repair to allow for proper suture placement. Forceps are most commonly used to grasp and manipulate the skin. **Smooth (nontoothed) forceps should never be used to grasp skin.** They require the application of a large amount of force to grasp the tissue. This can crush tissue very easily. An Adson forceps is the forceps of choice. It has fine teeth that grasp tissue securely with minimal force.

TABLE 93-3 Typical Suture Choices for Each Body Site

Anatomic site	Deep-layer suture size	Deep-layer suture material	Skin-layer suture size	Skin-layer closure material
Scalp	2–0, 3–0, or 4–0	Absorbable	4–0 or 5–0	Nylon, polypropylene, or staples
Eyelid	5–0, 6–0, or 7–0	Absorbable	6–0 or 7–0	Nylon or polypropylene
Face	4–0 or 5–0	Absorbable	5–0 or 6–0	Nylon or polypropylene
Neck	4–0 or 5–0	Absorbable	4–0 or 5–0	Nylon or polypropylene
Trunk	3–0 or 4–0	Absorbable	3–0 or 4–0	Nylon, polypropylene, or staples
Extremities	3–0 or 4–0	Absorbable	3–0, 4–0, or 5–0	Nylon, polypropylene, or staples
Hands and feet	Not advisable	Not applicable	4–0 or 5–0	Nylon or polypropylene
Sole of foot	3–0 or 4–0	Absorbable	3–0 or 4–0	Nylon or polypropylene

A skin hook is a sharp, pointed instrument that is inserted into the wound edge and grasps the tissue from the undersurface. It produces a small puncture wound in the subcutaneous tissues and does not penetrate the skin surface. Skin hooks are preferable to forceps, as they do not crush tissues. A skin hook is awkward to use at first. With proper instruction and experience, the Emergency Physician will most certainly prefer a skin hook to forceps.

Several types of scissors are required for proper wound closure. Iris scissors have sharp, delicate tips for making precise cuts in tissue. They should not be used to cut suture material, as this rapidly dulls and nicks the blades. Suture scissors have one blunt tip and one pointed tip. Both blades of the suture scissors are sharp. Suture scissors are used to cut adhesive tape, gauze, rubber drains, and suture material. Metzenbaum scissors should be used to debride heavy tissue, bluntly dissect tissue, and undermine tissue.

Hemostats are used to clamp small vessels that are bleeding, to explore a wound, and to grasp fascia. Hemostats are available in a variety of sizes and styles. A straight 6 in. hemostat is used for most purposes during wound repair. A curved 5 in. mosquito hemostat can be used for small wounds or delicate tissues. **Do not use a hemostat to grasp or drive the suture needle.** The suture needle can bend, rotate, and break as it enters tissue if driven by a hemostat.

Three different scalpel blades should be available when a wound is being repaired. A #11 blade is used to make stab incisions. It is often used for the incision and drainage of abscesses, cricothyroidotomies, and the removal of small or tight sutures. A #10 blade is used to make straight cuts in the skin and debride wound edges. It is rarely used in laceration repair. A #15 blade is small and curved to allow precise incisions. It is used for excising foreign bodies and wound debridement.

SUTURE TECHNIQUES

Proper wound closure requires an understanding of certain basic principles. **The needle should enter and exit the skin at a 90° angle and perpendicular to the wound edges.** By doing so, when the suture loop is closed, the wound edges will be everted. **Sutures should be placed as close to the wound edge as possible (2 to 3 mm) in order to avoid excessive tension on the wound.** More force will be required to close the wound if the sutures are placed too far from the wound edge. Edema develops in a wound in the first 48 hours after closure. Sutures placed too far from the wound edge can result in large scars when the edema subsides.

The layers of the wound should be matched evenly and each layer should be closed separately. If a wound involves the deeper layers of skin, fascia should be matched to fascia, dermis should be matched to dermis, and epidermis should be matched to epidermis. **The proper matching of layers avoids an uneven closure, helps to prevent an unnecessarily large scar, and eliminates dead space.**

The epidermal edges of the wound must be everted to allow for proper healing. Scars contract with time. They will flatten and heal with a better cosmetic result if the wound edge is everted and slightly elevated. The wound edges will contract into a "pit" below the plane of the skin, will be more noticeable, and the final result will be less appealing cosmetically if the wound edges are not everted.

Handle the tissues gently and do not squeeze or twist them too tightly with the instruments. This helps to avoid strangulation, which can result in tissue necrosis. **The sutures should be placed carefully and with the proper amount of tension to help promote healing.** Sutures should be snug. Attempts should be made to avoid excessive tension on the wound edges in order to prevent wound dehiscence. The use of the smallest suture size necessary to approximate the wound edges will reduce tissue damage and minimize scarring. **Table 93-3** lists the appropriate suture types and sizes for each body region.

If there will be a temporary delay in the closure of a laceration because of other injuries that may be life-threatening or of greater importance, cover the wound with a saline-soaked gauze in order to keep the tissues from drying.

PRINCIPLE OF HALVING

Large wounds gape open and are difficult to approximate. Closure of the deeper layers will often bring the skin edges into apposition. If not, the principle of halving may be used to approximate the wound (**Figure 93-2**). Identify the midpoint of the laceration. Place the first suture at the midpoint (**Figure 93-2A**). This stitch is known as the central suture. The next sutures are placed in halves on each side of the central suture (**Figures 93-2B & C**). Continue the process by placing sutures halfway between previous sutures until the wound is approximated. This results in even closure of the wound edge. This principle can be used for closure of both the deep layers and the skin.

TWO-HANDED SQUARE KNOT

This is the easiest and most reliable method of tying most suture materials. It involves the classic "right-over-left and left-over-right"

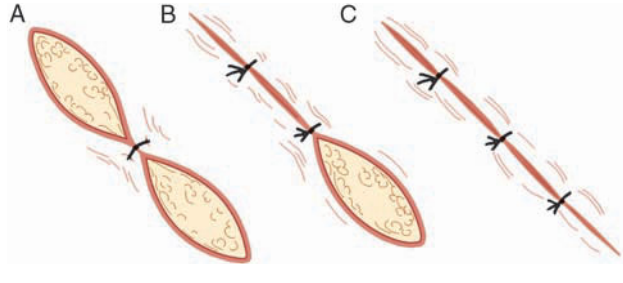

FIGURE 93-2. The principle of halving. **A.** The first suture is placed in the middle of the laceration. **B.** The second suture is placed halfway between the first suture and the upper end of the laceration. **C.** The third suture is placed halfway between the first suture and the lower end of the laceration.

tie (**Figure 93-3**). The incorrect "right-over-left and right-over-left" is a granny knot, which will slip if it is tied in this manner. This square knot is quick and simple to perform. However, it does take significant practice to master this technique.

Place a suture through the skin on both sides of the laceration (**Figure 93-3A**). Pull the suture through the wound until half is on each side of the laceration. Grasp the right half of the suture with the right thumb and index finger (**Figure 93-3A**). Grasp

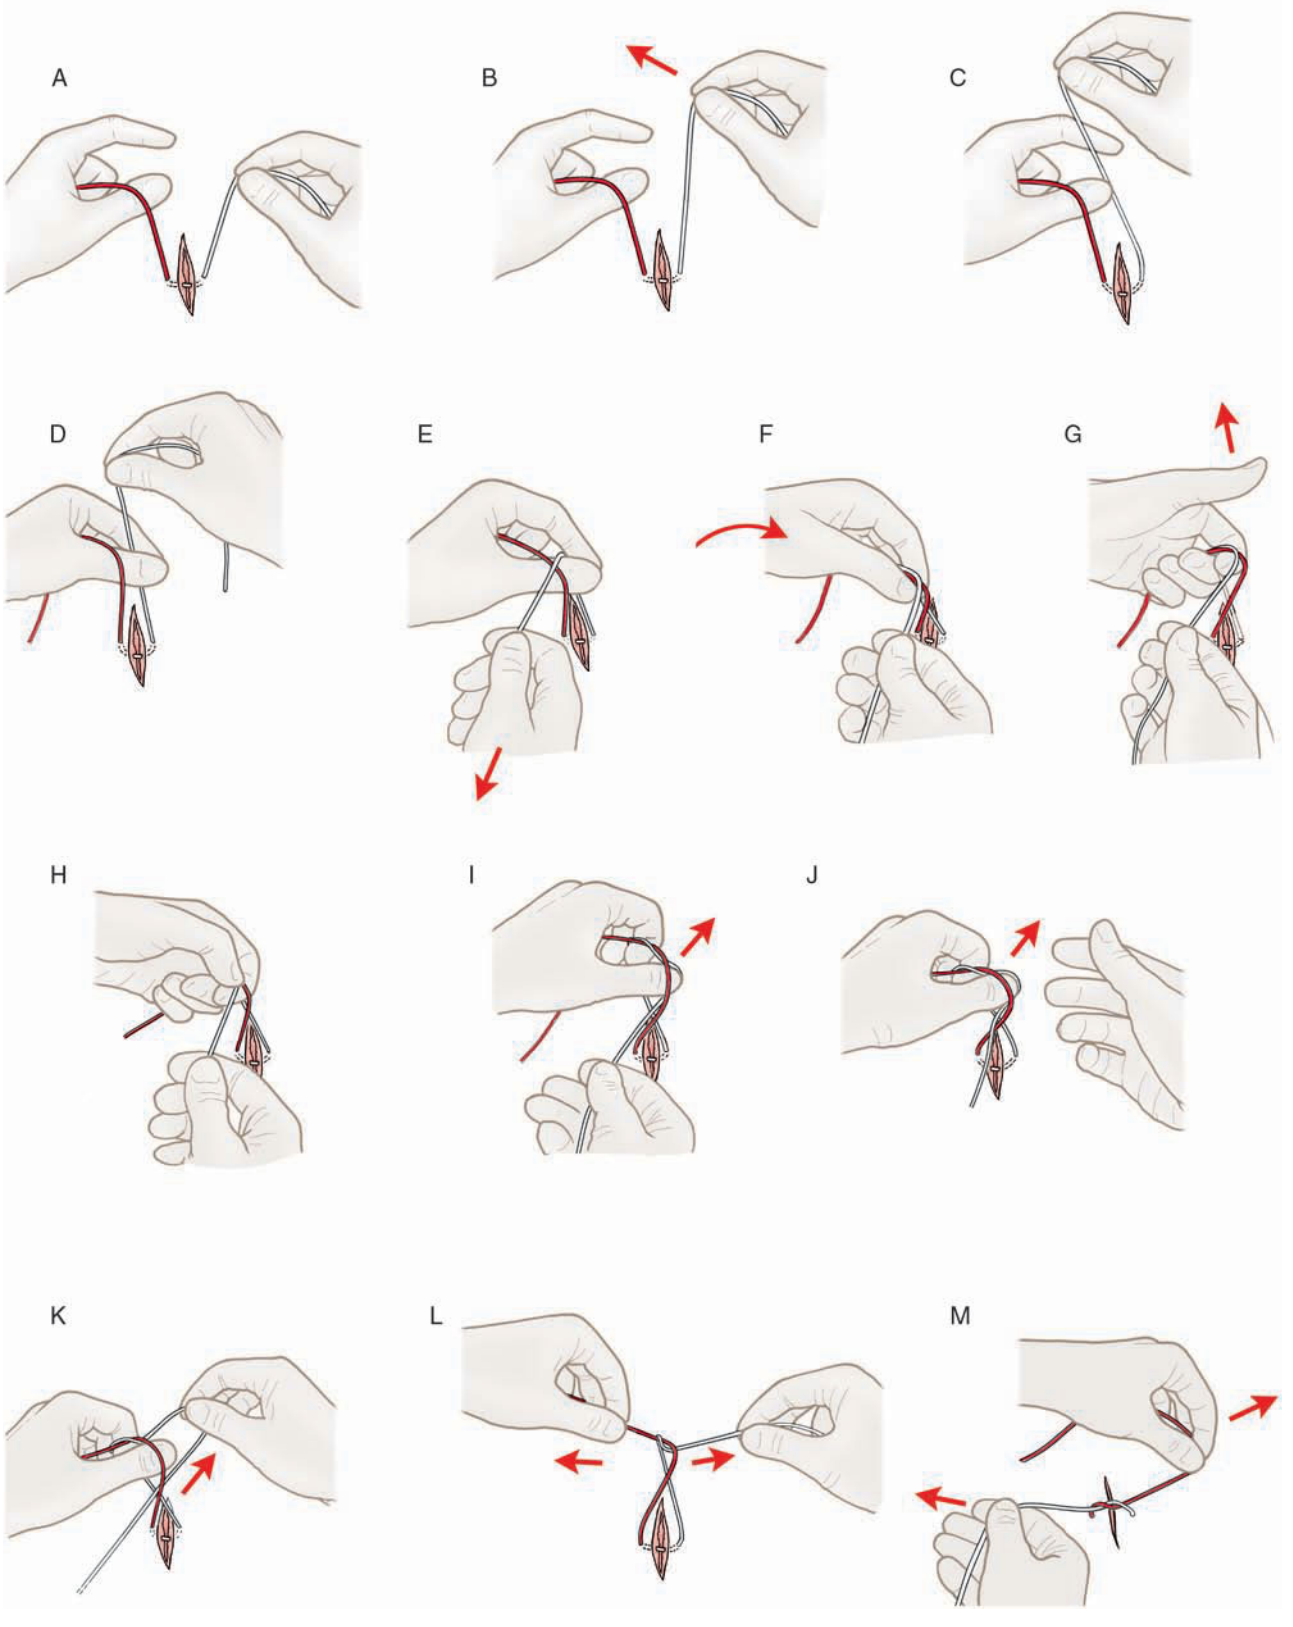

FIGURE 93-3. The two-handed square knot.

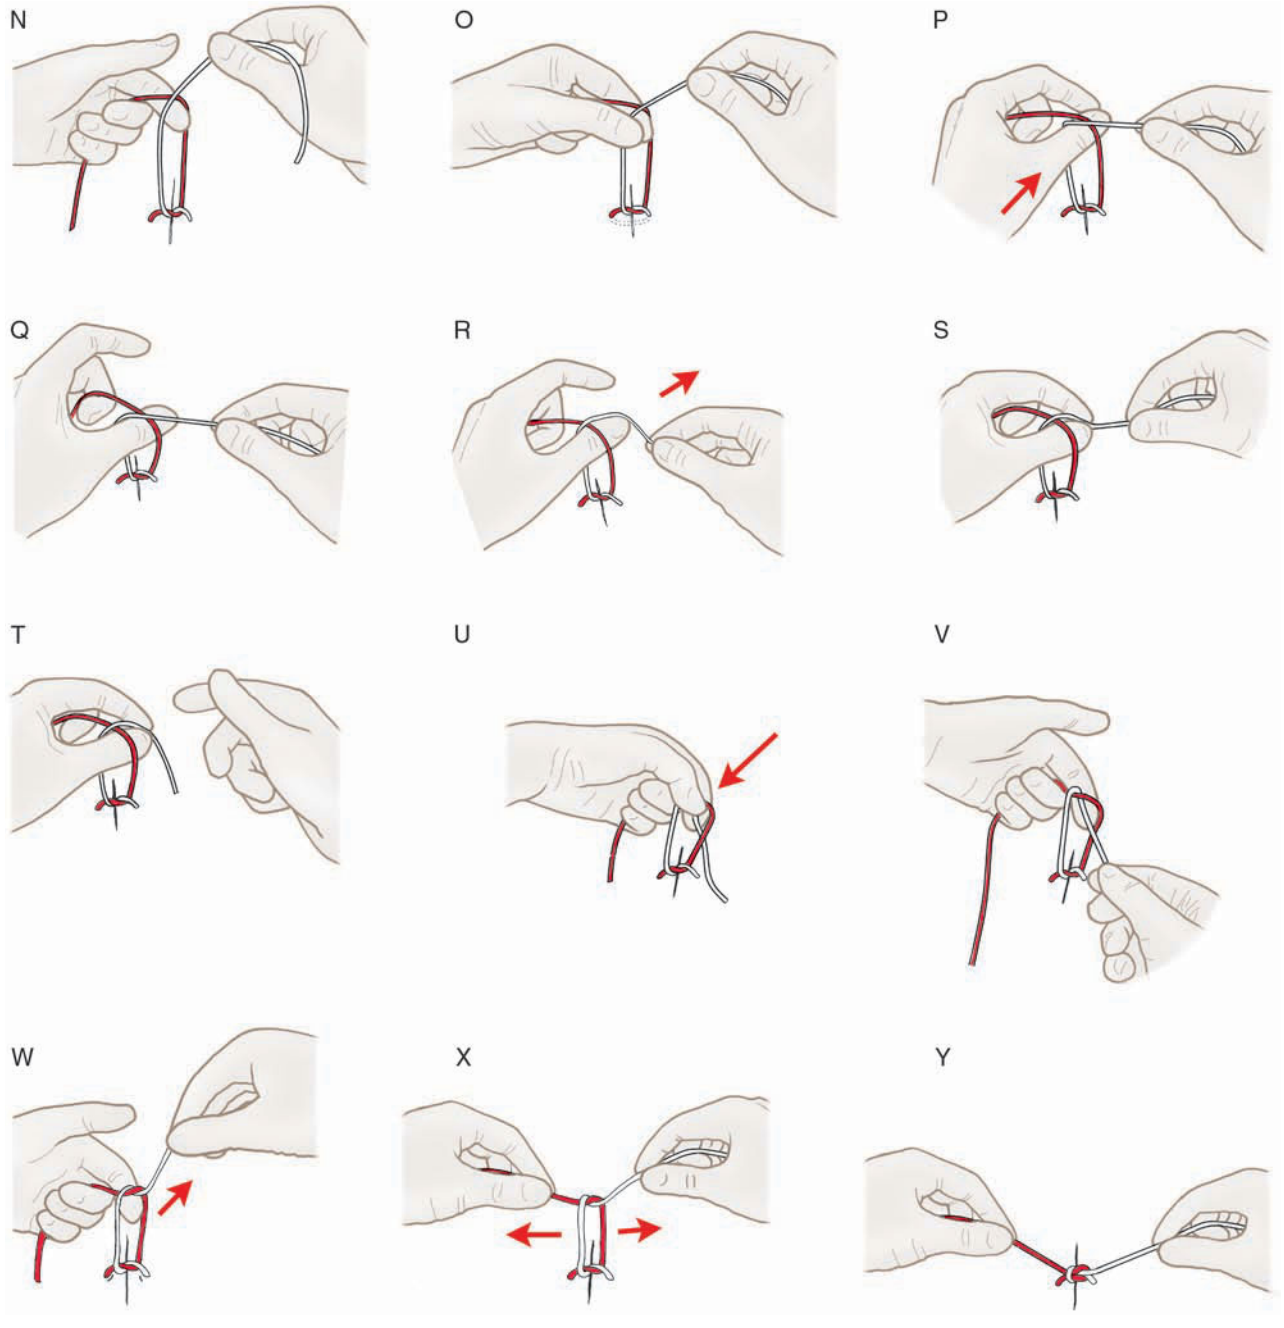

FIGURE 93-3. (*continued*)

the left half of the suture with the left third through fifth fingers and the suture draped over the thumb (**Figure 93-3A**). Cross the right hand toward the left hand (**Figure 93-3B**). Continue to move the right hand until the suture is between the left thumb and index finger (**Figure 93-3C**). Close the left thumb and index finger to entrap the right half of the suture in the pads of the fingers (**Figure 93-3D**). Pull the right hand down and to the left so that the two halves of the suture form an X over the left thumb (**Figure 93-3E**). Flex the left wrist to slide the X off the left thumb and onto the left index finger (**Figure 93-3F**). Lift the left thumb backward and upward so that the X overlies the tip of the left index finger (**Figure 93-3G**). Reapply the left thumb over the left index finger to entrap the X (**Figure 93-3H**). Extend the left wrist to push the left thumb and the X through the loop (**Figure 93-3I**). Release the suture held with the right hand (**Figure 93-3J**). Regrasp the suture with the right hand after it passes through the loop (**Figure 93-3K**). Pull the suture completely through the loop with the right hand. Simultaneously move the left hand toward the left and move the right hand toward the right (**Figure 93-3L**). Cross the hands so that the left hand goes toward the right side and the right hand goes toward the left side (**Figure 93-3M**). Continue to pull both sides of the suture until the knot lies flat and the skin edges are apposed (**Figure 93-3M**). The first half of the knot is now complete.

Make the second half of the knot to complete the square knot. Raise both hands upward and uncross them until an X is formed over the left index finger (**Figure 93-3N**). Close the left thumb and index finger to entrap the suture being held with the right hand (**Figure 93-3O**). Extend the left wrist to push the left thumb through the loop (**Figure 93-3P**). Lift the left index finger upward

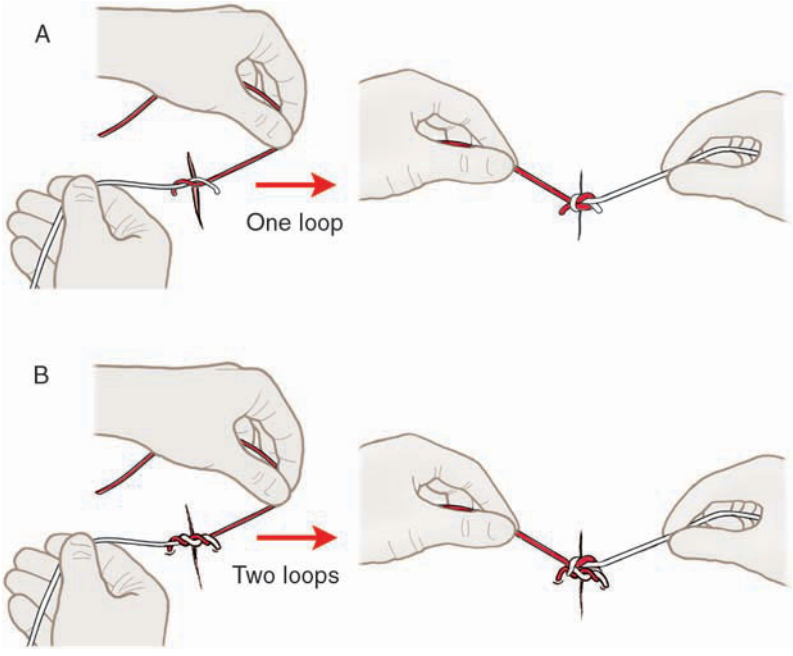

FIGURE 93-4. The square knot (**A**) versus the surgeon's knot (**B**). The first throw of the square knot has one loop (**A**), while that of the surgeon's knot has two loops (**B**). The second throw of both knots is a simple loop.

(**Figure 93-3Q**). Move the right hand away from you until the suture it holds drapes over the left thumb (**Figure 93-3R**). Reapply the left index finger onto the thumb to entrap the suture held with the right hand (**Figure 93-3S**). Release the suture held with the right hand (**Figure 93-3T**). Flex the left wrist to push the left index finger and suture through the loop (**Figure 93-3U**). Regrasp the free suture with the right hand after it passes through the loop (**Figure 93-3V**). Move the right hand upward and to the right to complete the second half of the knot overlying the left index finger (**Figure 93-3W**). Simultaneously move the left hand toward the left and move the right hand toward the right (**Figure 93-3X**). Continue to pull both halves of the suture until both halves of the knot come into contact (**Figure 93-3Y**). Pull both halves of the suture to secure the knot. The square knot is now complete. Continue the process to add additional knots onto the suture. Cut off excess suture on both sides of the knots.

SURGEON'S KNOT

The physician may choose to use a surgeon's knot instead of a square knot (**Figure 93-4**). The square knot has one loop in the first throw and one loop in the second throw (**Figure 93-4A**). The surgeon's knot has two loops in the first throw and one loop in the second throw (**Figure 93-4B**). The only difference between these two knots is the two loops in the first throw. The second throw and subsequent knots are exactly the same for both knots. The advantage of the surgeon's knot is that the two loops are more secure and stay in place while the second throw is being tied. The choice to use either knot is dependent on the experience and the training of the physician.

INSTRUMENT TIE

The instrument tie is the most efficient method to complete a simple interrupted suture (**Figure 93-5**). It is the tie that is most commonly used in the Emergency Department. An instrument tie is often quicker, requires less dexterity, and is easier to perform than the two-handed method. It may be used with the square knot or the surgeon's knot.

Place a suture through the skin on both sides of the laceration (**Figure 93-5A**). Carefully grasp the needle in its midportion and pull it through the laceration (**Figure 93-5B**). Continue to pull the needle until approximately 1 to 2 cm of suture on the tail end remains outside the laceration (**Figure 93-5C**). A large amount of suture will be wasted if the tail is left too long, as it will be later cut off and discarded. On first learning the instrument tie, it may be best to leave a tail of 3 to 4 cm until one is proficient with this technique.

Place the needle driver over the laceration but not touching it (**Figure 93-5C**). Loosely loop the needle end of the suture over (**Figure 93-5D**) and around (**Figure 93-5E**) the needle driver. Loosely loop the needle end of the suture over and around the needle driver a second time (**Figures 93-5F & G**). This will eventually result in the first half of a surgeon's knot. Looping the suture once around the needle driver will result in a simple square knot. Move the tip of the needle driver toward the tail of the suture without letting the loops fall off the needle driver (**Figure 93-5H**). Grasp the tail of the suture with the needle driver (**Figure 93-5I**). Pull the tail of the suture through the loop (**Figure 93-5J**). Pull the tail completely through the loops (**Figure 93-5K**). Simultaneously move the left hand toward the right and the right hand/needle driver toward the left (**Figure 93-5L**). Continue to pull both sides of the suture until the hands are opposite each other, the knot lies flat, and the skin edges are apposed (**Figure 93-5M**). The first half of the knot is now complete.

Make the second half of the knot. Continue to hold the needle and release the tail of the suture from the needle driver (**Figure 93-5N**). Place the needle driver over the laceration but not touching it (**Figure 93-5N**). Loosely loop the needle end of the suture over (**Figure 93-5O**) and around (**Figure 93-5P**) the needle driver. Move the tip of the needle driver toward the tail of the suture without letting the loop fall off the needle driver (**Figure 93-5Q**). Grasp the tail of the suture with the needle driver (**Figure 93-5R**). Pull the tail of the suture completely through the loop (**Figure 93-5S**). Simultaneously move the left hand toward the left and the right hand/needle driver toward the right (**Figure 93-5T**). Continue to pull both sides of the suture until both halves of the knot come into contact. Pull both sides of the suture to secure the knot. The knot is now complete. Continue

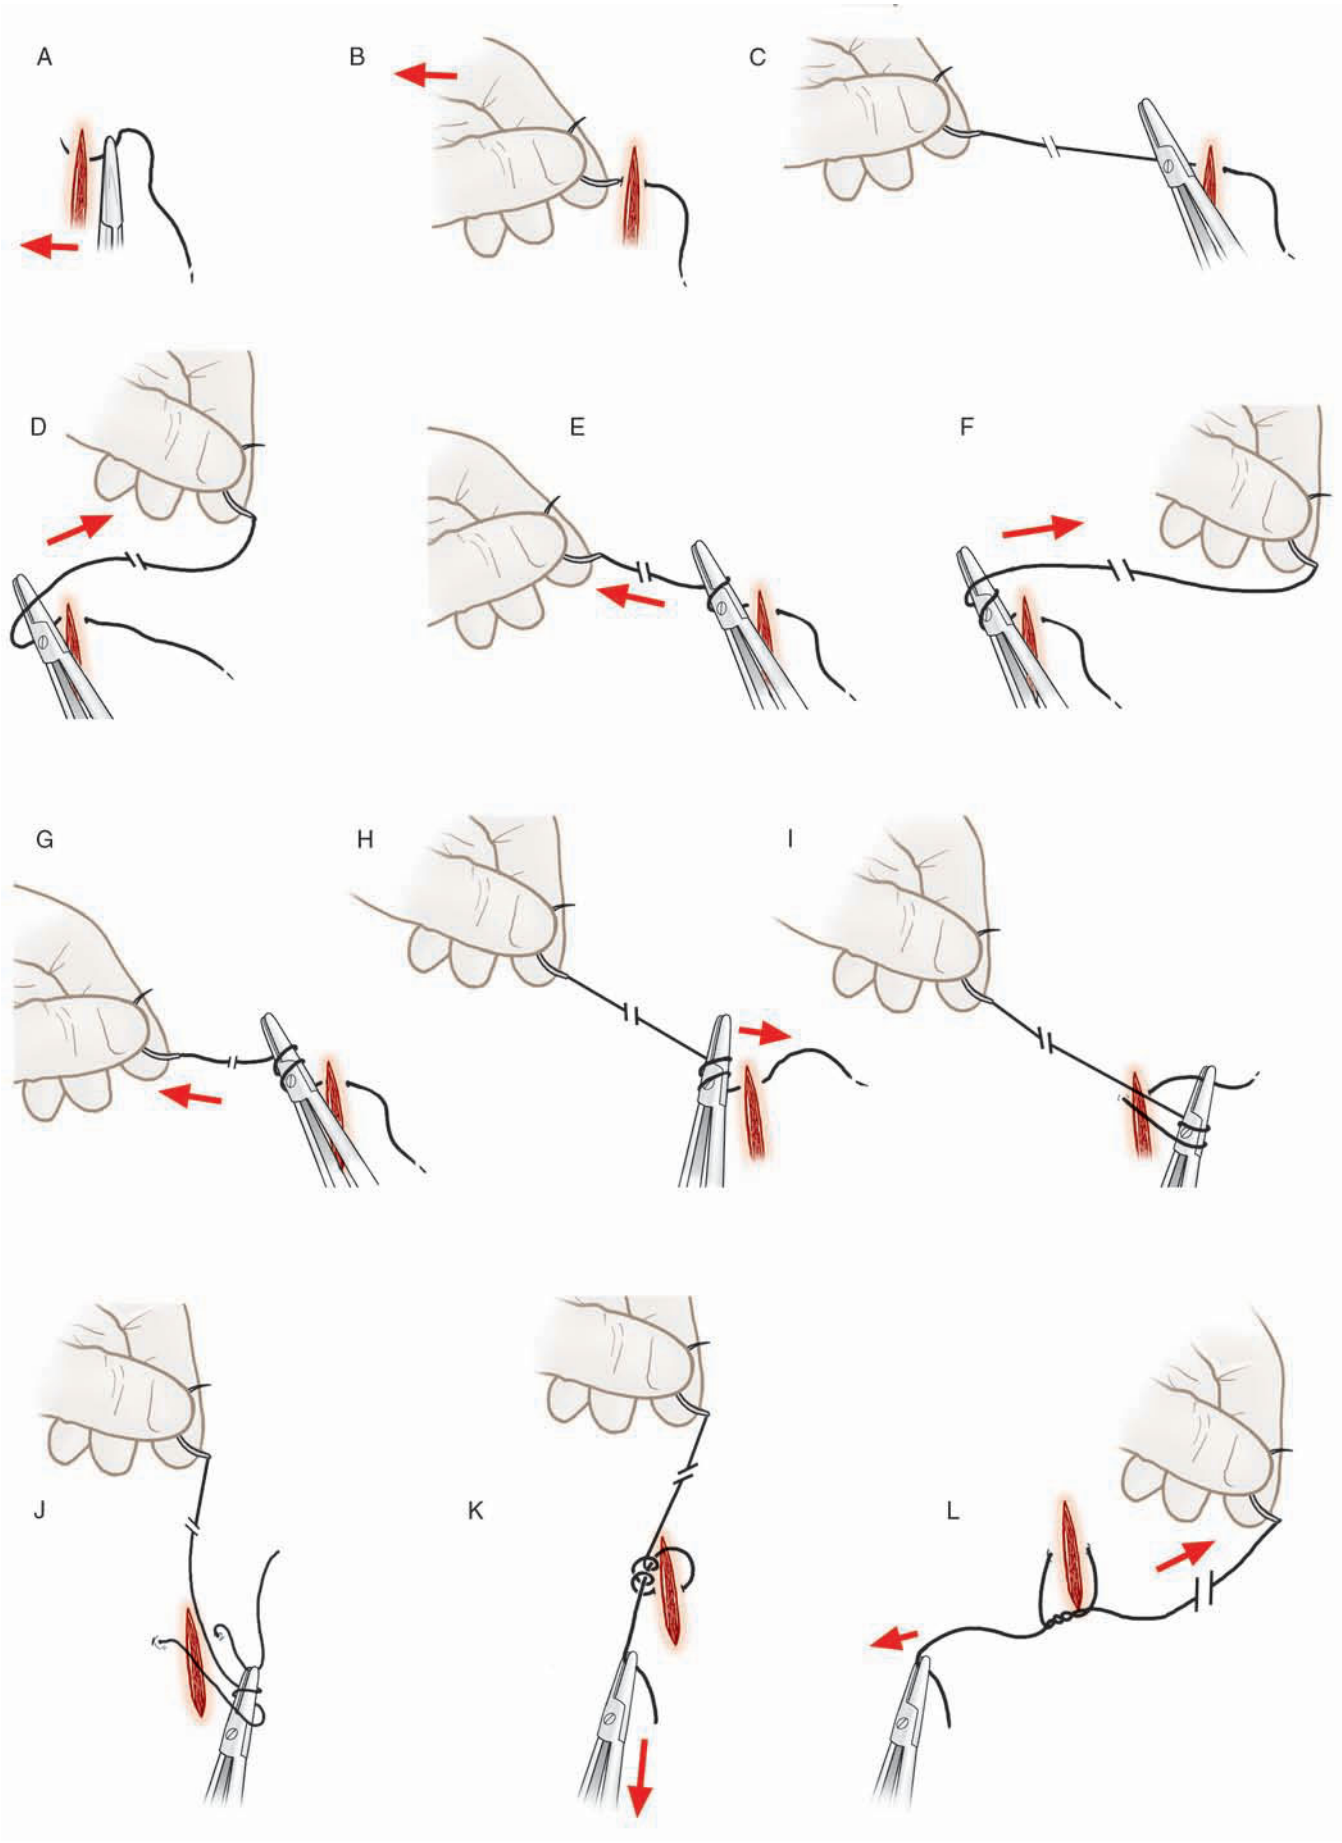

FIGURE 93-5. The instrument tie.

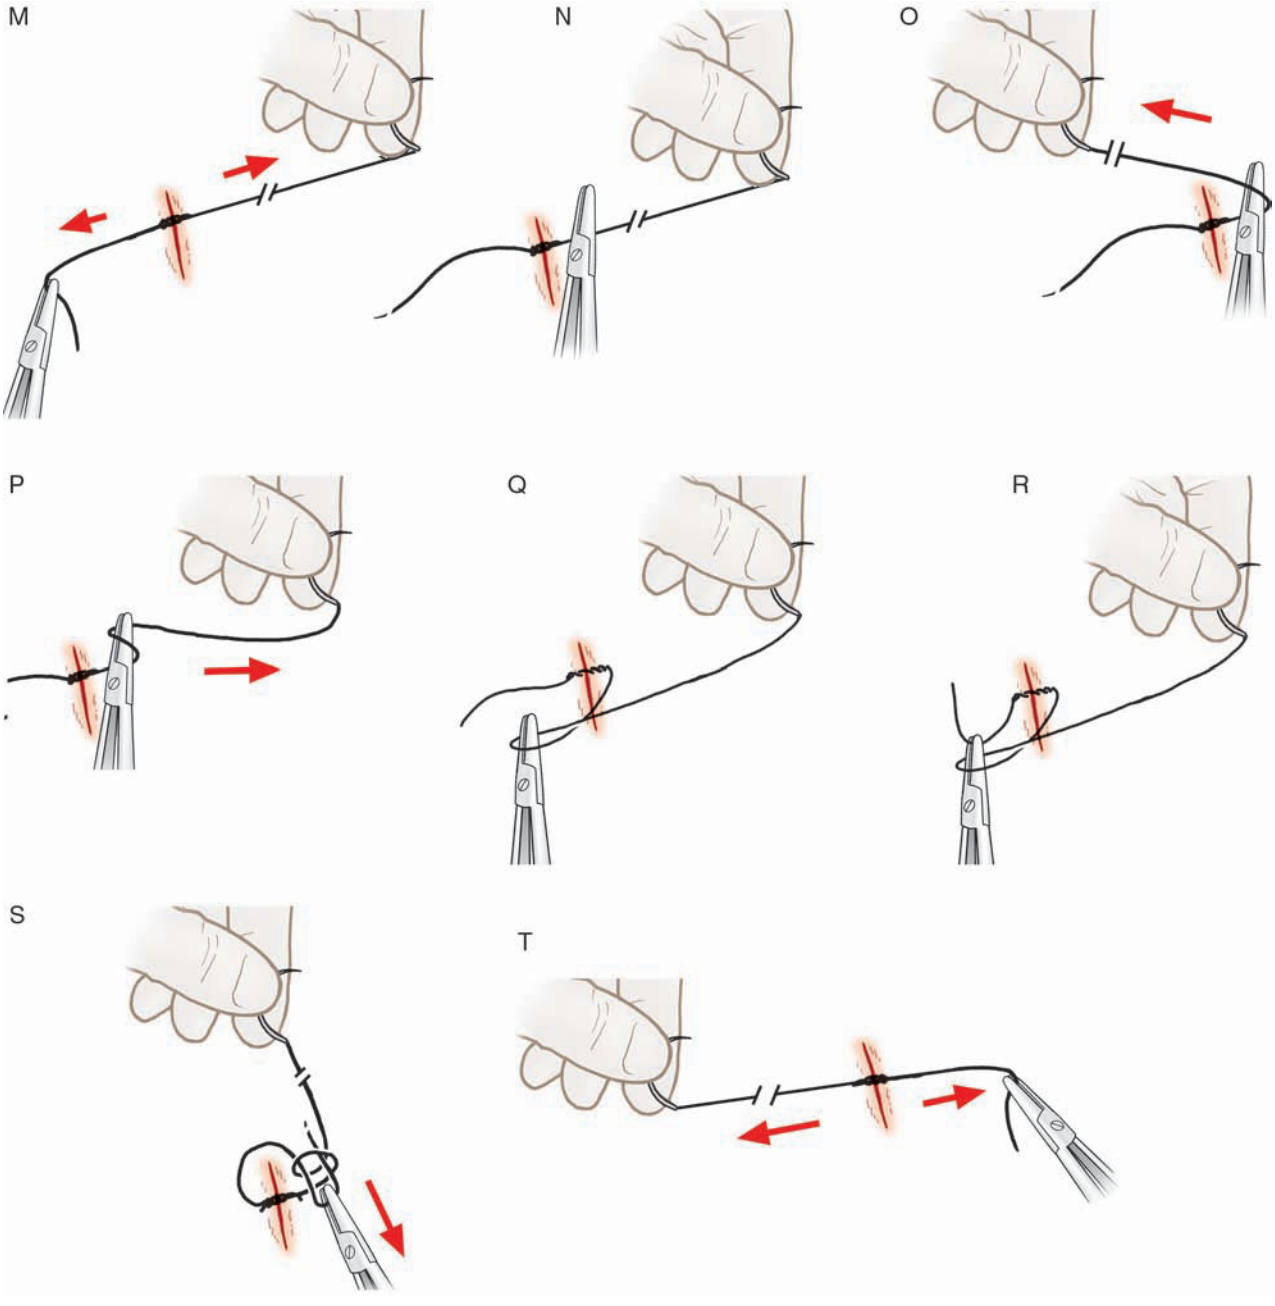

FIGURE 93-5. (*continued*)

this process three or four more times, each in alternative directions, to place additional knots. Cut off the excess suture on both sides of the knots.

SIMPLE INTERRUPTED STITCH

The simple interrupted stitch is the most commonly used suture technique and is useful in many situations (**Figure 93-6**). One major advantage is that each stitch is placed independent of the others. Therefore tension on each stitch can be adjusted separately. Additionally, the entire repair is not compromised if one suture should happen to come out. The other sutures will remain in place to help assure proper wound healing. **The needle must enter and exit the skin at a 90° angle to help evert the wound edges. Take equal volumes of skin from each side of the area being sutured. Drive the needle equidistantly into and out of the wound edges and incorporate the base of the wound.**

Insert the needle at a 90° angle to the skin (**Figure 93-6A**). Drive the needle through the tissue until the tip exits the skin (**Figure 93-6B**). Grasp the needle behind the tip and pull it through the wound (**Figure 93-6C**). **The suture should enter and exit the skin equidistant from the wound edges (Figure 93-6D). If it does not, pull the suture out and repeat the stitch so that it is equidistant from the wound edges.** Make a loop in the suture with the two-handed tie or the instrument tie. Pull the suture to appose the wound edges and cinch down the knot (**Figure 93-6E**). The tissue at the base of the wound will come into apposition before the tissue at the skin surface and thus evert the wound edge. Complete the knot to one side of the laceration (**Figure 93-6F**). Just prior to cinching the second throw onto the first, pull the ends so that the knot is not directly over the wound and the edges of the wound remain in apposition. Apply additional sutures equidistant from each other until the wound is closed (**Figure 93-6G**).

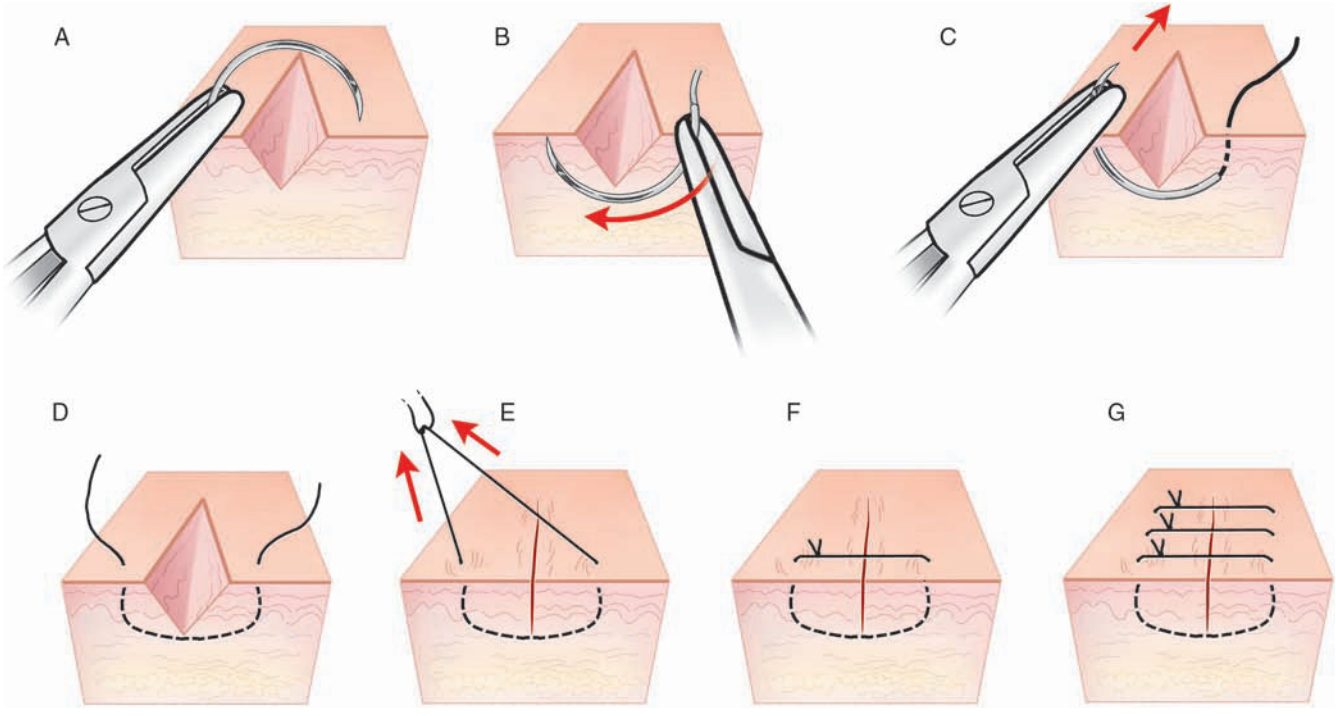

FIGURE 93-6. The simple interrupted stitch.

OPEN-LOOP SIMPLE INTERRUPTED STITCH

The open-loop simple interrupted stitch is a variation of the simple interrupted stitch (**Figure 93-7**). The same basic technique is used except that the knot is tied differently. The tie involves laying down the first knot with an instrument tie. However, the second knot placed on the suture is not pulled all the way down. Pull the second knot only until it is just above the first knot (**Figure 93-7A**). In other words, the second knot is loosely tied, leaving a loop between the first and second knots. Place a third knot as a single knot square to the second knot (**Figure 93-7B**). Cinch the third knot tightly to the second knot. This "locks" the third knot onto the second knot.

This knot is indicated when there is the possibility of edema forming at the suture site. If edema forms, the first knot will have room to open as it slides toward the second knot. This stitch avoids excessive tension on the wound and prevents the suture from cutting into the skin. This stitch facilitates suture removal when numerous small stitches are placed next to a wound edge. Cutting the open loop unravels the knot and allows for easy removal of the suture. This stitch should not be used in areas where the skin is thin or if there is little subcutaneous tissue (e.g., dorsal hand and foot). In these areas, the wound edges often become unopposed while the knot is being secured.

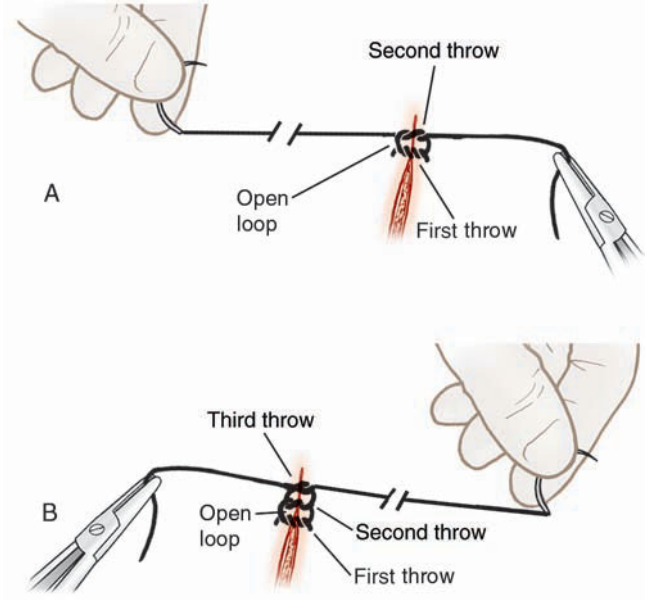

FIGURE 93-7. The open-loop simple interrupted stitch.

INTERLOCKING SLIP KNOT

This technique can be used in patients who will be traveling, camping, or otherwise away from their primary source of medical care (**Figure 93-8**). The patient can easily remove the sutures without having to find an unfamiliar or foreign healthcare provider for routine suture removal. The interlocking slip knot can be removed by hand without the use of a scissors or a scalpel. This can be useful for suture removal in pediatric patients, who may find it hard to sit still for suture removal.

Place a suture through the skin on both sides of the laceration (**Figure 93-8A**). Loop the tail end of the suture around the tip of the needle driver (**Figure 93-8A**). Grasp the needle end of the suture with the needle driver (**Figure 93-8B**). Pull the needle end of the suture through the loop while simultaneously pulling on the tail end of the suture with a second needle driver (**Figure 93-8C**). Continue to pull both suture halves in opposite directions until a knot is formed against the skin and the wound edges are apposed (**Figure 93-8D**). Release the needle driver holding the now formed loop. Insert the needle driver through the loop and grasp the tail end of the suture (**Figure 93-8E**). Grasp the needle end of the suture with the second needle driver (**Figure 93-8E**). Pull the

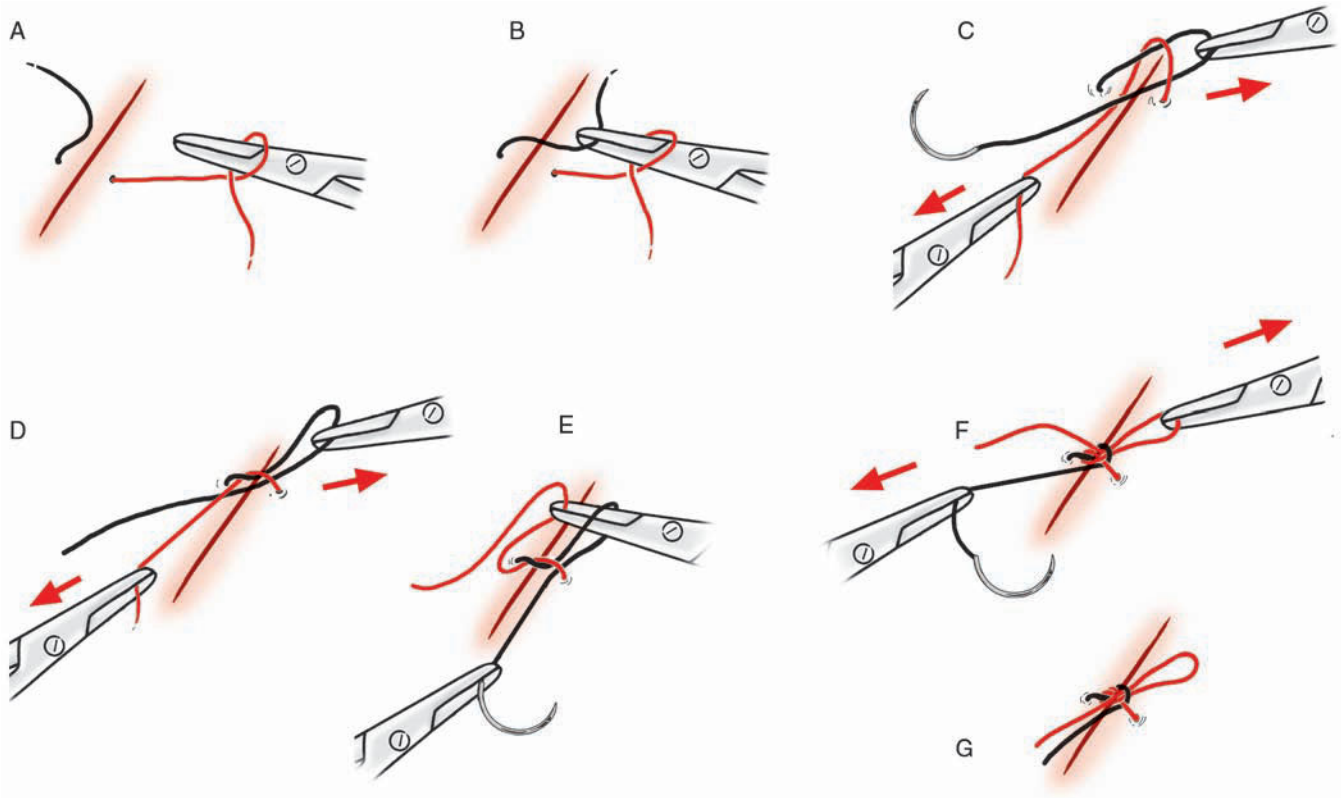

FIGURE 93-8. The interlocking slip knot.

needle drivers in opposite directions to lock and secure the knot (**Figure 93-8F**). The knot is now complete (**Figure 93-8G**). To remove the stitch, pull the free end of the suture to unlock the knot. Continue to pull the suture until it is free from the skin. This stitch can easily become loose or open before the wound is healed. Thus, it is recommended to cover the wound and sutures with skin closure tape (e.g., Steri-Strips).

CONTINUOUS OVER-AND-OVER STITCH (SIMPLE RUNNING STITCH)

Continuous (simple running) sutures minimize the time required for laceration repair. Stitches can be placed very quickly, since each individual stitch does not have to be tied. This stitch provides strength and applies equal tension on all sutures in the repair. This stitch can be used to achieve hemostasis. The wound must be long and straight. Simple running stitches can effectively be used in partial-thickness lacerations and wounds under minimal tension.

However, there are several disadvantages to this stitch. It can be associated with significant epithelialization of the suture track. This is especially true if the suture is not removed early and remains for a prolonged period of time. Inclusion cysts may form within a few weeks after removal of the sutures. **Simple running stitches should not be used on any wound under tension.** If one suture breaks, the entire wound may open. **This stitch should not be used when closing a wound where there is a risk of subsequent hematoma formation.** Hematoma formation would require the removal of all of the sutures in order to drain the hematoma. Although this suture is not commonly used in the Emergency Department, it can be very helpful for closing bleeding scalp wounds, as the injury will be covered with hair and cosmesis is a secondary concern.

Place the initial stitch as a simple interrupted stitch (**Figure 93-9A**). Do not cut the suture after the knots are securely tied. Place a second stitch 3 to 5 mm from the first stitch as if placing another simple interrupted stitch (**Figures 93-9B & C**). Place a third stitch 3 to 5 mm from the second stitch (**Figures 93-9D & E**). Continue to place additional stitches until the end of the laceration is reached. **Use care to ensure that the sutures are all lined up with each other and equidistant from the laceration.** Do not pull the last throw taut against the skin (**Figure 93-9F**). The loop will act as the tail end of the suture for knot tying. Loop the needle end of the suture twice around the tip of the needle driver (**Figure 93-9G**). Grasp the last throw with the tips of the needle driver (**Figure 93-9G**). Pull the last throw through the loops until the knot is against the skin (**Figure 93-9H**). Perform three to five more instrument ties to secure the knot. Cut off the excess suture (**Figure 93-9I**).

CONTINUOUS SINGLE-LOCKED STITCH (RUNNING-LOCKED CLOSURE)

This stitch may promote less epithelialization of the suture track than the continuous over-and-over stitch. It maintains the advantages of a continuous suture. This variation of the simple running closure locks each stitch after it is placed (**Figure 93-10**). It provides a secure apposition of the wound edges while each subsequent stitch is placed. The main disadvantage of this stitch is the time it takes compared to a continuous over-and-over stitch.

Place the initial stitch as a simple interrupted stitch (**Figure 93-10A**). Do not cut the suture after the knots are securely tied. Loop the tail end of the suture over the nondominant fifth finger (**Figure 93-10B**). Apply slight tension on the tail end of the suture while placing the second stitch (**Figures 93-10C & D**).

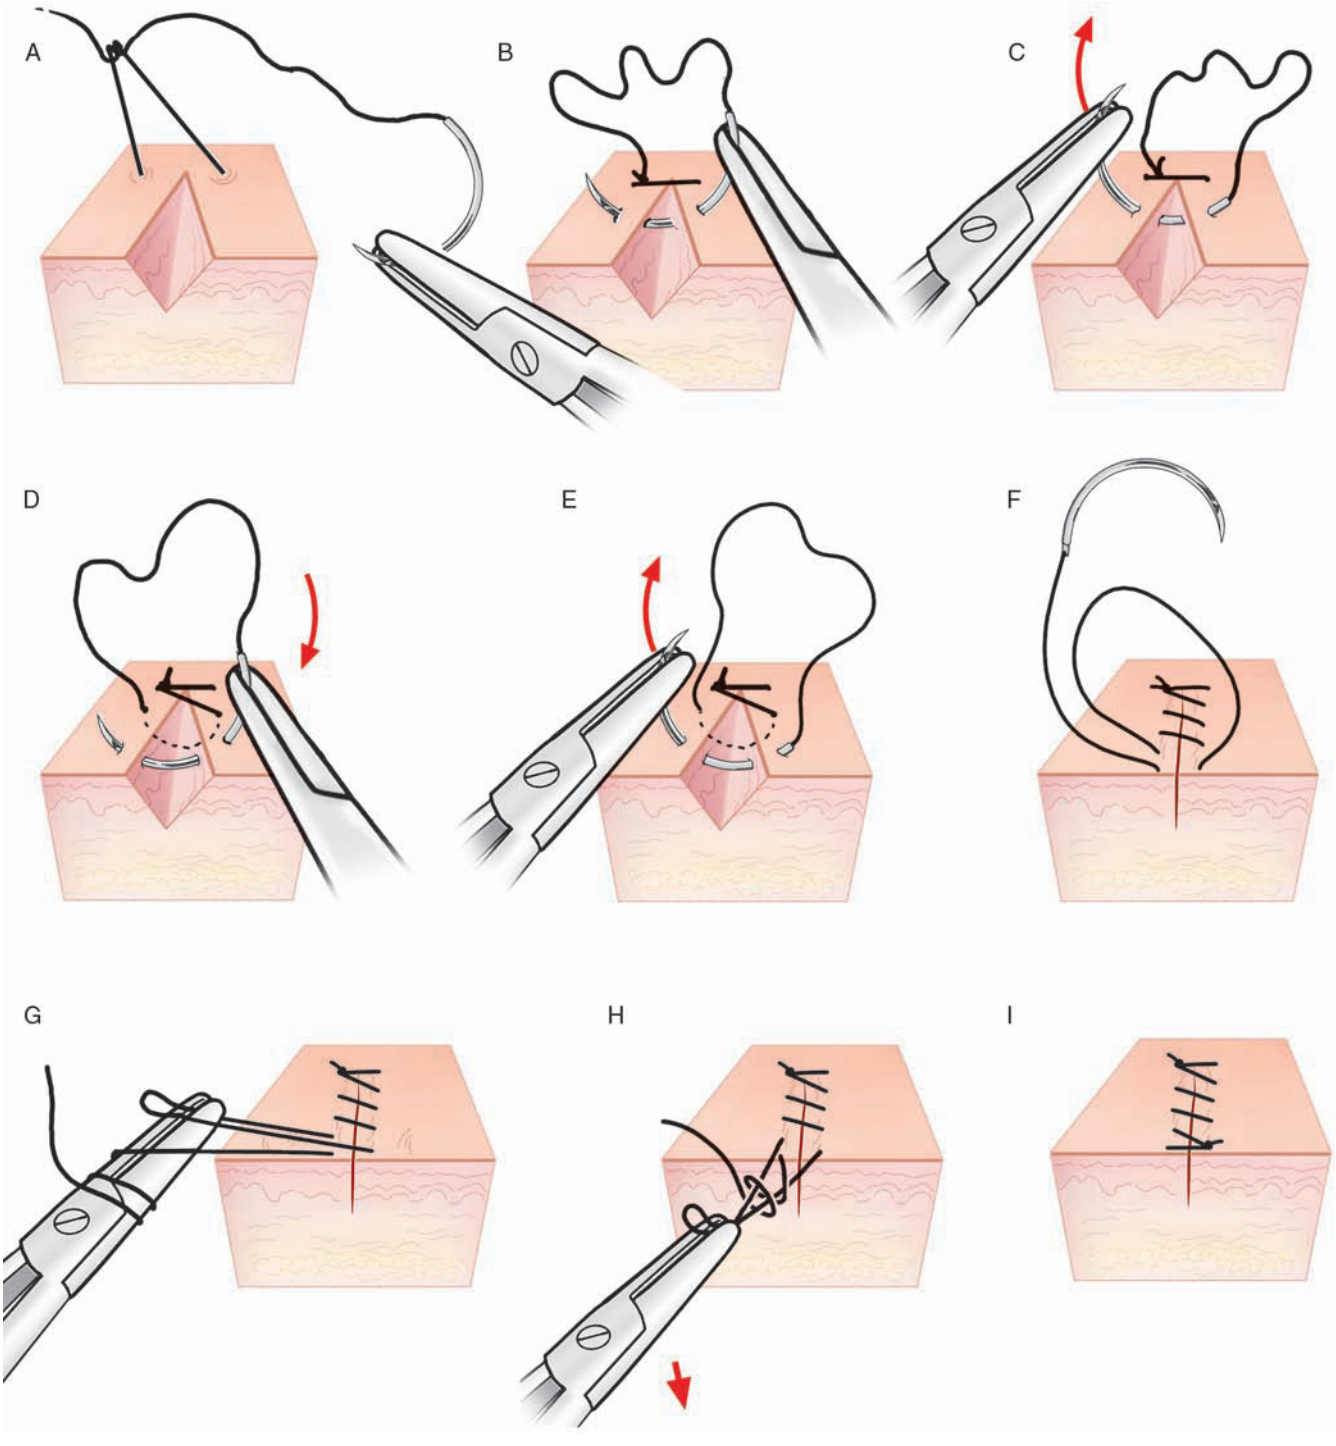

FIGURE 93-9. The continuous over-and-over or simple running stitch.

As the needle exits the skin, move the nondominant hand to bring the suture loop down and over the needle (**Figure 93-10E**). Grasp the front of the needle with the needle driver. Simultaneously pull the needle and suture through the laceration while releasing the loop from the fifth finger (**Figure 93-10F**). Repeat this procedure until the laceration is closed (**Figure 93-10G**). **Do not pull the last throw taut against the skin.** The loop will act as the tail end of the suture for knot tying. Loop the needle end of the suture twice around the tip of the needle driver (**Figure 93-10H**). Grasp the last throw with the tips of the needle driver. Pull the last throw through the loops until the knot is against the skin (**Figure 93-10I**). Perform three to five more instrument ties to secure the knot. Cut off the excess suture (**Figure 93-10J**).

VERTICAL MATTRESS STITCH

The vertical mattress stitch is a double stitch that provides for excellent wound eversion (**Figure 93-11**). It optimizes wound closure of lacerations under tension. This stitch is useful in areas where the skin is very lax, such as the elbow and the dorsum of the hand. This

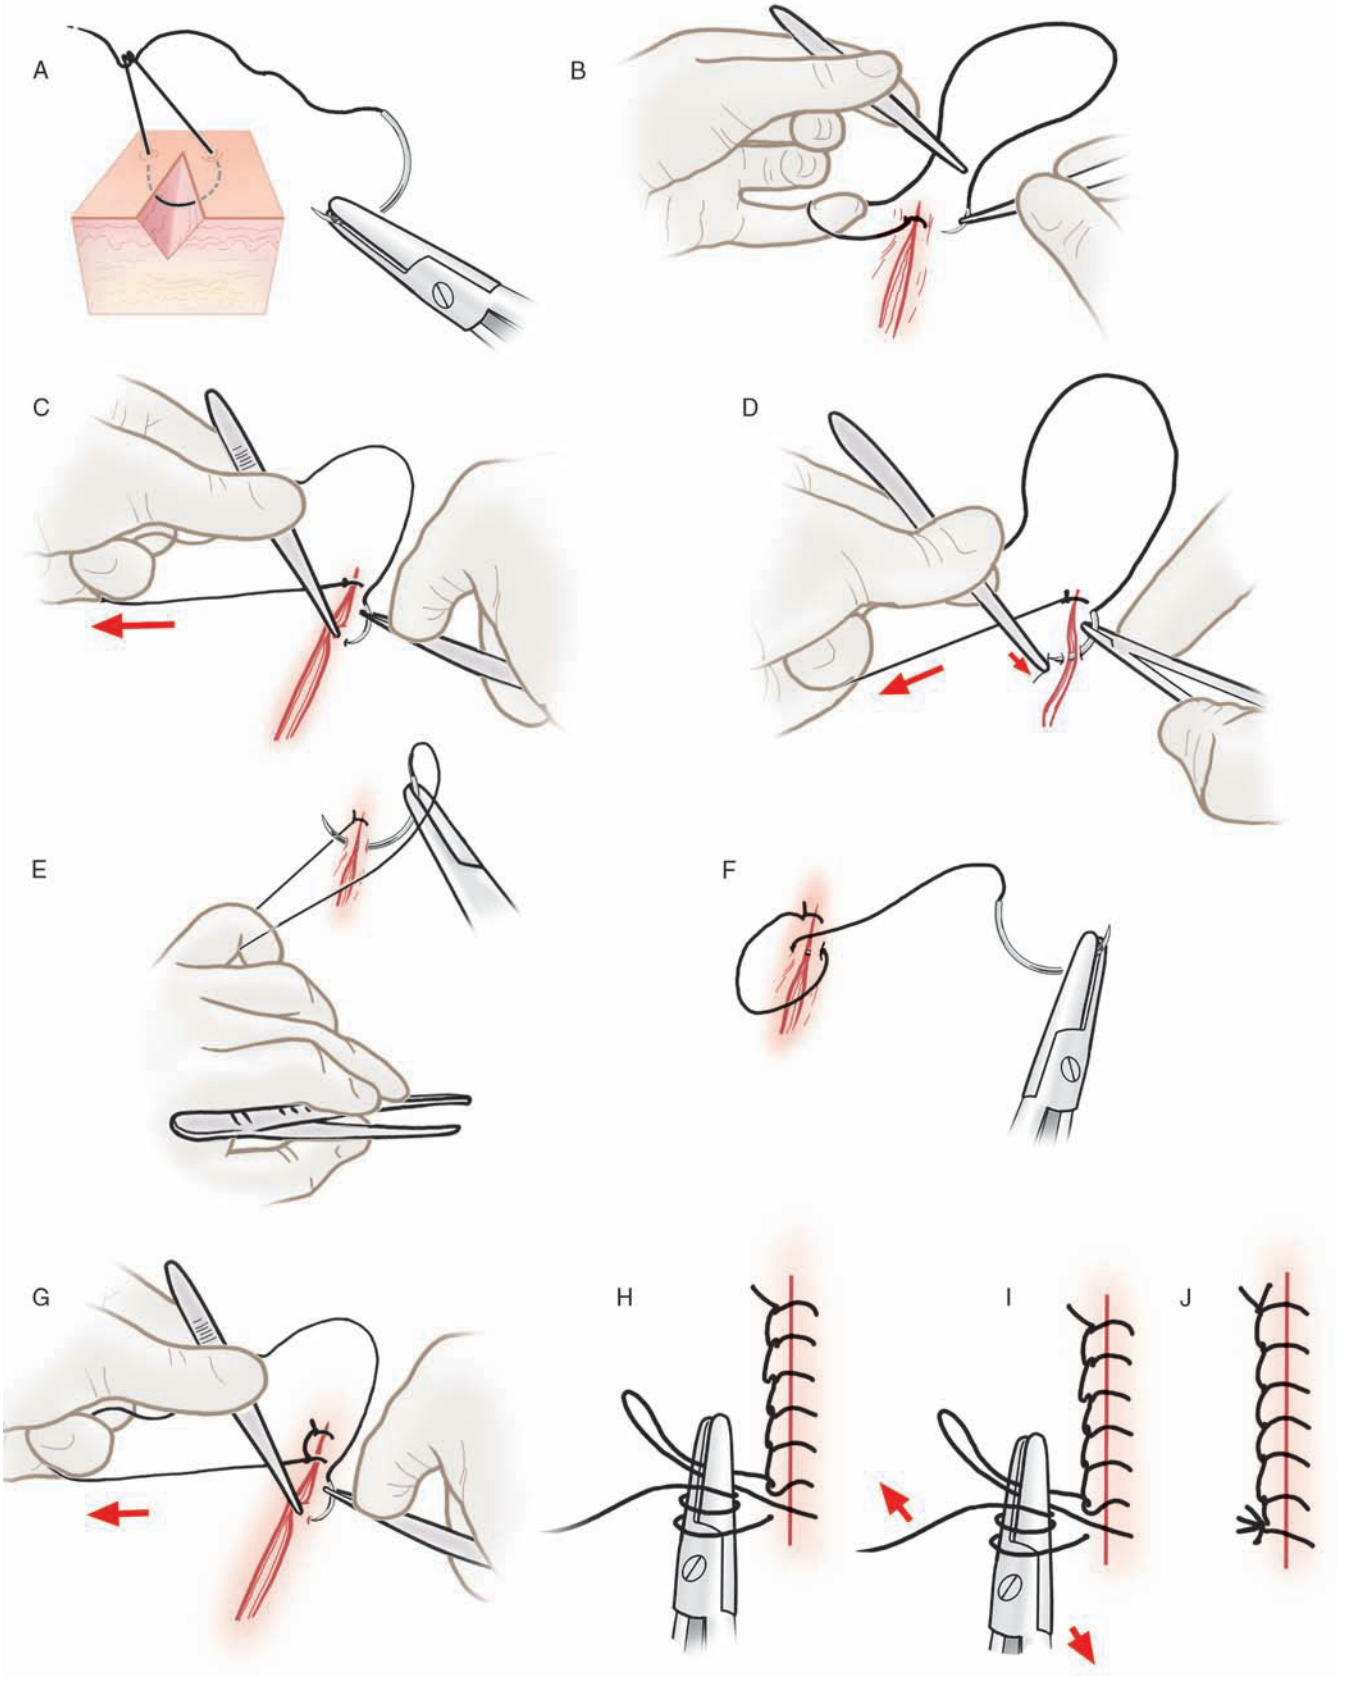

FIGURE 93-10. The continuous single-locked or running-locked stitch.

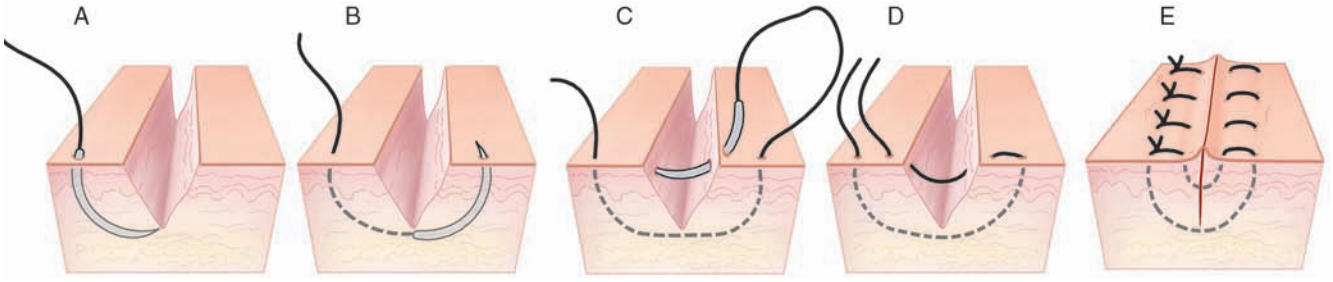

FIGURE 93-11. The vertical mattress stitch.

stitch provides for both superficial as well as deep closure of lacerations. **This stitch is contraindicated in lacerations involving the volar aspect of the hands and feet or the face, as it requires the blind placement of a deep suture.** The main disadvantage of the vertical mattress closure is the time it takes to place it.

Place the first throw much like a simple interrupted stitch with a few noted differences. The needle should enter and exit the skin 1.0 to 1.5 cm from the wound edge. The needle should traverse the base of the wound and grasp a large amount of tissue (**Figures 93-11A & B**). Reverse the needle. The second throw should enter and exit the skin approximately 2 to 3 mm from the wound edge (**Figures 93-11C & D**). **The first and second throws must be directly over each other and parallel.** Tie the suture to approximate the wound edges (**Figure 93-11E**). The first throw will close the wound base and relieve the tension at the skin surface. The second throw approximates and everts the skin edges.

The newer version of the classic vertical mattress is referred to as the "shorthand" vertical mattress stitch (**Figure 93-12**). It provides wound eversion in half the time as the traditional method. Place the first throw close to the lacerated wound edge to approximate the skin edges (**Figures 93-12A & B**). Grasp and pull the suture to elevate the wound edges (**Figure 93-12C**). This allows the needle to more easily take a large bite of tissue on the second throw. Place the second throw 1.0 to 1.5 cm from the wound edge (**Figures 93-12C & D**). Release the suture. Tie the suture to approximate the wound edges and evert the skin surface (**Figure 93-12E**). The final product looks exactly the same as the traditional vertical mattress suture (**Figure 93-12F**).

LOCKED VERTICAL MATTRESS STITCH

The locked vertical mattress stitch is useful in areas that are widely separated and where deep sutures must be avoided (**Figure 93-13**). This stitch helps to reduce the amount of tension needed to close a wound. It helps to avoid the pain and scarring that can result if too much tension is applied to a laceration. It does not put an

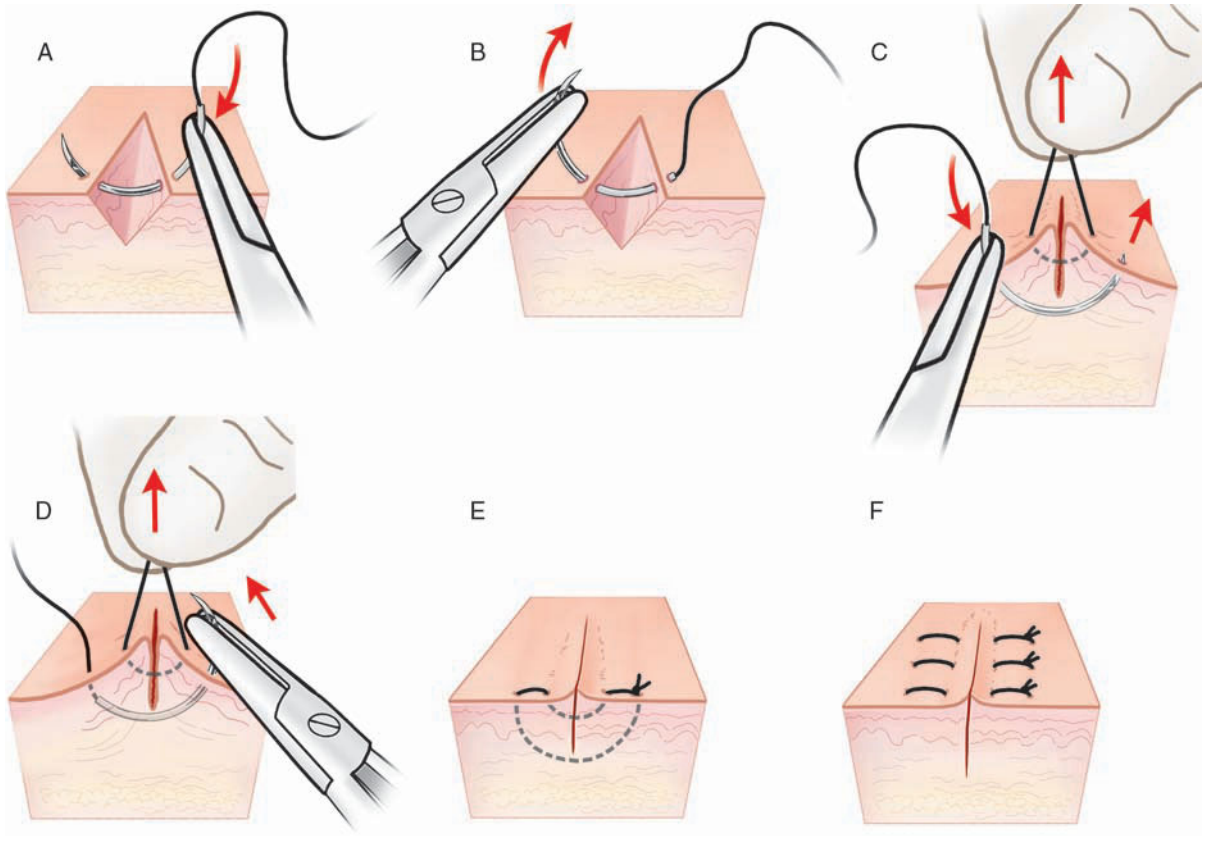

FIGURE 93-12. The "shortcut" vertical mattress stitch. An alternative method to place the vertical mattress stitch.

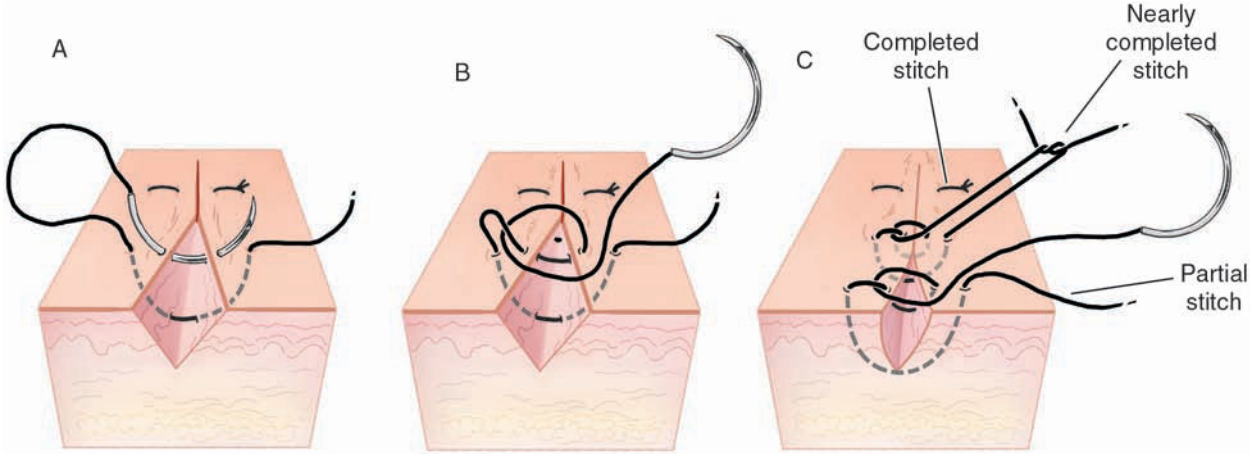

FIGURE 93-13. The locked vertical mattress stitch.

excessive amount of tension on the deep throw, as does the vertical mattress stitch.

This is a modification of the vertical mattress stitch (**Figures 93-11 & 93-12**). Place the first two throws as if placing a vertical mattress stitch (**Figure 93-13A**). Leave the suture lax with a loop above the wound surface. Pass the needle end of the suture through the open loop (**Figure 93-13B**). This step will form the locked portion of the stitch. Pull the needle end of the suture taut to appose the wound edges (**Figure 93-13C**). Tie and secure the suture in the standard manner.

HORIZONTAL MATTRESS STITCH

The horizontal mattress stitch is placed along the axis of the wound and helps to eliminate tension on the wound (**Figure 93-14**). It is a good closure technique for wounds with relatively poor circulation to the wound edges because, theoretically, no suture is placed through the wound edges. This helps to avoid tension on the wound edges from the suture and subsequent local necrosis. This stitch is placed more rapidly than the vertical mattress stitch. It requires fewer stitches to close a wound with horizontal rather than vertical mattress stitches. The throws are side by side rather than on top of each other, as with the vertical mattress, and each stitch closes more tissue. This closure may be used on the volar surfaces of the hands and fingers, as these delicate skin areas may swell and be cut by simple interrupted sutures. The main disadvantage of the horizontal mattress stitch is that it takes more experience to properly place this stitch to achieve wound eversion than with the vertical mattress stitch.

Place the first throw much like a simple interrupted stitch with a few noted differences. The needle should enter and exit the skin 0.5 to 1.0 cm from the wound edge. The needle should traverse the

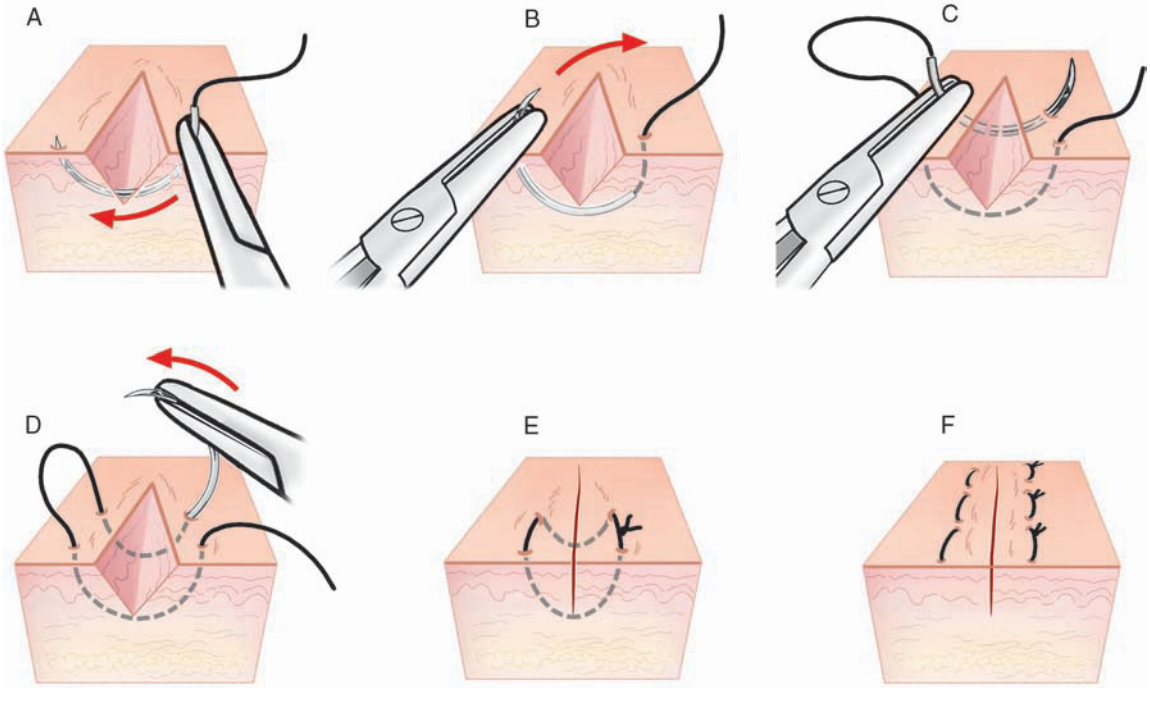

FIGURE 93-14. The horizontal mattress stitch.

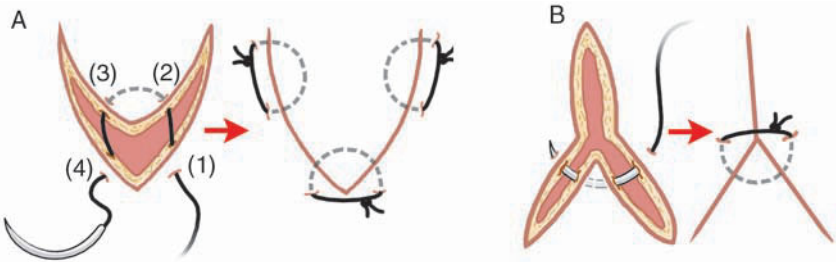

FIGURE 93-15. The half-buried horizontal mattress stitch is used to approximate a star-shaped (stellate) laceration (**A**) and a Y-shaped laceration (**B**).

base of the wound (**Figures 93-14A & B**). Reverse the needle and make a second throw 0.5 cm from the first (**Figure 93-14C**). **The needle must enter and exit the skin and the wound edges so that the first and second throws are parallel to each other** (**Figures 93-14C & D**). Pull the free ends of the suture taut to appose and evert the wound edges (**Figures 93-14E & F**). Tie and secure the suture in the standard manner.

HALF-BURIED HORIZONTAL MATTRESS STITCH

This is the stitch of choice to close complex wounds with multiple flaps in a single-layer closure. This stitch is ideal to close stellate, Y-shaped, V-shaped, and T-shaped lacerations. The half-buried horizontal mattress stitch allows a tissue flap to be reapproximated without tension on the edges of the flap. The vascular supply to a flap is derived from its base. The flaps sometimes have a limited or poor vascular supply. This stitch may be used to approximate a flap-like laceration in which the corner has limited vascularity and/or viability.

The key to this stitch is that the needle and suture pass through the dermis of the flap and not the epidermis (Figure 93-15). Begin by placing the first stitch percutaneously through the skin adjacent to the tip of the flap (**Figure 93-15A**). Advance the needle through the dermal layer of the flap, the dermal layer of the skin adjacent to the tip of the flap, and out the skin adjacent to the tip of the flap opposite to where the stitch began (**Figure 93-15A**). **The needle must traverse the dermis of the flap and adjacent tissue at the same level of the dermis to properly approximate the wound edges.** Gently pull on the free ends of the suture to approximate the flap against the adjacent skin edges. Tie and secure the suture in the usual manner. Secure the edges of the flap with half-buried horizontal mattress stitches (**Figure 93-15A**), simple interrupted stitches, vertical mattress stitches, or horizontal mattress stitches.

Stellate lacerations are often seen in the Emergency Department. They occur due to bursting of the skin from crush injuries. These lacerations are often encountered on the extremities, forehead, and scalp. Begin by inserting the needle through the skin of the largest flap. Advance the needle so that its tip exits the dermis. Continue to advance the needle through the dermis of each flap. The half-buried horizontal mattress stitch should encompass the tips of all the flaps (**Figure 93-15B**). The remainder of the procedure is as described above.

CONTINUOUS (RUNNING) HORIZONTAL MATTRESS STITCH

The running horizontal mattress stitch is indicated in areas of the body where there is loose skin that tends to overlap or invert, such as the skin of the upper eyelids or the dorsum of the hand. This stitch can also be used as the surface closure in a multiple-layer closure if there is a tendency for wound inversion. Like the traditional horizontal mattress stitch, it provides good apposition and can be placed rapidly. The running horizontal mattress stitch is contraindicated in wounds under tension if the goal of wound closure is optimal cosmesis.

This stitch begins with a simple interrupted stitch at one end of a laceration (**Figure 93-16**). The needle is then run along the length of the wound while placing horizontal mattress stitches. The difference between this and the standard horizontal mattress stitch is that the suture is not tied and cut after each individual stitch. Rather, the stitch is continued (running) the length of the laceration. At the end of the laceration, the stitch is tied and secured in the same way as the simple running stitch (**Figure 93-9**).

CONTINUOUS SUBCUTICULAR STITCH

This closure is ideal for lacerations of the face and neck. It provides excellent cosmesis, leaves no suture marks on the skin, and causes minimal scarring. It requires more time and skill to place than other types of stitches. It may be performed for the temporary pull-out (**Figure 93-17**) or permanent placement (**Figure 93-18**) of subcutaneous sutures. Polypropylene or nylon sutures must be used for this stitch. Polypropylene is preferred as it is stiffer, stronger, and easier to remove than nylon.

The use of this stitch is limited to lacerations that are clean, straight, have sharp edges, and are less than 6 cm in length. It may be extremely difficult to remove the suture material for the pull-out technique if the laceration is greater than 6 cm in length. The laceration can be longer if the permanent placement of absorbable sutures is being used. The dermis and subcutaneous tissue must be apposed before proceeding with this stitch. If necessary, apply buried absorbable sutures to appose the dermis before applying this stitch. **The superficial wound surface must be tension-free, as this stitch is for cosmesis and not strength.** The wound may require undermining to release the tension from the wound edges. Refer to Chapter 92 for details regarding wound undermining.

The pull-out technique allows the subcuticular stitch to be removed after the laceration heals (**Figure 93-17**). The subcuticular suture should enter the intact skin 3 to 4 mm from one end of

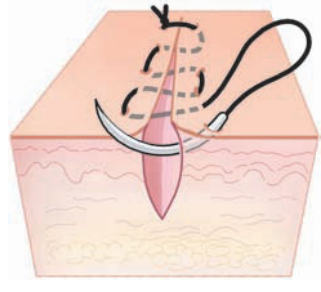

FIGURE 93-16. The continuous or running horizontal mattress stitch.

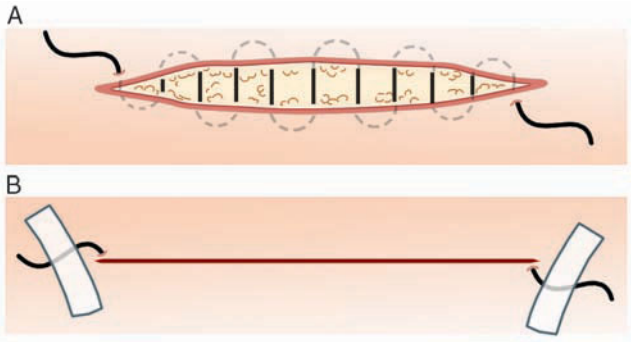

FIGURE 93-17. The continuous subcuticular pull-out stitch.

the laceration and burrow through the dermal-epidermal junction to emerge through the skin at the other end of the laceration (**Figure 93-17A**). The suture will continuously pass through the subcuticular layer on alternate sides of the laceration. **The point of entry of each stitch should be directly across from or slightly behind the exit point of the previous stitch. It is very important to keep the needle at the same level of depth throughout the wound. The tension on the suture should be adjusted to ensure that there is no puckering of the skin.** Tape the free suture at both ends of the laceration to the skin (**Figure 93-17B**). Place wound tape (e.g., Steri-strips) across the laceration to help maintain the apposition of the epidermis. This stitch is easily removed. Remove the wound tape and slowly pull one end of the suture with a needle driver.

As an alternative, the continuous stitch may be placed using absorbable suture material to provide longer-lasting strength to the wound (**Figure 93-18**). Suture material of choice includes Dexon, PDS, or Vicryl. The same indications, preparation, and stitch are used as with the pull-out technique. The only difference is in the starting and ending stitch. Place the first stitch into the dermis, just inside the laceration edge, as a buried knot (**Figures 93-18A to C**). Place the continuous suture until the opposite end of the laceration is reached (**Figure 93-18D**). The final throw should be left lax with a trailing loop of suture (**Figure 93-18E**). The loop should be used as the "tail end" to perform an instrument tie (**Figure 93-18F**). Tie three or four knots in the suture. Lift the free ends of the suture and cut them just above the knot. Apply wound tape across the laceration to help maintain the apposition of the wound.

BURIED (SUBCUTANEOUS) KNOT STITCH

This stitch helps to decrease potential dead space underneath a laceration and gives tensile support for up to 4 to 6 weeks, while the wound is still weak. The loop is constructed so that the knot lies at the bottom of the wound base (**Figure 93-19**). This helps to keep the skin surface smooth and flat. The buried knot stitch is most useful in closing subcutaneous tissue just under the skin surface.

This stitch requires practice to master. Insert the needle into one side of the base of the wound (**Figure 93-19A**). Drive the needle from deep to superficial and exiting at the dermal-epidermal junction (**Figure 93-19A**). Insert the needle through the dermal-epidermal junction on the opposite side of the wound and drive it through the base of the wound (**Figure 93-19B**). **The suture**

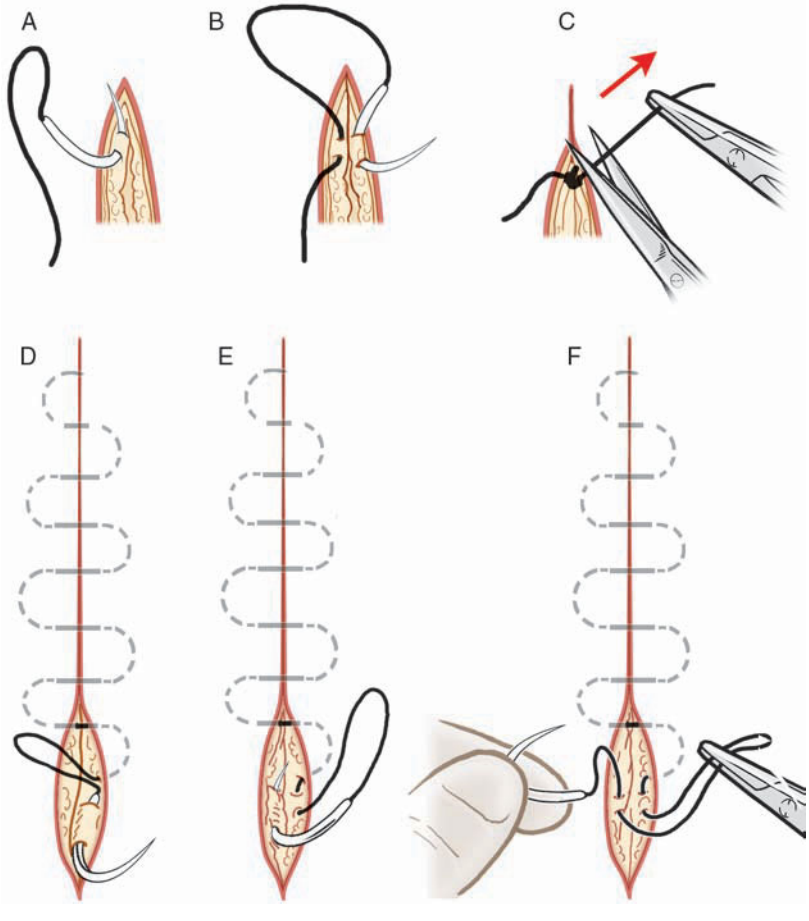

FIGURE 93-18. The continuous subcuticular permanent stitch.

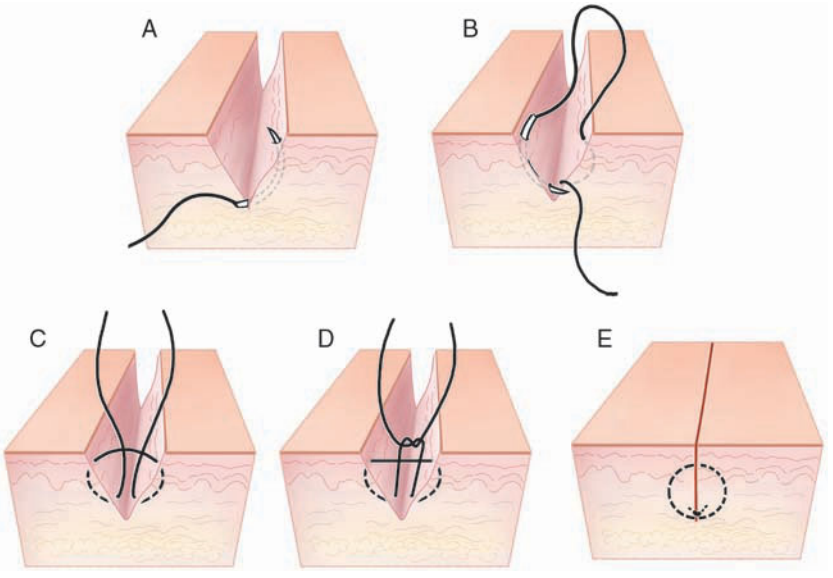

FIGURE 93-19. The buried (subcutaneous) knot stitch.

should exit the base of the wound across from and level with the entrance site of the first throw. Pull both free ends of the suture up and out through the laceration (**Figure 93-19C**). Tie a knot in the suture (**Figure 93-19D**). Pull both free ends of the suture to lower the knot to the base of the wound and appose the tissue (**Figure 93-19E**). Tie two additional knots to secure the suture. Cut off any excess suture.

REINFORCING (RETENTION) SUTURES FOR WOUNDS UNDER TENSION

Reinforcing or retention sutures are particularly useful for wounds in which the edges are widely separated or where the skin is too atrophic to approximate without the suture cutting through the skin. The reinforcing sutures help to decrease the tension on the wound by providing more support for the wound edges. Reinforcing sutures can be placed using sterile buttons or rubber tubing (**Figure 93-20**). Heavy sizes of nonabsorbable suture materials are used for reinforcing sutures. This is not for strength but to avoid the finer suture from cutting through the tissue.

Ideally, a double-swaged (needle) suture should be used to place suture from the inside of the wound toward the outside skin to avoid pulling potentially contaminated epithelial cells through the wound. The stitch is placed like the horizontal mattress stitch and sterile buttons or rubber tubing is used to achieve approximation to a point where the wound edges can be closed without significant tension (**Figures 93-20A & B**). **Do not attempt to appose the wound edges when using retention sutures.** Appose the remaining skin edges with simple interrupted, vertical mattress, or horizontal mattress stitches. The reinforcing sutures should remain in place after the skin sutures are removed. The reinforcing sutures should be removed after the wound has healed and gained significant tensile strength.

SUTURE REMOVAL TECHNIQUES

Remove sutures as soon as possible to avoid the possibility of infection and prevent the formation of suture marks. However, if they are removed too early, wound dehiscence may occur. Simple interrupted sutures should be cut at the end away from the knot and then pulled out (**Figure 93-21A**). This helps to prevent the outer contaminated portion of the suture from passing back through the wound. In order to remove a running simple or running-locked stitch, grasp the knot at the end of the closure and cut each loop

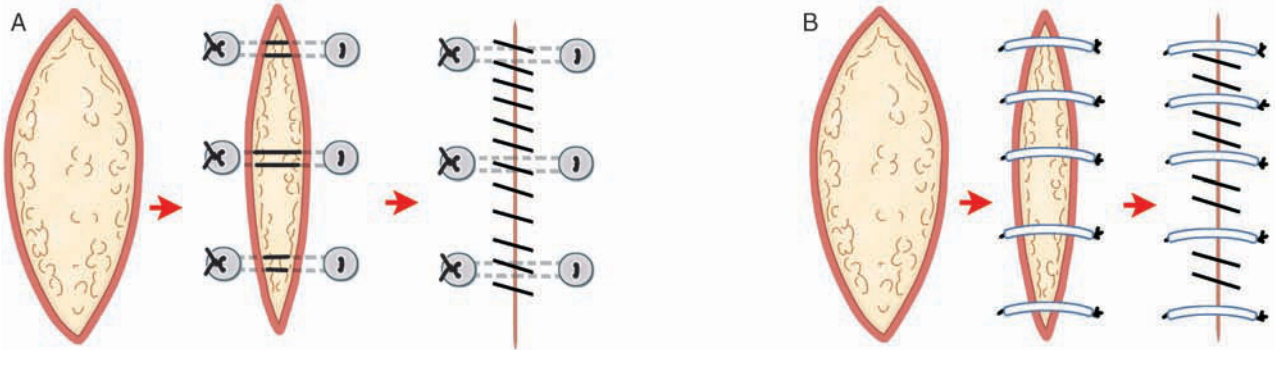

FIGURE 93-20. Reinforcing sutures for wounds under tension. Sterile buttons (**A**) or pieces of sterile rubber tubing (**B**) can be used to secure the suture and prevent injury to the soft tissues.

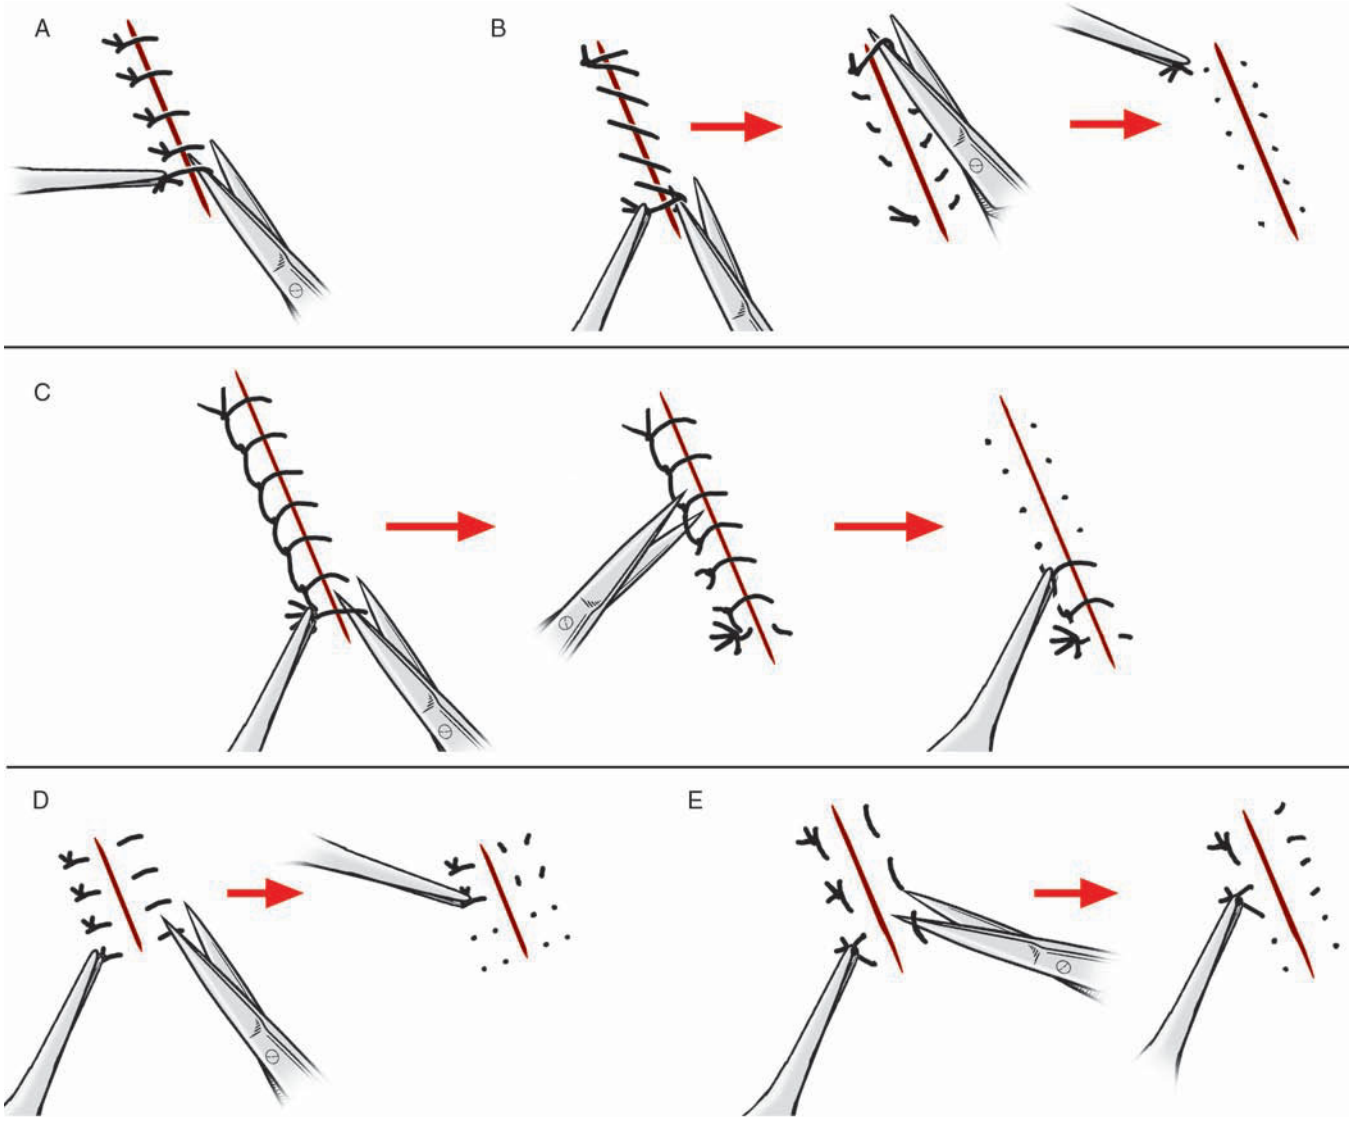

FIGURE 93-21. Suture removal techniques. **A.** Simple interrupted stitch. **B.** Simple running stitch. **C.** Running-locked stitch. **D.** Vertical mattress stitch. **E.** Horizontal mattress stitch.

(**Figures 93-21B & C**). Pull out each individual suture piece. Vertical and horizontal mattress sutures can be removed in much the same way as the simple interrupted stitch (**Figures 93-21D & E**).

TISSUE ADHESIVE CLOSURE (CYANOACRYLATES)

Tissue adhesives (skin glues) are best used to close low-tension, small, straight-edged, and superficial wounds (**Figure 93-22**). They should not be used for lacerations that are bleeding, lacerations over joints, or lacerations under tension. There must be adequate hemostasis and the tissue must be as dry as possible. The major advantage to the use of tissue adhesives is speed. Wounds can be repaired quickly and without anesthesia. Other contraindications to this type of closure are angled or beveled wounds. Petroleum-based ointments or similar products will dissolve the tissue adhesive and should be avoided on this type of closure. Refer to Chapter 94 for a more complete discussion of tissue adhesives.

Tissue adhesives come in a variety of forms and applicator tips (**Figure 93-22A**). Approximate the wound edges with forceps. Commercially available, disposable, single-patient-use tissue forceps can be used (Bionix Development Corp., Toledo, OH). These are specifically designed to approximate the wound edges prior to using cyanoacrylates (**Figure 93-22B**). Apply the adhesive in two or three layers along the wound edge (**Figure 93-22C**). The adhesive may also be applied in spots over the laceration (**Figure 93-22D**) or across the laceration, like wound tape (**Figure 93-22E**). Droplets or lines should be placed 0.5 cm from each other. Support the wound for 30 to 60 seconds while the adhesive dries.

SKIN CLOSURE TAPES

Skin closure tapes (e.g., Steri-Strips) are used to close very low tension wounds that are tidy and small. They can be used as the primary closure technique for superficial wounds (**Figure 93-23**) or they can provide reinforcement after sutures have been placed

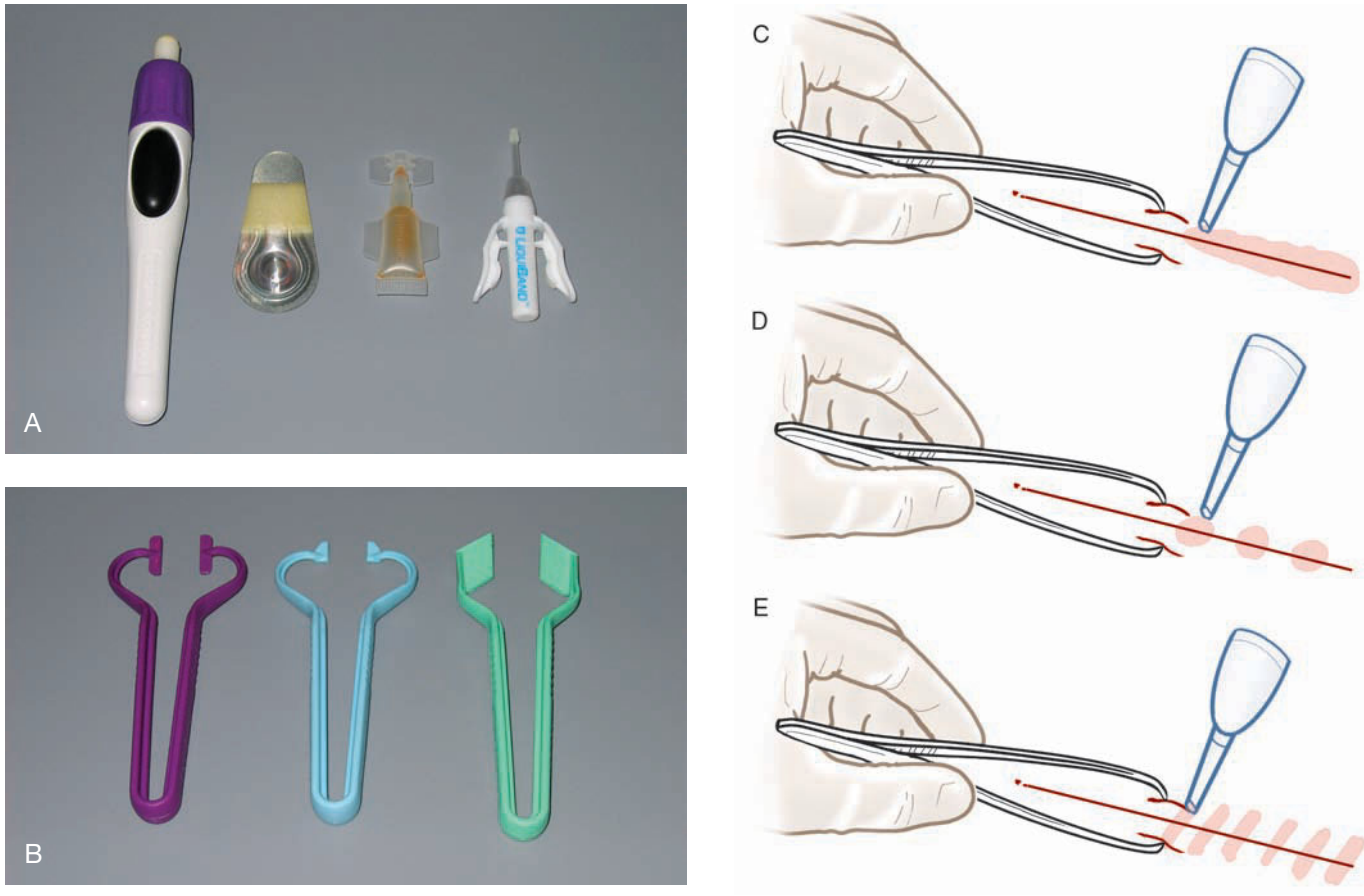

FIGURE 93-22. Laceration repair with cyanoacrylate tissue adhesive. **A.** Several examples of tissue adhesive. From left to right: Dermabond ProPen, SurgiSeal, Indermil Loctite, Liquiband Flow Control. **B.** Commercially available wound forceps (Bionix Development Corp., Toledo, OH). **C.** Tissue adhesive applied continuously over the laceration. **D.** Tissue adhesive applied in spots over the laceration. **E.** Tissue adhesive applied across the laceration.

(**Figure 93-24**). Skin tapes are easy to use and can be placed relatively quickly. They do not leave suture marks and have no skin reactivity.

Skin closure tapes should not be used in wounds where the edges are widely separated or on parts of the body where there is movement or moisture. This technique does not work well on irregularly shaped wounds or wounds where there will be a propensity for swelling of the wound edges. Care should be taken in using these tapes in a child. If they are not secured properly, the child may remove them prematurely.

After the initial cleansing of the skin, clean the skin surface with acetone or alcohol to remove any surface oils. Allow the skin to dry. Apply benzoin solution, or gum mastic (e.g., Mastisol), to the skin on both sides of the wound (**Figure 93-23A**). Allow 60 to 90 seconds for the liquid benzoin to dry and become tacky. Cut the skin closure tapes to the proper length (**Figure 93-23B**). Gently tear the end-tab off the back of the card to prevent the strips from deforming (**Figure 93-23C**). Remove a strip from the card (**Figure 93-23D**). Firmly secure the tape to one side of the wound (**Figure 93-23E**). Use the nondominant hand to appose the wound edges as the tape is brought over and secured to the skin on the opposite wound edge (**Figure 93-23F**). Place additional tapes at 2 to 3 mm intervals until the wound edges are apposed (**Figures 93-23G & H**). Place pieces of tape across the tape edges to prevent premature removal and skin blistering from the tape ends (**Figure 93-23I**).

Skin closure tapes may be placed over a sutured laceration (**Figure 93-24**). The tapes will provide additional support to the wound edge and help to prevent dehiscence. This technique is especially useful in areas of cosmetic concern, such as the face.

The skin closure tapes should remain in place for at least as long as the sutures. They must be kept dry to prevent them from coming off prematurely and the wound from dehiscing. The wound should be observed daily for signs of infection.

Skin closure tapes may be placed across a wound when sutures or staples are removed. The tapes will maintain the apposition of the epidermis as the wound matures. Apply benzoin solution to the skin before removing the sutures or staples. Remove several sutures or staples and apply the skin closure tapes. Continue this process until all the sutures or staples have been removed and the wound is covered with skin closure tapes. Alternatively, remove all of the sutures or staples and then apply the skin closure tapes.

Suturing lacerations in a thin-skinned individual is often difficult. The skin frequently tears as the wound is approximated and the suture is tied. The use of skin closure tapes can facilitate wound closure, strengthening the skin edges, and allow for a more secure wound closure. Clean, prep, and anesthetize the skin. Apply benzoin solution to the skin adjacent to and on both sides of the laceration. Allow the benzoin to sit and become tacky. Apply skin closure tapes over the benzoin on both sides of the laceration. Suture the laceration, ensuring that the needle enters the skin on one side of the laceration and exits the skin on the other side of the laceration through

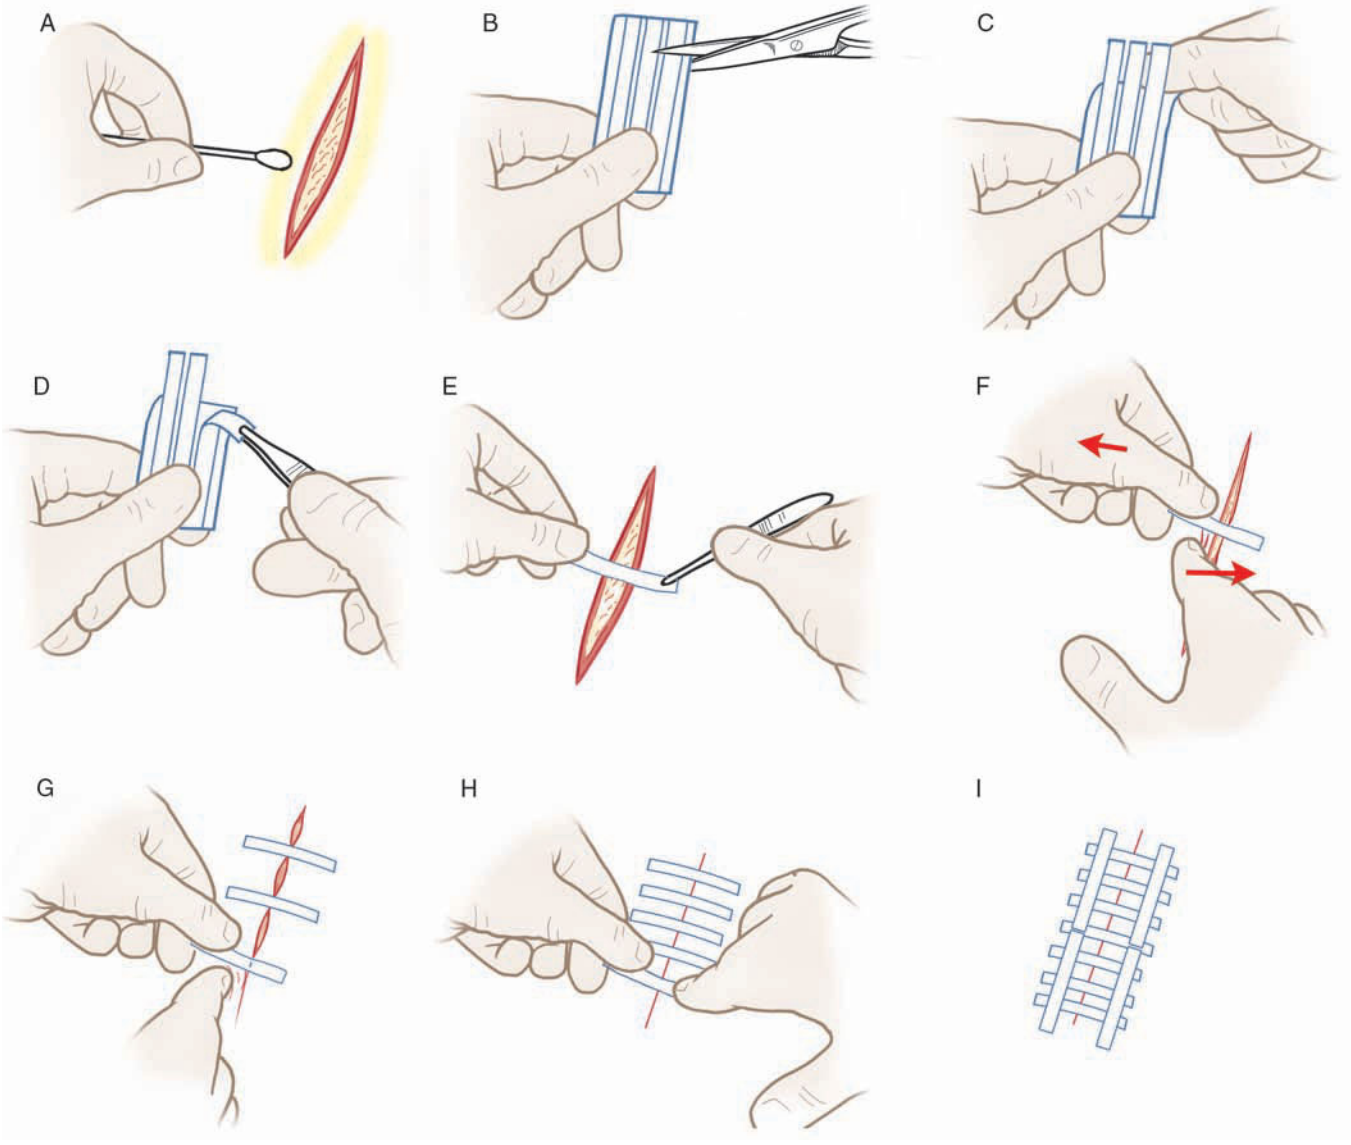

FIGURE 93-23. Skin closure tapes to primarily close a laceration.

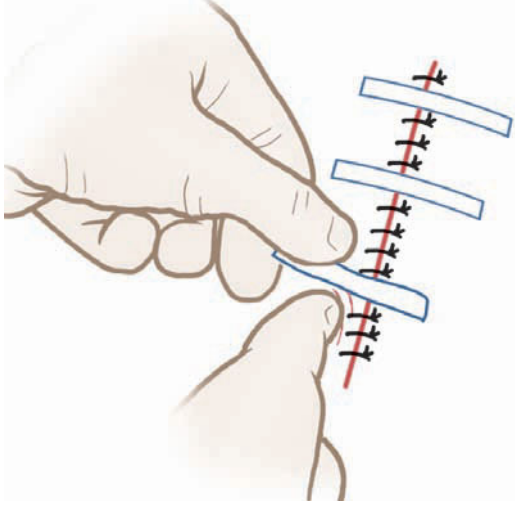

FIGURE 93-24. Skin closure tapes can provide reinforcement for sutures.

the skin closure tapes on each side. Remove the skin closure tapes at the time of suture removal.

Two advanced skin closure tape-based systems are the ClozeX (Clozex Medical LLC, Wellesly, MA) and the 3M Steri-Strip S Surgical Skin Closure (3M Healthcare, St. Paul, MN). These are nonlatex, disposable, single patient use, transparent, adhesive-based wound closure devices for the primary closure of lacerations and wounds not under tension. They align the wound edges and provide good cosmetic results. They come in a variety of sizes, ranging from 10 to 100 mm.

STAPLE CLOSURE

Stapling is a rapid closure technique that is useful for superficial scalp lacerations and linear lacerations of the trunk and extremities. Staples should not be used on the face, neck, hands, or feet. These areas have little subcutaneous tissue and the staples can damage underlying structures. Staples should also be avoided in any area of the body that will be exposed to computed tomography (CT) or magnetic resonance imaging (MRI). The staples are

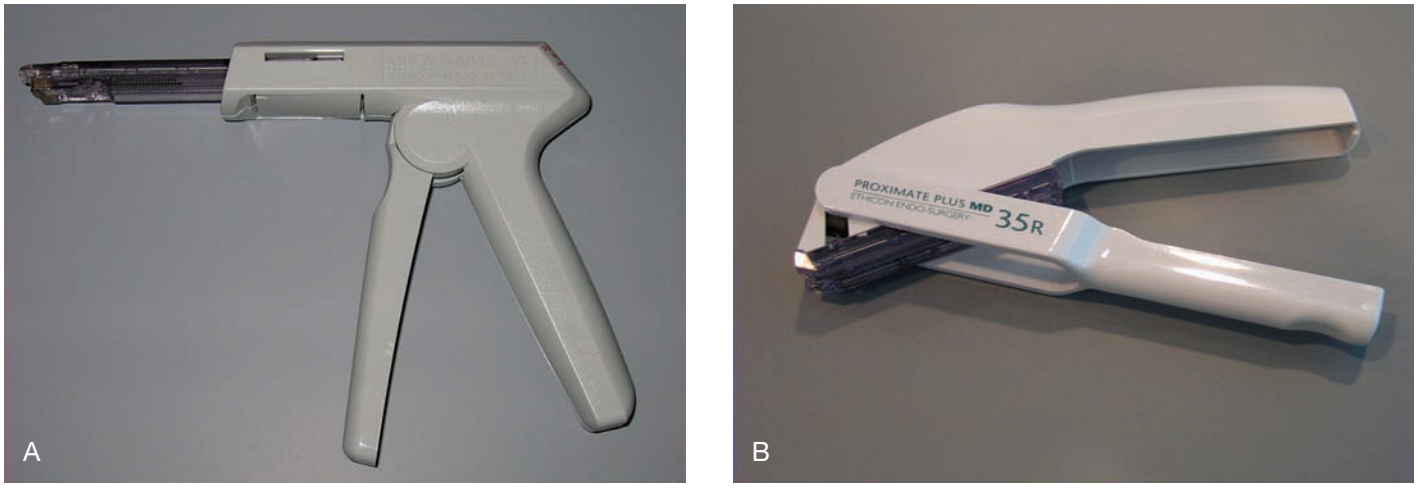

FIGURE 93-25. Examples of two styles of skin staplers.

made of an inert material, which helps to decrease tissue reactivity. Staples should not be used for wounds that are crush wounds, infected, irregular, macerated, over bony prominences, or under tension.

The skin stapler is a simple device (**Figure 93-25**). It is a single patient use, sterile, disposable unit that is preloaded with staples. It is grasped and held with one hand. When the handle is squeezed, a staple is inserted into the tissue. The stapler automatically loads the next staple after one staple is discharged. Skin staplers typically have 10 or 35 preloaded staples.

Prepare the wound for stapling. Place deep sutures to close the subcutaneous tissue and, if the wound is gaping, bring the wound edges into apposition. Approximate the skin edges with the dominant hand (**Figure 93-26A**). Evert the wound edges with a forceps

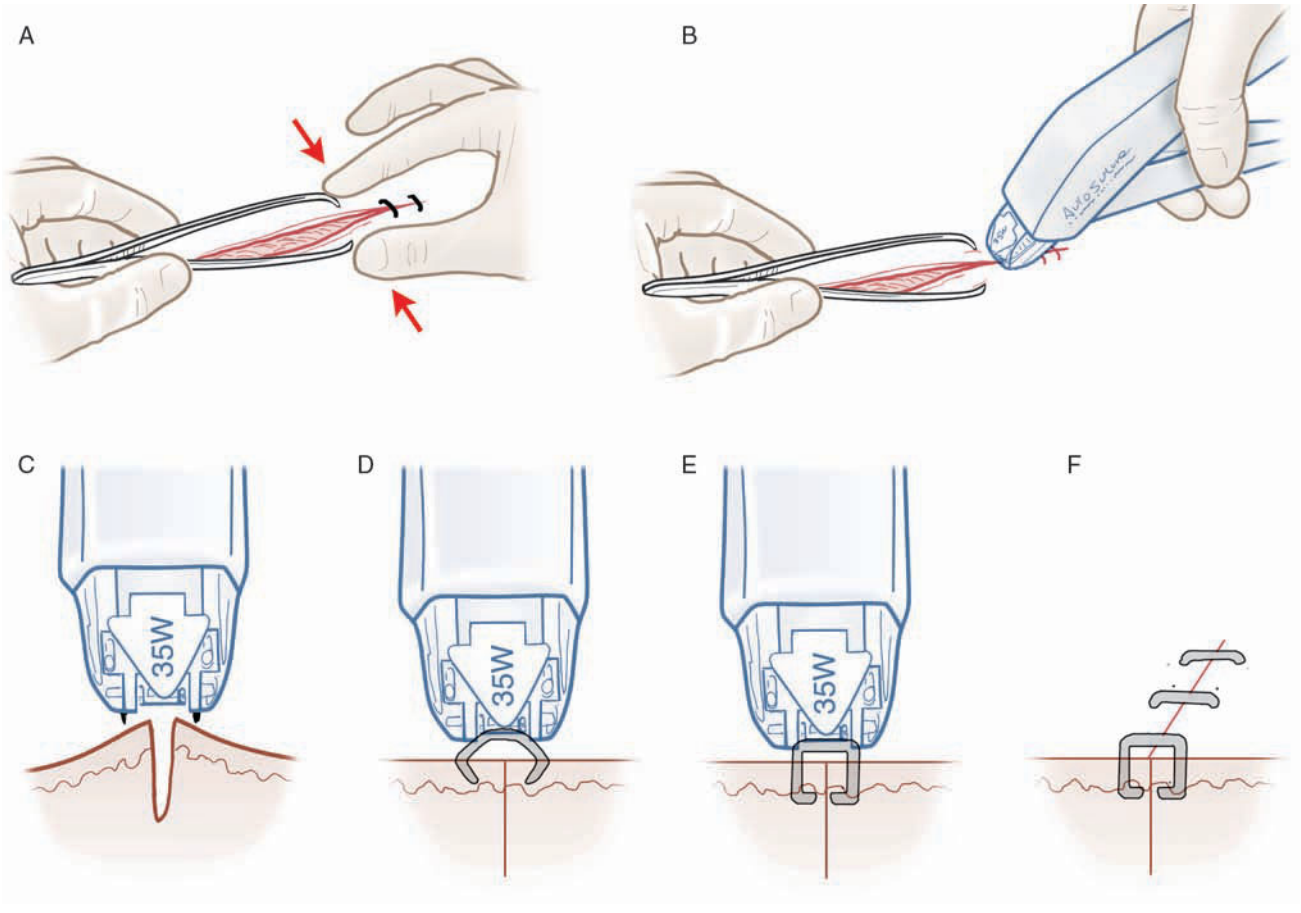

FIGURE 93-26. Laceration repair with staple closure. **A.** The wound edges are apposed and everted. **B.** The stapler is applied over the laceration. **C.** The stapler is applied over the everted wound edges. **D.** The plunger advances the staple into the wound margins. **E.** The anvil bends the staple into shape. **F.** The final product.

held in the nondominant hand (**Figure 93-26A**). Grasp the stapler with the dominant hand. Gently place the skin stapler over the laceration (**Figure 93-26B**). Start at one end of the laceration and work toward the opposite end. **Do not indent the skin with the stapler, as this will cause the staples to be placed too deep.** Align the arrow on the front of the stapler over the laceration (**Figure 93-26C**). Squeeze the handle of the stapler. A plunger will advance a staple into the wound margins (**Figure 93-26D**). An anvil will bend the staple into a square or rectangular shape to secure the staple (**Figure 93-26E**). Continue to evert the wound edges and apply staples every 3 to 5 mm until the wound is approximated and without any gaps (**Figure 93-26F**). A small space will be visible between the skin surface and the staple if it is properly positioned. If the staple is against the skin, it has been placed too deep. Remove the staple and replace it.

There are a few complications associated with staple use. Their removal can be uncomfortable or difficult. Minor bleeding can occur from the holes after the staples are removed. Staples placed on the face, feet, hands, and neck can damage superficial subcutaneous structures (e.g., blood vessels, muscles, nerves, and tendons). Improper wound eversion can result in wound dehiscence upon staple removal, larger scars, and poor wound healing. Staples can cause larger and more prominent skin marks and subsequent scarring when compared to sutures.

FIGURE 93-27. The staple remover. **A.** Overview. **B.** The tip with the jaws open.

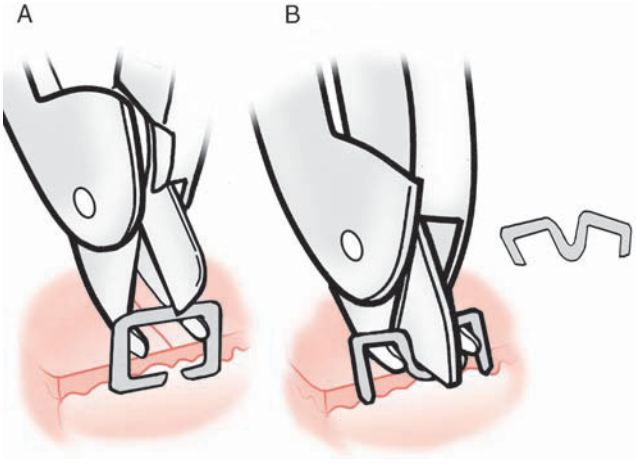

FIGURE 93-28. Staple removal. **A.** The lower jaw of the staple remover is placed under the staple. **B.** The upper jaw compresses the center of the staple and allows the staple arms to exit the skin.

STAPLE REMOVAL

Staples should remain in place for approximately 5 to 10 days, the same amount of time as sutures. They can remain longer if placed over a joint or in cases of slow wound healing. The staple remover is a disposable, sterile, single-patient-use device (**Figure 93-27A**). It is made of metal or plastic with metal tips. The lower jaw of the stapler has two upwardly angled metal prongs (**Figures 93-27B & 93-28**). The upper jaw of the stapler is a flat piece of metal. Insert the prongs of the lower jaw of the staple remover between the staple and the skin (**Figure 93-28A**). Close the handles of the staple remover. This will cause the upper jaw to compress the center of the staple and the arms of the staple to withdraw from the skin (**Figure 93-28B**). Lift the staple remover and staple off of the skin. Discard the staple and continue the process until all the staples have been removed. A patient who plans to follow-up in a clinic or office should be given a staple remover to take with them, as many clinics and offices do not routinely stock these devices.

HAIR APPOSITION

Scalp wounds can be closed using hair-tying, also known as the hair apposition technique (HAT).[11–15] This technique is relatively painless, does not usually require anesthesia, results in a shorter procedure time, eliminates the need for staple or suture removal, is cost-effective, and the wound outcome is similar or superior to sutures.[11,12,15] This technique should not be used on wounds under tension, wounds with ongoing hemorrhage, wounds that are grossly contaminated, or if the hair is <3 cm in length.

Clean, prep, anesthetize, and dry the laceration and surrounding skin. Start at one end of the laceration and grasp 5 to 15 hairs on each side of the laceration. Twist the hair strands on each side of the laceration to form a single "rope." Tie the two "ropes" of hair together to close the wound and appose the edges. Use a hemostat and an instrument tie to make the process simpler and easier. Continue this process until the entire laceration is closed with hair ties. As the laceration heals, the hair know will grow away from the wound edges. The hair knot can be cut off by a family member, friend, or primary care provider in 2 to 4 weeks.

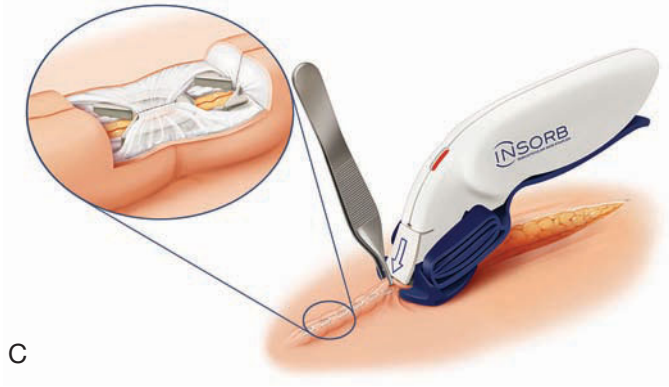
An alternative HAT uses tissue adhesive instead of making a hair knot (**Figure 94-5**).[15] Clean, prep, anesthetize, and dry the laceration and surrounding skin. Start at one end of the laceration and grasp 5 to 15 hairs on each side of the laceration. Twist the hair strands on each side of the laceration to form a single "rope." Twist the two "ropes" of hair together to close the wound and appose the edges. Apply tissue adhesive to the twisted hair and apposed skin segment of the laceration. Allow 30 seconds for the tissue adhesive to dry. Apply a second layer of tissue adhesive and allow it to dry. Continue this process until the entire laceration is closed. This method does not require the later cutting away of the hair knot. Unfortunately, this technique may not produce as much hemostasis or wound eversion as tying a hair knot.[15]

MISCELLANEOUS WOUND CLOSURE DEVICES

V-LOC ABSORBABLE WOUND CLOSURE DEVICE

The V-Loc (Covidien, Norwalk, CT) is an absorbable, disposable, single use, unidirectional barbed wound closure device. The proximal end is the suture needle attached to an absorbable barbed suture. The distal end is a fixed loop of the suture material. This self-anchoring loop and barb combination eliminates knot tying when closing wounds. It is placed similar to a running subcuticular stitch. The barbs are circumferentially distributed on the suture strand and spread tension evenly across the wound. This device is mostly used for postoperative skin wounds but may become more popular in the Emergency Department.

INSORB SUBCUTICULAR SKIN STAPLER



The Insorb subcuticular skin stapler (Incisive Surgical, Plymouth, MN) combines absorbable sutures and a device similar to a skin stapler (**Figure 93-29**). This is a sterile, single patient use device that deploys up to 20 absorbable subcutaneous staples (**Figure 93-29A**). The subcutaneous staples are horse shoe-shaped (**Figure 93-29B**). The device allows wound eversion with no external sutures or metal staples that require later removal (**Figures 93-29C & D**). The final cosmetic results are similar to sutures or skin staples. The company also sells a reusable three-arm proprietary forceps to make wound approximation easier for one person.

SUMMARY

There are multiple techniques available for closing wounds. The principles and techniques discussed will help to provide the most appropriate closure for the various types of wounds that are seen in the Emergency Department. Care should be taken to provide the best closure possible to provide good cosmesis and avoid complications.

94 Tissue Adhesives for Wound Repair

Hagop M. Afarian

INTRODUCTION

The year 1942 marked the discovery of cyanoacrylate, the chemical found in adhesives such as Superglue™.[1] The use of cyanoacrylates for wound closure has been described since the 1960s when it was first assessed for military use. It was not until 1998 that *N*-2-octylcyanoacrylate (Dermabond) was approved by the FDA for use in the United States. Tissue adhesives have since redefined the overall approach to laceration repair, especially in the Emergency Department. Their ease of use, relative painlessness, and simplicity of aftercare make it an ideal tool for small straight wounds and use in children.[2]

ANATOMY AND PATHOPHYSIOLOGY

Cyanoacrylates are a monomer liquid. When activated by water, they polymerize via an exothermic reaction to form a strong bond. Heat is released by this polymerization reaction and may cause some discomfort. Cyanoacrylates are classified as either butyl or octyl based on the length of their side chain.[20,23] Butyl cyanoacrylates have short and straight side chains. This allows them to form bonds that are strong, tight, and poorly flexible. Unfortunately, these bonds can become brittle and fracture. Butyl cyanoacrylates are best suited for short lacerations under no tension. Examples of butyl cyanoacrylates include Histoacryl (B. Braun, Bethlehem, PA) and Indermil (Syneture, Norwalk, CT). Octyl cyanoacrylates have longer side chains. This allows them to form bonds that are strong, flexible, and less likely to fracture. Octyl cyanoacrylates can be used on lacerations of any length. Examples of octyl cyanoacrylates include Dermabond (Ethicon Corp., Norwood, MA) and SurgiSeal (Adhezion Biomedical, Wyomissing, PA). Newer agents are a combination of the strong and fast-setting butyl cyanoacrylates with the flexibility of the octyl cyanoacrylates. An example is LiquiBand (MedLogic Global Ltd., Plymouth, UK).

The nonmedical and medical adhesives contain similar ingredients. The differences between these two types are sterile production, sterile packaging, and the attached alcohol chain in medical grade tissue adhesives. Converting a methyl to an octyl group reduces the heat produced by polymerization and decreases the amount of direct tissue inflammation caused by the breakdown products of the adhesive.[1,3]

The major advantage to the use of tissue adhesives is speed. Wounds can be repaired quickly and without anesthesia. Tissue adhesives have been shown to offer similar wound closure and cosmetic results as sutures and adhesive strips (e.g., Steri-strips).[4,18,19,24] The initial tensile strength of wounds repaired with tissue adhesives are not equivalent to wounds closed with sutures.[5,6] Within 7 days, however, any differences in tensile strength are no longer present.[5,6] The cost to the patient is less for lacerations repaired with tissue adhesives compared to suturing.[7,18] This takes into account physician time, procedure time, materials, and repeat visits for suture removal.[7,24] There is less need for the painful injection of local anesthetic solution. The risk of a needlestick injury is decreased when not suturing. An additional benefit of tissue adhesives is that they provide an occlusive covering for wounds, keeping them moist, water tight, and providing protection from invading microbials.[8] Wounds closed with tissue adhesive do not require routine follow-up like those sutured closed do for suture removal.

INDICATIONS

Tissue adhesives are best used to close low-tension, small, straight-edged, and superficial wounds. Although not an absolute contraindication, specific precautions should be taken when using tissue adhesives near the eye. The liquid adhesive has a tendency to run. If the eyelid margins are not protected, the tissue adhesive can cause iatrogenic sealing of the eyelids.[9] Tissue adhesive may be used for wounds that are deep or under tension as a superficial closure layer only after the subcutaneous layer has been repaired to bring the wound edges together and relieve tension. Most wounds on the head, neck, torso, and proximal extremities can be closed with tissue adhesive. Flap type lacerations and lacerations of thin skin can be closed where the use of sutures can compromise the skin. Long lacerations can be divided into segments and each segment closed as if it were a small laceration.[19]

CONTRAINDICATIONS

Tissue adhesives should not be used on wounds which are actively infected, heavily contaminated, greater than 6 to 12 hours old, a result of a crush injury, punctures, on the eyelids or surrounding skin, or due to bites. Tissue adhesives can only be used on the skin surface and not used within wounds, on mucous membranes, or on mucocutaneous junctions (e.g., the mouth and lips). Do not use tissue adhesives on patients with a known hypersensitivity to cyanoacetate and formaldehyde, as cyanoacrylates degrade into these byproducts. It is recommended that tissue adhesives not be used in areas of the body that are exposed to heavy moisture (e.g., the perineum and axilla) and parts of the body prone to frequent movement (e.g., hands, feet, and over joints).[10] Wounds must be dry. Do not use tissue adhesives on wounds that are actively bleeding or oozing. Tissue adhesive use in these areas may lead to wound dehiscence as the adhesive cracks and/or peels.[10] Stop the bleeding with direct pressure or the injection of local anesthetic solution with epinephrine prior to the application of tissue adhesive. They may be difficult to use in areas covered densely with hair (i.e., the scalp and axilla) since the tissue adhesive will not bond adequately to the skin. They are not recommended for stellate wounds because of the difficulty of adequately approximating the many wound edges. Other contraindications to this type of closure are angled or beveled wounds, unless deep sutures are first placed to approximate the wound edges and relieve any tension.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Gloves
- Wound adhesive (**Figure 94-1**)
- Wound cleaning and irrigation supplies (Chapter 92)
- Forceps

FIGURE 94-1. Several examples of tissue adhesive. From left to right: Dermabond ProPen, SurgiSeal, Indermil Loctite, and Liquiband Flow Control.

FIGURE 94-2. Commercially available wound forceps (Bionix Development Corp., Toledo, OH).

- Petroleum jelly
- Acetone or nail polish removal pads
- Gauze squares
- Occlusive dressing (e.g., Tegaderm)

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain a signed consent for the procedure. Anesthetize the wound. Cleanse the wound and surrounding skin of any dirt and debris. Irrigate the wound with normal saline or tap water. If the wound is dirty, consider the use of a wound irrigation device as described in Chapter 92. Injuries which require substantial cleaning may not be good candidates for tissue adhesive closure. Inspect the wound for any retained foreign bodies or injuries to deep structures. All bleeding must be controlled prior to the application of the wound adhesive. Repair lacerations with continued or heavy bleeding with sutures to achieve adequate hemostasis. Dry the skin surrounding the laceration with gauze squares.

TECHNIQUES

GENERAL TISSUE ADHESIVE TECHNIQUE

The general technique will be described. There are some differences in the type of applicator. Prepare the tissue adhesive. Some only require the removal of a twist-off plastic cap. Others are supplied in ampules that must be crushed and allowed to soak the foam tip of the applicator. Use the tissue adhesive immediately after opening the container as it dries within minutes and may not continue to flow freely for very long.

Approximate the wound edges with forceps. Commercially available, disposable, single-patient-use tissue forceps can be used (Bionix Development Corp., Toledo, OH). These are specifically designed to approximate the wound edges prior to using tissue adhesives (**Figure 94-2**). Alternatives to these devices are Adson forceps or using gloved fingers. Place a thin layer of tissue adhesive over the wound and extending 5 to 10 mm beyond the wound margins (**Figure 94-3A**). The tissue adhesive may also be applied in spots over the laceration (**Figure 94-3B**) or across the laceration like wound tape (**Figure 95-3C**). Apply the droplets or lines of tissue adhesive approximately 0.5 cm from each other. **Hold the wound edges together for 30 to 60 seconds following the application of the first layer of tissue adhesive to allow for optimum polymerization.**

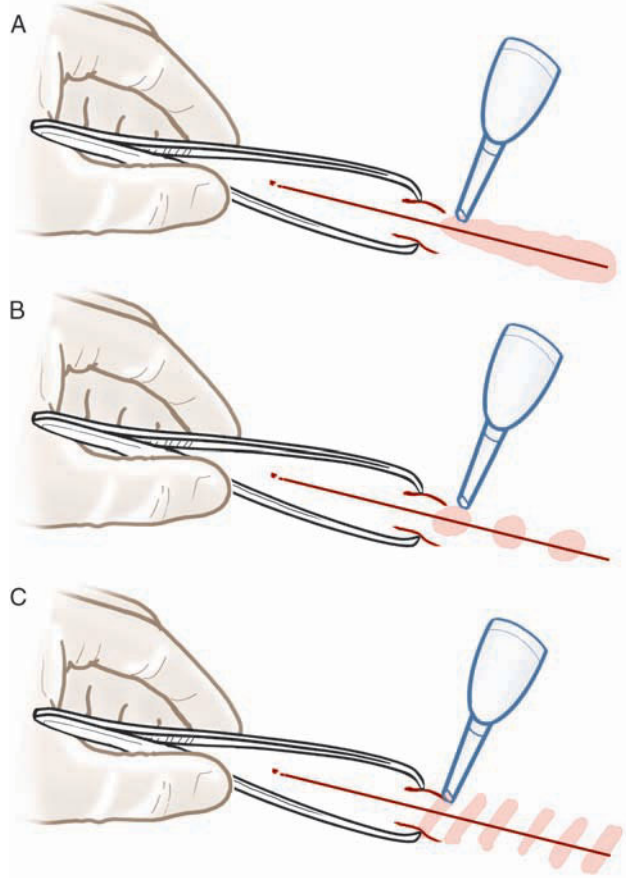

FIGURE 94-3. Laceration repair with tissue adhesive. **A.** Tissue adhesive applied continuously over the laceration. **B.** Tissue adhesive applied in spots over the laceration. **C.** Tissue adhesive applied across the laceration.

Apply a total of three to four thin layers of tissue adhesive. Allow each layer to dry for approximately 30 to 60 seconds before applying the next layer. Each successive layer will take longer to dry as the water available for the polymerization reaction has been covered by the previous layer. **Be careful to use only thin layers and not large drops of adhesive to assist drying time and prevent discomfort from any heat released by the exothermic polymerization reaction. Tissue adhesive should not be allowed to flow into the wound.** It can remain in the wound long after it has healed leading to delayed healing, prolonged inflammation, and tattooing.[20,21]

Do not touch the layers of wound glue as they are drying to prevent cracking and inadvertent adhesion of foreign bodies to the wound. If gloved fingers or other foreign bodies have become attached to the wound, gently peel them away from the most recent layer before it dries. Tissue adhesive applied to an area where it does not belong should be wiped away within 10 seconds.

PREVENTING THE TISSUE ADHESIVE FROM RUNNING

Techniques have been described for use when working around areas that must not come in contact with the tissue adhesive, such as the eye. The first and easiest precautionary technique is patient positioning. Position the patient so that the tissue adhesive will not run away from the wound. Ideally, the wound surface should be parallel to the floor. Unfortunately, this is not always possible to accomplish. Alternatively, position the patient in a manner such that the wound rests below the sensitive area. Gravity allows any of the liquid tissue adhesive to run away from the area of concern. Avoid squeezing the tissue adhesive container too much to control the amount expressed. This can help to minimize any runoff. Consider placing a piece of gauze or occlusive dressing over the area of concern to protect it from any runoff.

A barrier can be created between the wound and the sensitive area. Place a thin film of petroleum jelly between the wound and the sensitive area. This will ensure that if the tissue adhesive were to run, it will not spread beyond the barrier. Alternatively, apply the petroleum jelly in a wide circle surrounding the wound, creating a valley for the tissue adhesive to fill if it runs. It may become difficult, however, to hold the wound edges together in a small space covered with petroleum jelly. The oil-based petroleum jelly, if it gets on the skin immediately adjacent to the wound, may prevent adequate binding of the tissue adhesive.

A final technique to keep the wound adhesive from running is through the use of an occlusive dressing such as a Tegaderm (**Figure 94-4**).[11] Obtain an occlusive dressing large enough to cover the area in question (**Figure 94-4A**). Fold the dressing in half (**Figure 94-4B**). Cut a hemi-ellipse out of the dressing (**Figure 94-4C**). Unfold the dressing and center the cut-out ellipse over the wound (**Figure 94-4D**). Make sure that the newly created hole in the center is large enough to include the entire laceration and some surrounding skin. If not, cut additional material from the dressing. Remove the protective tape from the back of the dressing and apply it to the skin. Approximate the wound edges and apply tissue adhesive (**Figure 94-4E**). Cover the entire precut hole and some of the surrounding dressing with the tissue adhesive. Allow the layers of tissue adhesive to completely dry. Carefully remove the dressing. The result is a well-demarcated, circular film of tissue adhesive overlying the closed laceration (**Figure 94-4F**).

HAIR APPOSITION TECHNIQUE

Scalp wounds can be closed using hair-tying, also known as the hair apposition technique (HAT).[11–16] This technique is relatively painless, does not usually require anesthesia, results in a shorter procedure time, eliminates the need for staple or suture removal, is cost-effective, and the wound outcome is similar or superior to sutures.[12,13,16] This technique should not be used on wounds under tension, wounds with ongoing hemorrhage, wounds that are grossly contaminated, or if the hair is <3 cm in length.

Clean, prep, anesthetize, and dry the laceration and surrounding skin. Start at one end of the laceration and grasp 5 to 15 hairs on each side of the laceration (**Figure 94-5A**). Twist the hair strands on each side of the laceration to form a single "rope." Tie the two "ropes" of hair together to close the wound and appose the edges. Use a hemostat and an instrument tie to make the process simpler and easier. Tissue adhesive can be applied to the hair knot for added security. Continue this process until the entire laceration is closed with hair ties. As the laceration heals, the hair know will grow away from the wound edges. The hair knot can be cut off by a family member, friend, or primary care provider in 2 to 4 weeks.

An alternative HAT uses tissue adhesive instead of making a hair knot.[16,22] Clean, prep, anesthetize, and dry the laceration and surrounding skin. Start at one end of the laceration and grasp 5 to 15 hairs on each side of the laceration with your gloved fingers or a hemostat (**Figure 94-5A**). Twist the hair strands on each side of the laceration to form a single "rope." Twist the two "ropes" of hair together to close the wound and appose the edges (**Figures 94-5B & C**). Apply tissue adhesive to the twisted hair and apposed skin segment of the laceration (**Figure 94-5D**). **Do not allow the tissue adhesive to run into the wound.** Allow 60 to 90 seconds for the tissue adhesive to dry. Apply a second layer of tissue adhesive and allow it to dry. Continue this process until the entire laceration is closed. This method does not require the later cutting away of the hair knot. Unfortunately, this technique may not produce as much hemostasis or wound eversion as tying a hair knot.[16]

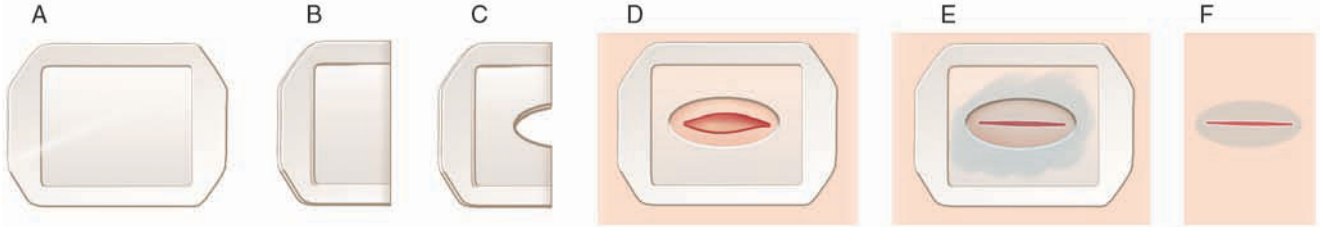

FIGURE 94-4. The use of an occlusive dressing for protection of nearby sensitive structures when using tissue adhesives. **A.** The occlusive dressing. **B.** The dressing is folded in half. **C.** A hemi-ellipse is cut out of the dressing. **D.** The dressing is opened with the cut-out ellipse centered over the wound. The protective tape is removed and the dressing adhered to the skin. **E.** The wound is approximated and tissue adhesive is applied. **F.** The result after the dressing has been removed reveals a well-circumscribed area of tissue adhesive.

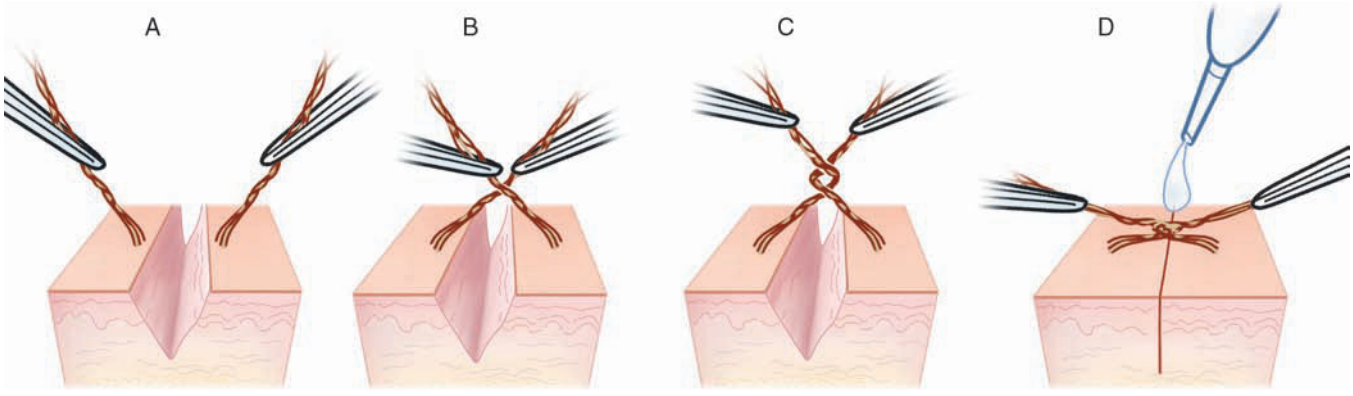

FIGURE 94-5. The hair apposition technique (HAT) to close a scalp laceration. **A.** Grasp 5 to 15 hairs on each side of the laceration. Twist the hair strands on each side of the laceration to form a single "rope." **B.** Cross the hair ropes to opposite sides of the laceration. **C.** Twist the two "ropes" of hair together to close the wound and appose the wound edges. **D.** Apply tissue adhesive to the twisted hair and apposed skin segment of the laceration.

PEDIATRIC CONSIDERATIONS

Pediatric patient movement is the factor that causes the greatest difficulties when working with wound adhesives. Although tissue adhesives are most useful in the pediatric population, this specific population has the greatest risk of movement as well. Movement will permit running of the adhesive and leakage onto uninvolved areas. Extra caution must be incorporated when working around sensitive areas. A high viscosity tissue adhesive may be used to limit leakage when working around sensitive areas or on children who have trouble remaining still.

ASSESSMENT

Assess the closed wound to ensure that the edges are approximated. Tissue adhesive that has adhered and dried on uninvolved areas may be removed using petroleum jelly or topical antibiotic ointment. Apply the oil-based jelly or ointment to the dried tissue adhesive and let it stand for 30 minutes. Gently peel away the tissue adhesive. Use acetone or nail polish remover pads to remove the tissue adhesive more quickly instead of waiting the time for the oil-based products to work.[17] **Be careful to not let acetone drip into the eye or on mucous membranes.**

Tissue adhesive occasionally does enter the eye or the eyelids become glued shut. Tissue adhesives are not toxic to the globe and will not cause damage to the conjunctiva or cornea. **Do not attempt to pry open the eyelids or cut between the eyelid margins to separate the eyelids.** Immediately wipe away any excessive adhesive and flush the eye with saline or tap water. If the eyelids are sealed shut, apply an ophthalmic antibiotic ointment to the eyelids. Allow the ointment to sit for 30 minutes. Instruct the patient to open their eyelids. If they can open their eyelids, gently wipe the ointment and adhesive from the eyelids. If they cannot open their eyelids, instruct them to apply the ointment five to six times a day and gently attempt to open their eyelids. Within 2 to 3 days at most, their eyelids will separate.

AFTERCARE

Instruct the patient that oil-based substances should not be used on any wound repaired with tissue adhesives.[1] Tissue adhesive does not need to be removed. It will peel away within 5 to 10 days as new epithelial layers are formed below it. Wounds repaired with tissue adhesive may briefly come in contact with water (e.g., showering), but should not be scrubbed clean. Do not soak the wound, whether in a bathtub, spa, or pool. Instruct the patient to return immediately to the Emergency Department or to their primary care provider for any signs of a wound infection.

COMPLICATIONS

Many of the complications associated with the use of tissue adhesives are preventable. The Emergency Physician must choose the proper patient, the proper wound, and the appropriate wound location. These few things in association with the appropriate tissue adhesive application technique will avoid most complications. The details of these have been described previously in the indications, contraindications, and techniques sections.

A certain percentage of repaired wounds will become infected. Minimize any infections by properly preparing the wound (Chapter 92). This includes the use of anesthesia if appropriate, wound irrigation, wound debriding, wound undermining, wound exploration for foreign bodies, and the use of deep sutures to release tension.

SUMMARY

Tissue adhesives have changed the face of laceration repair. Wounds are repaired more quickly with tissue adhesives and often at a lower cost compared to suturing. Patient satisfaction is increased. There are very few limitations to the use of tissue adhesives. Proper patient selection, proper wound selection, and proper wound preparation will minimize any complications.

95 Advanced Wound Closure Techniques

Eric F. Reichman

INTRODUCTION

Traumatic wounds or skin lacerations are among the most common injuries, occurring in people of all ages, that require evaluation and treatment in the Emergency Department. The result of many if not all wound closures is scar formation. Although most wounds heal with a surprisingly pleasing cosmetic transformation from their initial presentations, it is not uncommon for some wounds to present

complications during the healing period as well as to produce an undesirable scar. A systematic approach to wound management serves to help in deciding how to close complicated wounds, reduce the risk for infection, and minimize less favorable outcomes.

Wound management in the Emergency Department includes an assessment of the mechanism and conditions that were present at the time of injury. Initially, one must address the concerns of the patient, family members, or friends with a concise explanation of how the wound will be treated and what can be anticipated for aftercare. Many lawsuits and concerns of poor care evolve from poor cosmetic outcomes. **It is recommended that verbal wound care instructions be offered once wound closure is completed, in addition to giving the patient written discharge instructions.**[1]

Regardless of the severity of the wound or possible inherent complications associated with the injury, many patients are primarily concerned with the potential for scarring or disfigurement. Most patients expect cosmetic and functional perfection as an ultimate result after their wounds are treated and the healing process is completed. These expectations are often not clearly expressed during the evaluation and treatment in the Emergency Department. **The Emergency Physician must openly explain and discuss the fact that virtually no wound heals without a scar following wound closure.**[1,2] A clear understanding of this is not to be used as an explanation for a poor outcome but to counter any misconception that a wound will heal to look exactly like the previously intact skin. Treatment is rendered to offer the best possible functional and esthetic outcome while reducing the risk of potential soft tissue infection.

An overall plan of wound site preparation and closure will be needed to provide the greatest likelihood of a pleasing cosmetic result.[1] The mechanism of injury, severity of the wound, location of the wound, and the presence or risk of necrotic tissue can all influence the risk of infection. Additionally, the decision of how to approach wound closure will be affected by the patient's skin type, age, gender, occupation, and hobbies.

Wound healing ultimately takes place over at least 6 to 9 months. Any wound presenting with concerns for a poor outcome or an obvious likelihood of wound revision in the future should be evaluated and treated by a Plastic Surgeon when possible.[1,2] All other wounds requiring complex closures should be properly assessed and treated by the Emergency Physician.

ANATOMY AND PATHOPHYSIOLOGY

In order to have a better understanding of scar tissue formation and the antecedent techniques of wound closure, the Emergency Physician should have knowledge of specific physiologic conditions and anatomic areas that may increase the chances of unfavorable scarring following wound repair.[2,3] The age of the patient and appearance of the patient's intact skin should be taken into consideration. The younger patient tends to heal more rapidly, while the older patient tends to have a more favorable cosmetic outcome with wound closure. Older patients have less overall elastic and subcutaneous tissue and more wrinkling, thus decreasing the tension on the healing wound and making scarring less noticeable.[2,3] Wrinkling, or lines of minimal tension, makes wound repair more technically challenging.

Suturing of asymmetrical, deep, or large wounds requires particular attention to the preexisting lines of minimal tension or lines of facial expression. Without properly addressing such preexistent anomalies, the cosmesis of wound repair can be grossly affected.[2,3] Scars from wounds closed perpendicular to preexisting functionally anatomic lines undergo repetitive physical stress and may result in hypertrophic scar tissue. With markedly less skin elasticity and subcutaneous fat, older patients will often experience more favorable cosmetic results from less complex wound closures. However, younger patients will benefit from more advanced wound closure techniques to properly close large or complicated wounds. Rotational and advancement flaps are frequently performed to make scarring less obvious when suturing across lines of tension.[3]

The type of skin, regardless of age, will affect scar formation.[3,4] Oily or hyperpigmented skin more frequently has poor scar tissue formation, resulting in scars that are hypertrophic, deep, and asymmetrical. Consideration of wound outcome should be given to areas of the skin that are rich in sebaceous glands or simply hyperpigmented (from environmental exposure or ethnicity). Patients with underlying connective disease disorders or conditions with a high likelihood of concomitant vitamin deficiencies should also be scrutinized, as wound closure and healing may be compromised in such cases, resulting in highly variable and less predictable outcomes.

The mechanism of injury, including environmental exposure to underlying tissue, should not be overlooked, so that adequate debridement and preparation may be done prior to a complex wound closure. This allows the Emergency Physician to better visualize the anatomic layers of the skin. It can be difficult to determine a clear delineation between the anatomic layers of the skin when the wound was a result of a crush injury, shredding mechanism, or any circumstance resulting in uneven or macerated wound edges. Delineate the pigmented epidermis from the thicker underlying dermis, especially when multilayer wound closures are required, as suturing may then become unnecessarily complicated and affect the overall integrity of the wound closure.

It should be noted that the literature supports a significant underutilization of multilayer closures, though these are often necessary. Single-layer closures and excessively large suture materials are the greatest causes of residual scar tissue.[1] It is recommended to prepare the wound edges by creating a bevel or undercutting of the wound margin to allow subtle epidermal eversion, thus augmenting the natural process of scar formation.[1,2] This allows the natural flattening and depression of the forming scar to occur without excessive depression from the wound margins.[2] This will also help to reduce the thickness of the scar tissue and decrease the refraction of light from the scar, making it less noticeable.

Depending on the presentation of the tissue defect, more than one wound closure technique may be used to adequately close a wound. Utilizing more than one technique will help remove underlying tension and allow better approximation of the epidermis. With the help of specific camouflage techniques used in closing the epidermis, irregularly shaped wounds can heal with less obtrusive scarring. Familiarity with a few of these techniques and their application will allow the Emergency Physician to comfortably close the more challenging wounds encountered, with expectantly more favorable cosmetic prognoses.

INDICATIONS

Advanced wound closure techniques are indicated for closing wounds with irregularly shaped defects or defects too large for primary closure. They can be used to close circular, square, elliptical, or asymmetrical skin defects. Advanced wound closure techniques are beneficial when there is a need to reduce skin tension and contracture, which are likely to result in hypertrophic scar formation.[3,4] Rotational and advancement flap techniques are useful in areas where tissue loss must be avoided and the undermining of wound edges must be minimized. This is often encountered with facial wounds in proximity to the eyelids, eyebrows, canthi, nasolabial folds, or lip borders. These techniques allow the initial shape of the wound to be altered such that there is reduced tension on the wound edges, which may then be closed simply.

CONTRAINDICATIONS

Specific wound closure techniques should take into account the potential for scar formation to occur in an undesirable location. This can happen when a wound must be elongated to create parallel lines and to decrease the tension on the wound edges. Elongation of a wound may bring it into proximity of other anatomic positions or landmarks, thus further complicating the healing process. If not planned well, excessively large defects may result, making it more likely that the scar will require later revision. More obvious conditions may exist that compromise complex wound closures. Particular attention must be given to crush injuries with devitalized or contaminated tissues. Severely contaminated wounds, including those with prolonged exposure, generally are at greater risk of infection with multilayer closures. Do not perform these techniques if the patient is at risk for poor wound healing (i.e., diabetes, poor vascular supply to the area, or prior radiation therapy to the area), keloid formation, or coagulopathic. Careful wound assessment may result in a decision to use simple approximation of the wound edges with close follow-up for ongoing wound care. Contraindications to complex wound closures will at times be reliant on temporal factors, such as the need to close a wound prior to the patient receiving surgical intervention for more life-threatening injuries. There must be a commonsense approach in deciding how to close more challenging wounds in the Emergency Department.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Needle drivers, 4.5 and 6.0 in.
- Skin hooks
- Scalpel blades (#10, #11, and #15)
- Scalpel handles
- Iris scissors, straight 4 in. and curved 4 in.
- Suture scissors, 6 in.
- Forceps, toothed Adson
- Metzenbaum scissors, curved 6 in.
- Hemostats, straight 6 in., and curved mosquitoes
- Suture material
- Skin closure tapes
- Benzoin solution, swabs or spray
- Tissue adhesive
- Tissue adhesive forceps
- Gauze, 4 × 4 squares
- Overhead light source or headlight

The above equipment can be purchased in single-use, sterile, and disposable plastic surgery wound kits from several commercial manufacturers. These kits tend to be expensive and occasionally have a limited amount of equipment. Many hospitals package and sterilize their own wound repair kits. This decreases the cost, as the equipment can be repeatedly sterilized and reused. It also allows the kits to contain a wide variety of instruments for multiple situations (e.g., minor laceration, large laceration, and plastics closure).

Needle drivers come in a variety of sizes. A 4.5 in. needle driver can be used comfortably with most types of needles. A 6 in. needle driver may be required if large needles are used to close a wound. Hold the needle driver with the fingertips to provide greater flexibility. The fingers can also be placed through the finger holes, but this is not as efficient when closing a wound. Grasp the needle one-third of the way from the swag (distal) end with the tip of the needle driver.

The skin must be grasped and manipulated during wound repair to allow for proper suture placement. Forceps are most commonly used to grasp and manipulate the skin. **Smooth (nontoothed) forceps should never be used to grasp skin.** They require the application of a large amount of force to grasp the tissue. This can crush tissue very easily. An Adson forceps is the forceps of choice. It has fine teeth that grasp tissue securely with minimal force.

A skin hook is a sharp, pointed instrument that is inserted into the wound edge and grasps the tissue from the undersurface. It produces a small puncture wound in the subcutaneous tissues and does not penetrate the skin surface. Skin hooks are preferable to forceps, as they do not crush tissues. A skin hook is awkward to use at first. With proper instruction and experience, the Emergency Physician will most certainly prefer a skin hook to forceps.

Several types of scissors are required for proper wound closure. Iris scissors have sharp, delicate tips for making precise cuts in tissue. They should not be used to cut suture material, as this rapidly dulls and nicks the blades. Suture scissors have one blunt tip and one pointed tip. Both blades of the suture scissors are sharp. Suture scissors are used to cut adhesive tape, gauze, rubber drains, and suture material. Metzenbaum scissors should be used to debride heavy tissue, bluntly dissect tissue, and undermine tissue.

Hemostats are used to clamp small vessels that are bleeding, to explore a wound, and to grasp fascia. Hemostats are available in a variety of sizes and styles. A straight 6 in. hemostat is used for most purposes during wound repair. A curved 5 in. mosquito hemostat can be used for small wounds or delicate tissues.

Three different scalpel blades should be available when a wound is being repaired. A #11 blade is used to make stab incisions. It is often used for the incision and drainage of abscesses, cricothyroidotomies, and the removal of small or tight sutures. A #10 blade is used to make straight cuts in the skin and debride wound edges. It is rarely used in laceration repair. A #15 blade is small and curved to allow precise incisions. It is used for excising foreign bodies and wound debridement.

PATIENT PREPARATION

Explain the risks, benefits, and complications of the wound closure to the patient and/or their representative. The risks include poor healing, wound dehiscence, bleeding, pain, a worse scar, infection, loss of the tissue, and further surgery. The benefits include improved cosmesis and wound healing. Alternatives to advanced wound closure include wet-to-dry dressings and allowing the wound to granulate or follow-up with a Plastic Surgeon for closure or a skin graft. Discuss the presence of a visible scar after the repair, which may require subsequent revision. Explain the aftercare and follow-up. Obtain a signed informed consent for the procedure.

Place the patient in a position of comfort that is equally comfortable for the Emergency Physician. This should allow for appropriate stretcher or seat height, lighting, and maneuverability so that physical obstacles are not a complicating variable during the wound repair. Clean the wound and surrounding skin of any dirt and debris. Flush the wound with normal saline. Apply povidone iodine or chlorhexidine solution to the surrounding skin, not the wound, and allow it to dry. Anesthetize the area using local or regional anesthesia (refer to Chapters 123 through 127).

Examine the wound for obvious foreign bodies or contaminants. Remove these with pressure irrigation using sterile saline. Apply sterile drapes to demarcate a sterile field. Apply the drapes so that the wound may be approached easily from different angles and without the risk of contaminating the site or any of the materials being used. There can be a great degree of variability in sterile techniques;

therefore, it is important to note that the best way to avoid wound infections is to employ and maintain consistency with sterile procedures throughout the wound repair.

TECHNIQUES

Z-PLASTY

It can be challenging to change the axis of orientation of a wound. **The reason for changing the orientation of a wound is to create a more functionally and cosmetically pleasing scar.** The Z-plasty has been described as a basic technique for scar revision, though its application also proves useful to lengthen and reorient wounds.[5] Wound lengthening reduces the formation of contractures, which often occur when the wound crosses areas of flexion. The Z-plasty should not be used for wounds from burn injuries where normal skin is not present. It also breaks up a linear scar into an accordion-like scar that has some degree of elasticity.

The Z-plasty is generally described to redirect a wound occurring across a flexion crease, over a joint, or on the face. It requires two incisions that create two triangular flaps with approximately 60° of separation between the flaps, though the angle may vary between 30° and 90° (**Figure 95-1**).[5] The greater the angle, the greater the gain in wound length. Sharper angles increase the risk of necrosis in the tip of the flap. Broader angles result in difficulty in rotating the flaps. Angles of 60° increase the wound length by 75%. Angles of 45° increase the wound length by 50%. Angles of 30° increase the wound length by 25%. **The length of both arms of the incision must be the same length as the wound.** The undermining and separation of the two triangular flaps lengthens the wound and allows it to be reoriented perpendicularly to the original location. Additionally, small Z-plasties may be used in sequence to offset the appearance of straight wounds crossing lines of flexion or where contractures are likely to occur, so that the wound site then becomes parallel to the lines of flexion, further reducing the occurrence of contracture formation.[3,4]

Clean, prep, and anesthetize the wound and surrounding skin. If the wound edges are irregular, sharply debride them using a #15 scalpel blade to form straight edges (**Figure 95-1A**). Measure and draw 60° angles from the ends of the laceration (**Figure 95-1B**). Draw the arms of the Z on the patient's skin with a skin-marking pen. **The arms must be the same length as the original laceration.** Incise the arms of the Z using a #15 scalpel blade (**Figure 95-1C**). Undermine the flaps of the Z and the surrounding skin. Elevate the flaps of the Z (**Figure 95-1D**). Transpose the flaps so that the wound is reoriented (**Figure 95-1E**). Place simple interrupted sutures to approximate the wound edges (**Figure 95-1F**).

APPROXIMATING THE EDGES OF A LACERATION WITH GROSSLY UNEQUAL LENGTHS

Creating an equilateral triangle from the midpoint of the longest wound edge allows wound edges of unequal length to be closed easily (**Figure 95-2**).[3–5] Determine the widest point between the two wound edges. Determine which of the two wound edges is longer. Mark the middle of the longest wound edge (**Figure 95-2A**). Draw an equilateral triangle centered at this mark (**Figure 95-2B**). **The sides and base of the triangle must all be of equal length and the same length as the widest part of the original wound.** Incise the arms of the equilateral triangle with a #15 scalpel blade and remove the tissue (**Figure 95-2B**). Undermine the wound edges. Close the wound and the perpendicular incision from the triangle with simple interrupted or running sutures (**Figure 95-2C**). Closure of the two wounds results in a clean linear wound with a short perpendicular linear wound offsetting the previously unequal edges (**Figure 95-2C**).

CLOSING A SQUARE-SHAPED DEFECT

Wounds are rarely square-shaped after an injury (**Figure 95-3A**). Debride the wound to make a square-shaped defect (**Figure 95-3B**).

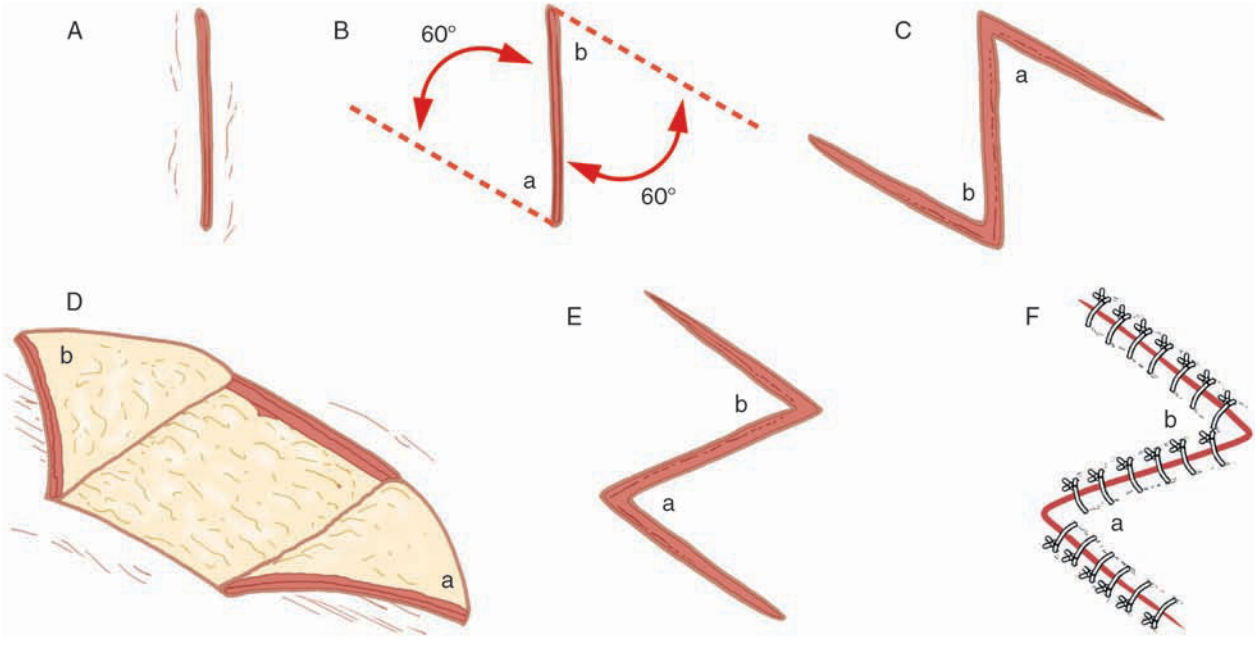

FIGURE 95-1. The Z-plasty. **A.** The original laceration. **B.** Draw the arms of the Z at a 60° angle from the ends of the lacerations. The arms must be the same length as the laceration. **C.** The skin has been incised to form the Z. **D.** Undermine and elevate the flaps. **E.** Transpose the flaps to reorient the wound. **F.** Approximate the wound edges with simple interrupted sutures.

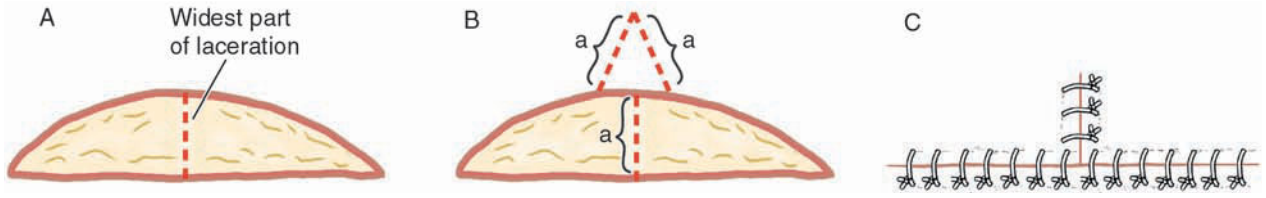

FIGURE 95-2. Approximating edges of grossly unequal lengths in repairing a laceration. **A.** The laceration. **B.** Draw an equilateral triangle along the longest side and centered about the widest part of the laceration. The sides of the triangle must be equal to the length of the widest part of the original laceration. **C.** Approximate the wound edges with simple interrupted sutures.

Square-shaped defects can be difficult to close and require a single pedicle advancement flap.[3] Elongating two sides of the square allows small- and moderate-sized defects to be closed primarily (**Figure 95-3C**). Draw lines to extend two parallel edges of the square by twice their length (**Figure 95-3C**). Draw Burow's triangles on the ends of the extended lines (**Figure 95-3C**). These triangles will be removed, allowing the flap to be transposed into the wound and creating a more symmetrical flap.[3–5] Draw the Burow's triangles as equilateral triangles whose sides are half the length of the square defect (**Figure 95-3C**).

Incise along the extended lines and Burow's triangles with a #15 scalpel blade. Remove the tissue of the Burow's triangles. Undermine the rectangular flap and the area surrounding the base of the flap. **Do not undermine the area lateral to the extended lines.** Advance the tissue flap to close the defect (**Figure 95-3D**). Place a simple interrupted suture in the center of the short edge of the flap to hold it in position. Place half-buried horizontal mattress sutures to secure the corners of the flap. Approximate the wound edges with simple interrupted sutures along the long arms. Approximate the corner of the Burow's triangles with half-buried horizontal mattress stitches and the rest of the triangle with simple interrupted sutures.[3–5]

CLOSURE OF A DIAMOND-SHAPED DEFECT

Diamond- or rhomboid-shaped defects require the rotation of a flap referred to as a Limberg flap. **The Limberg flap is a transposition flap suitable only for closing a diamond- or rhomboid-shaped defect. It requires the formation of two adjacent angles of the rhomboid that must be 60° and 120° for an optimal flap.**

Wounds are rarely diamond-shaped after an injury (**Figure 95-4A**). Debride the wound to make a diamond-shaped defect (**Figure 95-4A**). Draw a line to extend the distance of the short diagonal of the defect to double its total length (**Figure 95-4B**). Draw a line from the extended line and parallel (back cut) to the adjacent wound edge that is equal to the length of the extended line (**Figure 95-4B**). Incise along the extended lines with a #15 scalpel blade. Undermine the flap and adjacent skin. Rotate the flap into the diamond-shaped defect (**Figure 95-4C**). Approximate the wound edges with simple interrupted sutures along the linear edges and half-buried horizontal mattress sutures at the intersection or angles of the wound edges (**Figure 95-4D**).[3–5] Depending on the location of loose tissue and adjacent structures, one of four Limberg flaps can be created to close the defect (**Figure 95-4E**).

CLOSURE OF AN ELLIPTICAL DEFECT

Wounds are often irregular and elliptical (**Figure 95-5A**). Creating an ellipse from a wound allows more even closure of asymmetrical wounds. This is also referred to as an S-plasty. This technique may be used when there is concern of significant scarring and contracture formation from an associated thermal burn injury and Z-plasties are not recommended.[4] The less acute and more rounded edges of the ellipse tend to result in less tissue necrosis.[3,4]

Draw lines to debride the wound and form an S-shaped defect (**Figure 95-5A**). Incise the extended lines with a #15 scalpel blade

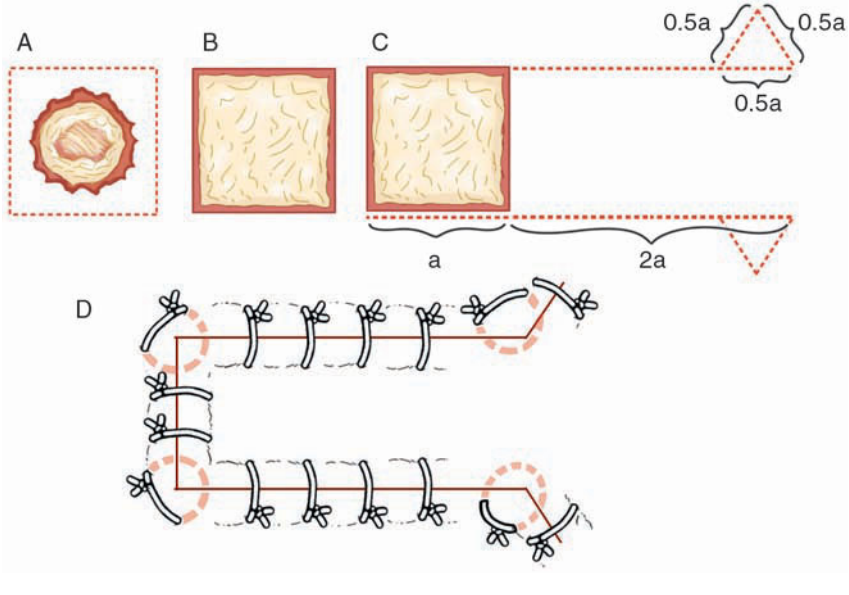

FIGURE 95-3. Closure of a square-shaped defect. **A.** The original tissue defect. Draw lines around the defect to form a square. **B.** The skin has been incised and the original defect removed to create a square-shaped defect. **C.** Draw lines to extend two sides of the square into a rectangle. Draw Burow's triangles at the ends of the rectangular lines. **D.** Advance the flap and approximate the wound edges.

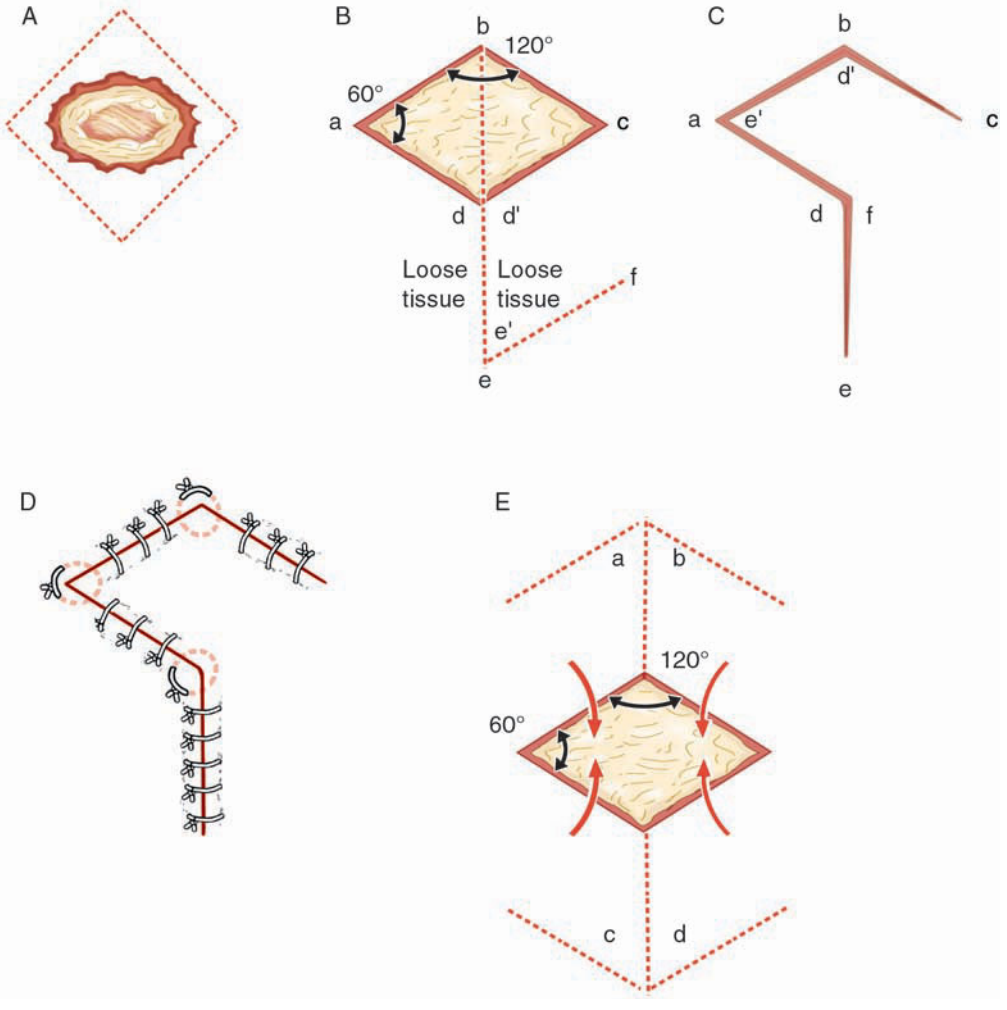

FIGURE 95-4. Closure of a diamond- or rhomboid-shaped defect. **A.** The original tissue defect. Draw lines around the defect to form a diamond or rhomboid. **B.** The skin has been incised to create a diamond-shaped defect. Draw lines to form the flap. Extend the short diagonal (BD) by one times its length to form line DE. Draw line EF parallel to line CD and the same length as line CD. **C.** Transpose the flap to close the defect. **D.** Approximate the wound edges. **E.** The four available Limberg flaps that can be created to fill the defect.

to form the S-shaped defect and excise the wound (**Figure 95-5B**). Undermine the wound edges. Place buried sutures to close the wound and prevent tension on the wound edges. Approximate the wound edges by placing simple interrupted sutures alternating at each end of the S-shaped defect and ending in the middle (**Figure 95-5C**). Suturing from the ends and moving inward reduces the tension on the wound edges.[3,4]

CLOSURE OF A V-Y ADVANCEMENT FLAP

The V-Y flap is not a rotational flap but rather a V-shaped flap created away from the wound site, which then allows the skin to be advanced into the defect (**Figure 95-6**).[3–6] These advancement flaps may be used to avoid defects from lacerations of the fingertips, lips, or face.

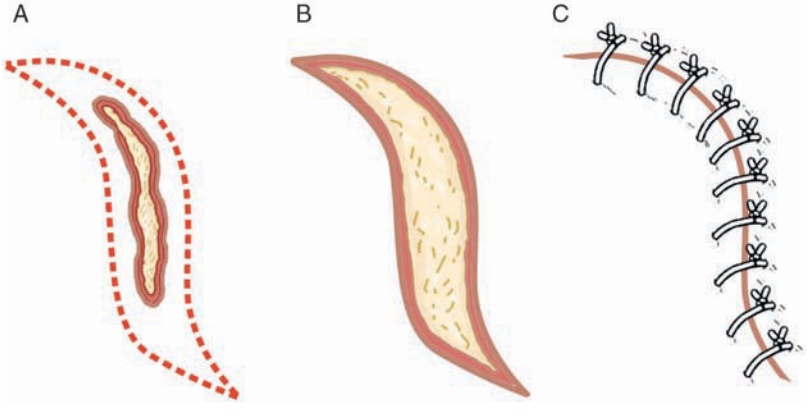

FIGURE 95-5. Closure of an elliptical defect. **A.** The original tissue defect. Draw lines around the defect to form an S-shaped defect. **B.** The skin has been incised and the original defect removed to create an S-shaped defect. **C.** Approximation of the wound edges with simple interrupted sutures.

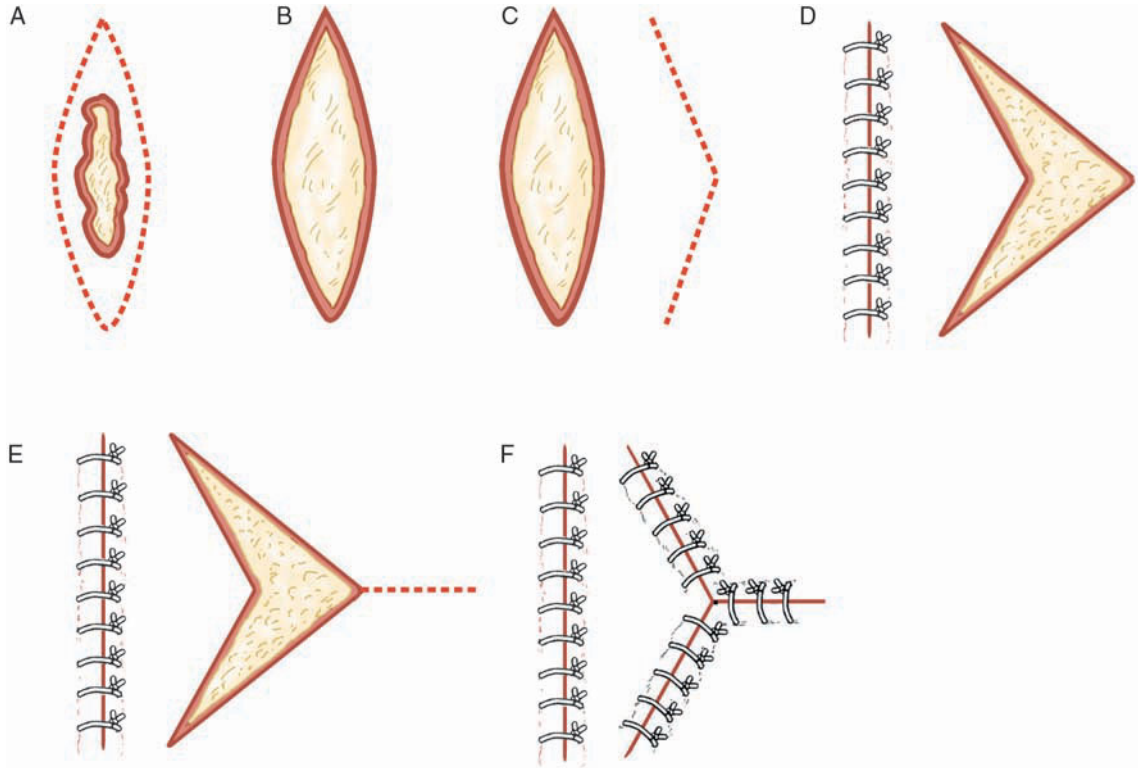

FIGURE 95-6. Closure of a V-Y advancement flap. **A.** The original tissue defect. Draw lines around the defect to form an oval. **B.** The skin has been incised and the original defect removed to form an oval-shaped defect. **C.** Draw a V-shaped line adjacent to the oval defect. It should be positioned the maximum width of the oval defect from the wound edge. **D.** Incise the V and undermine the skin edges. Approximate the oval-shaped defect with buried sutures and simple interrupted sutures. **E.** Draw and incise a line perpendicular to the apex of the V and equal to the maximum width of the V-shaped defect. This forms the V into a Y. **F.** Approximation of the Y-shaped defect.

Wounds may be oval and elliptical (**Figure 95-6A**). Creating an oval from a wound allows more even closure of asymmetrical wounds. Draw lines to debride the wound and form an oval-shaped defect (**Figure 95-6A**). Incise along the lines with a #15 scalpel blade to form the oval-shaped defect and excise the wound (**Figure 95-6B**). Draw a V-shaped line adjacent to the oval-shaped defect (**Figure 95-6C**). **The line should be the length of the oval-shaped defect and approximately the width of the original wound away from the defect along its entire length.** Although the two sites do not directly communicate with each other, the V-shaped incision allows the original wound to be closed primarily and without tension. Undermine the wound and the V-shaped incision. Approximate the oval-shaped defect with buried sutures, if necessary, and simple interrupted sutures (**Figure 95-6D**). This will result in an opening of the V-shaped defect (**Figure 95-6D**). Draw and incise a line perpendicular to the apex of the V-shaped defect with a #15 scalpel blade (**Figure 95-6E**). The line should be as long as the width of the V-shaped defect. Approximate the three arms of the defect with simple interrupted sutures to form a Y (**Figure 95-6F**).

An alternative V-Y advancement flap can be used to close the injury without making a second wound (**Figure 95-7**). Draw lines to debride the wound and form a V-shaped defect (**Figure 95-7A**). Incise along the lines with a #15 scalpel blade to form the V-shaped defect and excise the wound (**Figure 95-7B**). Draw and incise a line

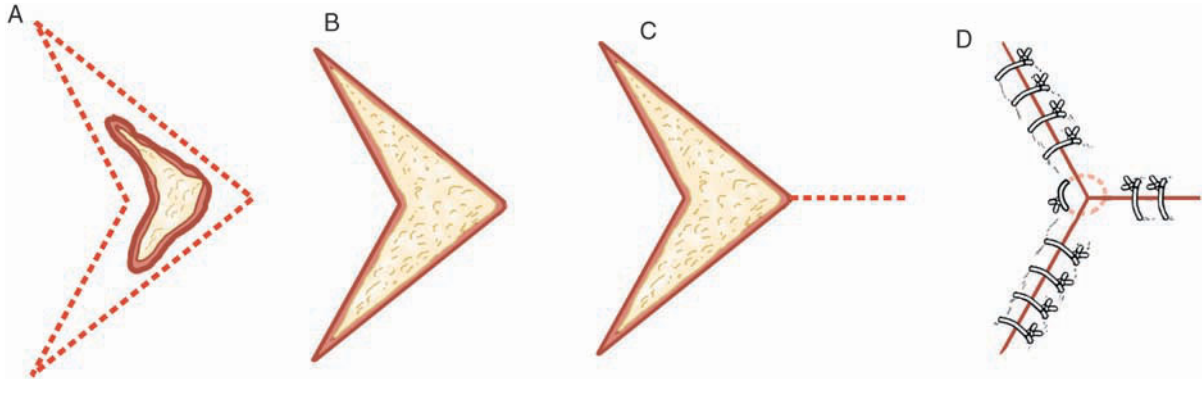

FIGURE 95-7. An alternative V-Y advancement flap closure. **A.** The original tissue defect. Draw lines around the defect to form a V. **B.** The skin has been incised and the original defect removed to form a V-shaped defect. **C.** Draw and incise a line perpendicular to the apex of the V and equal to the maximum width of the V-shaped incision. **D.** Approximate the center of the Y with a half-buried horizontal mattress suture. Approximate the arms of the Y with simple interrupted sutures.

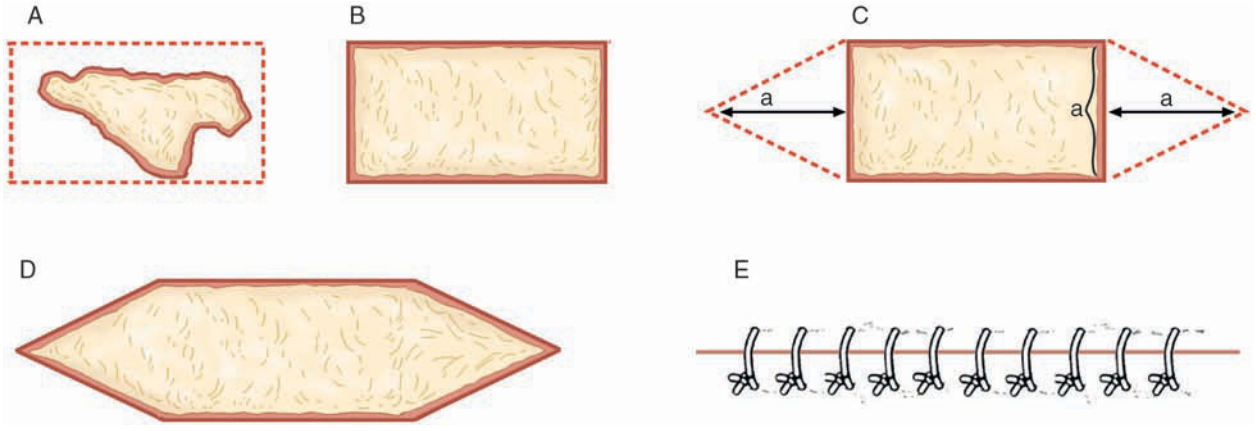

FIGURE 95-8. Closure of a rectangular defect. **A.** The original defect. Draw lines around the defect to form a rectangle. **B.** The skin has been incised and the original defect removed to form a rectangle. **C.** Draw triangles along the short sides of the rectangle. The length from the apex to the base of the triangle must be equal to the width of the rectangle. **D.** The resulting defect after incising and removing the triangles. **E.** Approximation of the wound edges to form a linear scar.

perpendicular to the apex of the V-shaped defect with a #15 scalpel blade (**Figure 95-7C**). The line should be as long as the width of the V-shaped defect. Undermine the V-shaped defect and the perpendicular line. Place a half-buried horizontal mattress suture to close the center of the Y (**Figure 95-7D**). Approximate the edges of the defect with simple interrupted stitches (**Figure 95-7D**).

CLOSURE OF A RECTANGULAR DEFECT

Wounds may be in the form of an ellipse or oblong (**Figure 95-8A**). These can be converted into a rectangular defect to allow primary closure.[3] Draw lines to debride the wound and form a rectangular defect (**Figure 95-8A**). Incise along the lines with a #15 scalpel blade to form the rectangular defect and excise the wound (**Figure 95-8B**). Draw lines to convert the short ends of the rectangle into triangles (**Figure 95-8C**). **The width of the rectangle should serve as the measurement to create an equal distance between the base and the apex of the triangle.** Excising triangles from the ends of the rectangular defect reconfigures the ends of the wound. Incise along the lines with a #15 scalpel blade and remove the triangles (**Figure 95-8D**). Undermine the skin surrounding the defect. Approximate the wound edges with simple interrupted sutures to form a straight line (**Figure 95-8E**).

CLOSURE OF A TRIANGULAR DEFECT (ROTATION FLAP)

Closing of a triangular defect can be accomplished with the use of a rotational flap (**Figure 95-9**). These flaps can be turned on a pivot point. **The flap must be planned carefully so that the direction of rotation coincides with the geometry of the defect.[3–5] Always plan and draw the arch of the flap carefully to visualize the pivot point and direction of rotation prior to making the incision. The creation of a rotation flap is a significant procedure. It can result in a vascular disaster and leave a deformity greater than the original defect it was supposed to correct. Do not create a rotation flap unless you have experience with this technique and know that the flap has an adequate vascular supply.**

Wounds are often irregular and elliptical (**Figure 95-9A**). Draw lines to debride the wound and form an isosceles triangular defect. Incise along the lines with a #15 scalpel blade to form the triangular defect and excise the wound (**Figure 95-9B**). **Draw the rotation flap very carefully.** The edge of the flap is an arch from the

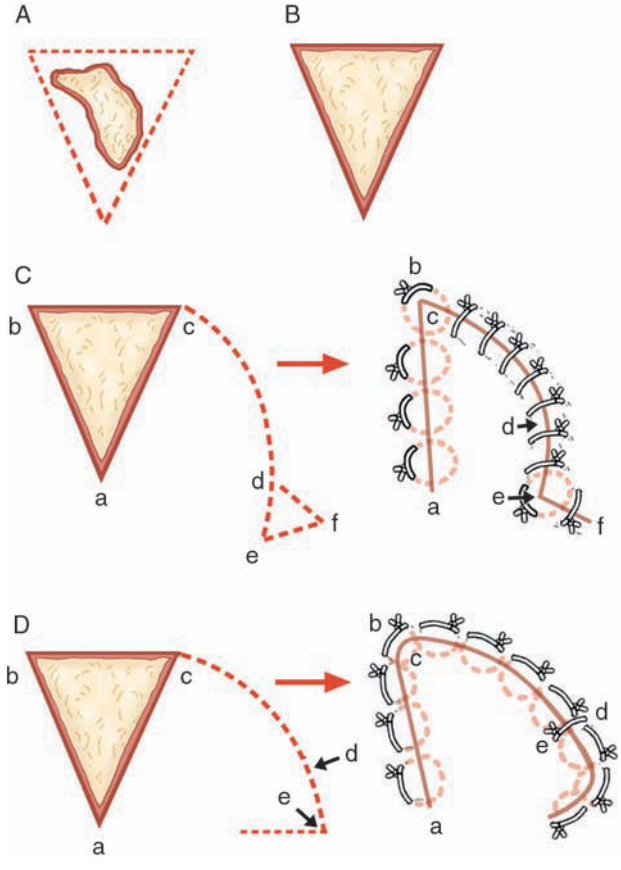

FIGURE 95-9. Closure of a triangular defect. **A.** The original defect. Draw lines around the defect to form a triangle. **B.** The skin has been incised and the original defect removed to form a triangle. **C.** Draw a line to extend the base of the triangle in a wide arc that is three to four times the length of the base of the triangle. Make sure that the arc is drawn beyond the line from point a to point d. Draw a Burow's triangle at the end of the arc. The base of the Burow's triangle should be half the length of the base of the triangular defect. Approximate the triangular defect and any corners with halfburied horizontal mattress sutures. **D.** An alternative technique. Draw a wide arc from the base of the triangle similar to that in (**C**) but which ends opposite the apex of the triangle (point a). Draw a line to make a back-cut that is three-fourths the length of the base of the triangular defect. Approximate the entire wound edge with half-buried horizontal mattress sutures.

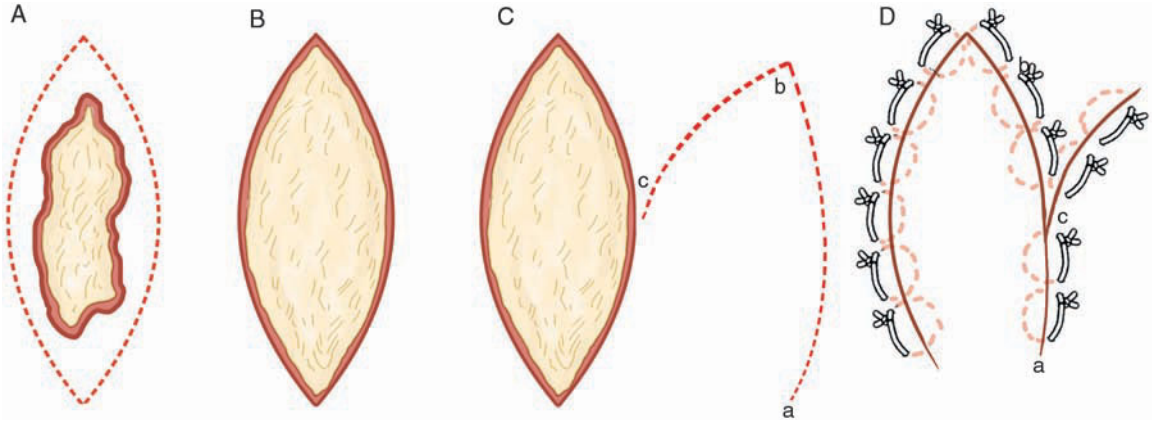

FIGURE 95-10. Closure of an oval-shaped defect. **A.** The original defect. Draw lines around the defect to form a rectangle. **B.** The skin has been incised and the original defect removed to form an oval. **C.** Draw a mirror image of the defect so that it is abutting the defect. **D.** The flap has been rotated and the wound margins approximated with half-buried horizontal mattress sutures.

base of the triangle and three to four times longer than the actual base of the triangle (**Figures 95-9C & D**).[3] Draw a second triangle as a Burow's triangle in the area next to the pivot point of the flap (**Figure 95-9C**).[3–5] **The base of the Burow's triangle should be half the length of the base of the triangular defect, with one corner of the base formed by the end of the arch.** Incise along the lines with a #15 scalpel blade. Remove the Burow's triangle. Undermine the rotation flap and the surrounding skin. Rotate the flap to close the defect and approximate the wound edges with interrupted sutures (**Figure 95-9C**). Place half-buried horizontal mattress sutures to approximate the triangular defect and any corners. Place simple interrupted sutures to approximate the remaining wound edges.

A triangular defect may be closed with a modification to the above technique when there is minimal room to form and excise the Burow's triangle or if lines of skin tension limit the location of the pivot point.[3] **This modified technique should be considered only when necessary, which may occur from poor planning of the initial flap or in areas where fascia can be separated from the subcutaneous layer (e.g., scalp wounds and areas involving the trunk).**[3–5] Form the triangle to debride the wound and draw the arch as described previously. **Do not draw the area beyond the point perpendicular to the apex of the triangle (Figure 95-9D).** Rather than drawing a Burow's triangle for excision, draw a line to make a back-cut from the pivot point (the end of the arc) and along the base of the flap (**Figure 95-9D**).[3,5] **This line should be three-fourths the length of the base of the triangular defect.** Incise along the lines with a #15 scalpel blade. Undermine the defect and the rotation flap. Rotate the flap to close the defect and approximate the entire wound edge with half-buried horizontal mattress sutures (**Figure 95-9D**). Suture the back-cut prior to closing the triangular defect or the arch.[3] **This alternative technique carries the risk of having a poor blood supply to the flap due to its small base.**

CLOSURE OF AN OVAL DEFECT

Oval defects can be closed by creating a rotational or interpolation flap from the intact adjacent tissue (**Figure 95-10**).[3] Wounds are often irregular and elliptical (**Figure 95-10A**). Choose a side of the oval defect to form the flap. The adjacent skin used to make the flap must be vascularly intact to avoid the risk of tissue necrosis once the flap is sutured into position. Draw lines to debride the wound and form an oval defect (**Figure 95-10A**). Incise along the lines with a #15 scalpel blade to form the oval defect and excise the wound (**Figure 95-10B**). **Draw the rotation flap very carefully. Draw a mirror image of the defect abutting the original wound (Figure 95-10C).** Incise only along the lines noted with a #15 scalpel blade. Undermine the rotation flap and surrounding skin. Rotate the flap to close the defect (**Figure 95-10D**). Approximate the edges of the flap with half-buried horizontal mattress sutures (**Figure 95-10D**). Approximate the wound from where the flap originated with simple interrupted sutures, if it is not excessively large or under tension, or with half-buried horizontal mattress sutures.

CLOSURE OF A CIRCULAR DEFECT

Some defects can be closed primarily. Examples include circular defects or triangular defects that are converted to ellipses (**Figure 95-11**). Excise the tissue defect to form a circle. Excise a surrounding ellipse of tissue centered about the circle (**Figure 95-11A**). **The ellipse must be 2½ to 3 times as long as its greatest width.** Undermine the edges of the ellipse. Close the resulting defect with deep sutures if required and cutaneous sutures (**Figure 95-11B**).

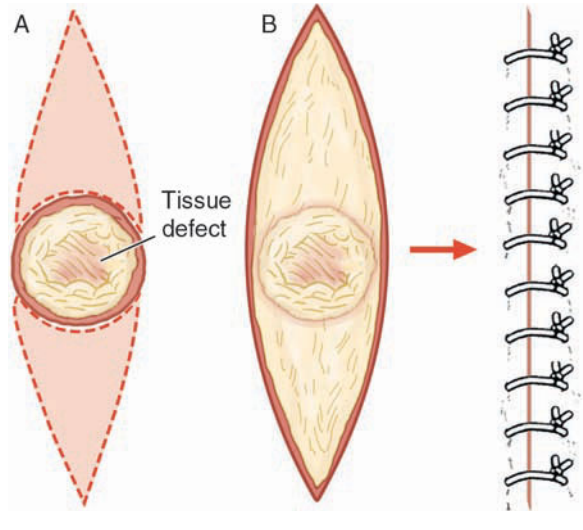

FIGURE 95-11. Closure of a circular tissue defect. **A.** Draw lines around the defect to form an ellipse. **B.** The skin has been incised and the original defect removed to form an ellipse. The wound edges are approximated with deep and cutaneous sutures.

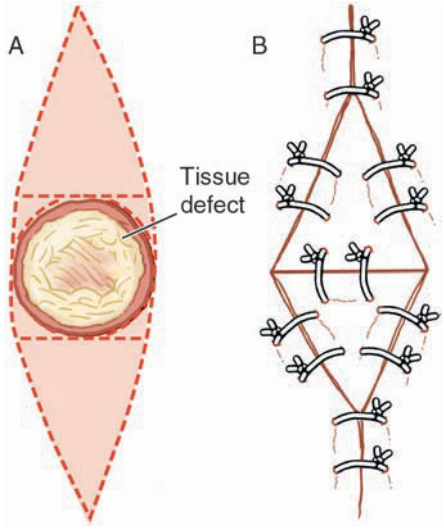

FIGURE 95-12. The double V-Y closure to repair a tissue defect. **A.** Create an ellipse centered about the tissue defect. Remove the tissue defect and form straight edges at the bases of the triangular flaps. **B.** Approximate the bases of the triangular flaps, followed by the arms and bases of the "Y's," using simple interrupted sutures.

Larger defects require the use of a double V-Y closure (**Figure 95-12**). Create two sliding pedicle flaps with a #15 scalpel blade. **Incise the skin and dermis but not the underlying subcutaneous tissue,** to form an ellipse centered about the tissue defect (**Figure 95-12A**). Remove the tissue defect and debride the tissues at the base of the flaps to form two straight edges (**Figure 95-12A**). Gently undermine the edges of the ellipse. **Do not undermine the triangular tissue flaps, so that their vascular supply is preserved.** Slide (advance) the flaps on their subcutaneous pedicles until the bases are touching. Approximate the base of one flap to the other using simple interrupted sutures (**Figure 95-12B**). Approximate the arms and bases of the Y's using simple interrupted sutures.

ASSESSMENT

Inspect the wound edges carefully for adequate approximation. Observe the wound for a period of time to make sure that it remains viable and is not compromised due to a poor blood supply or tight sutures. **A nonviable repair requires immediate removal of the sutures and consultation with a Plastic Surgeon.**

AFTERCARE

Pull the suture knots lying directly over the wound margin to one side so that all the knots lie on the same side. Wipe off any residual povidone iodine or chlorhexidine solution with sterile saline. Apply a topical antibiotic ointment to the wound, followed by a nonadherent dressing. Arrange follow-up in 24 hours with the patient's Primary Care Provider, a Plastic Surgeon, or the Emergency Department. Consider the use of prophylactic antibiotics even though there is no evidence to support or refute this practice.

Instruct the patient and/or their representative regarding wound care and dressing changes. Provide clear instructions of what to look for regarding possible signs of early infection, both localized around the wound site as well as systemic symptoms. Any patient who experiences excessive swelling, erythema, a purulent or foul smelling discharge, significant pain from the wound site, or fever should return to the Emergency Department immediately.

COMPLICATIONS

A brief discussion of the complications of wound closure is presented below. Refer to Chapter 92 for a more complete discussion. The complications of any wound can be greatly affected by the preparation of the wound prior to wound closure. The maintenance of sterile technique throughout wound closure and adequate irrigation of the wound will limit the risk of infection. It is unrealistic to expect any wound site to be bacteria-free.

Wounds may show poor scar formation or delayed healing due to several factors. Poor aftercare without adequate dressing changes or neglect (including premature exposure to environmental irritants such as dirty water, direct and excessive sun exposure, or chemicals) will likely result in a less favorable and unpredictable healing process. The wound site should be protected from excessive contact or use during the initial healing period. Mechanical trauma or overuse can increase the chance of edema or hematoma formation, leading to wound dehiscence or atypical scar formation.

Proper follow-up should be arranged and stressed within the initial 24 to 48 hours following the treatment and thereafter as may be warranted. Awareness that wound healing takes place in sequential physiologic steps is needed to properly direct patients, so that the risk of complications or the need for antibiotics will be minimal.

SUMMARY

Patients present to the Emergency Department with a wide variety of wound types. The use of local flap techniques allows the Emergency Physician to close difficult and complex wounds. If primary closure is not possible, these techniques decrease the tension on a wound and allow for appropriate cosmesis. They require close follow-up and appropriate patient selection if complications are to be prevented.

96 Management of Specific Soft Tissue Injuries

Christopher J. Russo and Ajay Desai

INTRODUCTION

Blunt and penetrating trauma can lead to a myriad of soft tissue injuries. The management of the majority of these injuries is discussed elsewhere in this text. Some specific soft tissue injuries require detailed explanations for their repair. These injuries are discussed below.

MULTIPLE FOREHEAD LACERATIONS

Forehead lacerations are common in all age groups, occurring most frequently during early childhood. While most forehead lacerations are not associated with any other significant injuries, their location demands a complete head and neck evaluation.[1] Furthermore, their visibility requires meticulous attention to detail. Knowledge of the principles regarding their repair allows for good cosmesis. The repair of forehead lacerations differs from that of other soft tissue injuries due to the role of skin tension lines, the lack of extra tissue, and scarring promoted by too many deep dermal sutures.[2–4] Forehead injury repair is governed by three principles: (1) skin tension lines run parallel to the skin creases and play a major role in the outcome of any forehead laceration; (2) lacerations running perpendicular to skin tension lines are more likely to result in a

noticeable scar[2,3]; and (3) there is little excess tissue on the forehead to allow later wound revisions. **Resist the temptation to excise ragged wounds.**[4] This leaves enough tissue for the Surgeon to work with if further revision is required. **Place as few deep sutures as possible,** as they tend to promote more tissue reaction and more noticeable scar formation.

Many forehead lacerations require repair in order to promote cosmesis and provide hemostasis. Perform primary repair at any time up to 24 hours after the initial insult. This allows referral to a consultant if there is any question about one's ability to achieve satisfactory cosmesis or if the wounds are so extensive as to take the Emergency Physician away from their departmental responsibilities for an unacceptably long time regardless of the level of complexity.

Laceration repair is dependent on the type of laceration. Small and uncomplicated lacerations can be closed with simple interrupted 6-0 nonabsorbable sutures (e.g., nylon or Prolene).[1] Flaps smaller than 5 mm can be closed using simple interrupted 6-0 nonabsorbable sutures (e.g., nylon or Prolene). Larger flaps can be closed using the half-buried horizontal mattress stitch. Partial-thickness abrasions and gouges less than 1 cm wide and 2 mm deep should be allowed to heal by secondary intention.[2,5,6] Bunched-up, small flap lacerations can be excised together and the resulting defect repaired primarily.[6] This technique is described under "Multiple Small Skin Flaps" in this chapter.

Deeper transverse lacerations that involve the deep fascia, the frontalis muscle, and the periosteum should be repaired in layers using 5-0 absorbable suture (e.g., nylon or Prolene).[1] The epidermal layer can be closed with either simple interrupted 6-0 nonabsorbable sutures (e.g., nylon or Prolene), skin closure strips over adhesive adjuncts, or with tissue adhesive. The latter two are an especially attractive alternative method of wound closure if the patient is at risk to develop keloids or hypertrophic scars. Skin folds, skin creases, and the hairline should be approximated with great precision.

EYELID LACERATIONS

The objective of eyelid repair is the restoration of normal alignment and anatomic function. Eyelid lacerations are classified as marginal if they cross the eyelid margin or extramarginal if they do not cross the eyelid margin.[7] **A careful history and a thorough physical examination looking for concealed injury or foreign bodies is imperative.** The examination must specifically address and exclude canthal injuries, lacrimal apparatus (most commonly canalicular) injuries, and/or injuries to deep structures. Injuries medial to the lacrimal punctum must prompt the Emergency Physician to explicitly address the possibility of a lacrimal apparatus or canalicular injury. Consult an Ophthalmologist for a probe evaluation of the lacrimal apparatus. Failure to identify canalicular interruptions can compromise outcome, as canalicular repair delayed beyond several days is less successful than primary repair. A delay of 2 to 3 days may be advantageous, as the cut medial ends may become edematous, whitened, and easier to locate.[8,9]

Recognition and management of injuries to deep structures—including the lacrimal apparatus, orbicularis oculi muscle, levator palpebrae muscle, tarsal plates, and medial or lateral canthal tendons—is necessary to prevent dysfunctional tearing, lid malalignment, ptosis, functional abnormalities, and cosmetic defects. Awareness of the eyelid's complex anatomy is essential to the proper recognition and repair of less-evident impairment due to injury. Certain key features are reviewed here as they are necessary to prevent overlooked injury and understand proper repair.

The eyelid's skin is the thinnest in the body, with that of the upper eyelid being thinner than that of the lower eyelid. The skin moves freely over the deeper tissues and is easily mobilized with forceps. Surface landmarks include—from posterior (nearest the globe) to anterior (nearest the skin)—the mucocutaneous junction, the orifices of the meibomian glands, the gray line, and the lash line. The gray line is a key landmark. It is located on the palpebral edge and consists of an isolated strip of pretarsal orbicularis oculi muscle just anterior to the tarsus (Riolan's muscle). Lacerations through the gray line require diligent reapproximation and should be referred to an Ophthalmologist.[10] There are three or four irregular rows containing approximately 100 lashes on the upper eyelid and two or three rows of approximately 50 lashes on the lower eyelid.

The levator palpebrae muscle arises from the roof of the orbit. It inserts into the midtarsus and overlying skin, intimately associating with the orbicularis oculi muscle. Suspect levator injuries with any horizontal laceration of the upper eyelid. Improper repair or failure to repair a laceration may result in ptosis or a deformity of the supratarsal fold.

Canthal injuries must be actively sought. Determine whether the medial or lateral canthal tendon is injured. Apply lateral traction on the eyelid. Displacement of the punctum laterally may be due to a disruption of the medial canthal tendon. Such a disruption is likely to be associated with nasal fractures, orbital fractures, ethmoid fractures, and canalicular injuries.[11] Apply medial traction on the eyelid. Displacement of the lateral canthus medially is due to a disruption of the lateral canthal tendon. Inspection and/or probing through the wound may confirm a canalicular interruption. Early repair is preferred, as the tissue becomes more difficult to identify and repair when swollen. However, the value of early repair of canalicular lacerations is debated.[12] Early repair may exacerbate the degree of canalicular damage, the risk of stenosis, and may result in damage to other parts of the canalicular system.[12] Consult an Ophthalmologist, as meticulous repair is mandatory to avoid damaging the lacrimal apparatus.

The orbicularis oculi muscle closes the eyelids tightly. Failure to properly repair the levator muscle, the tarsal fascia, or the orbicularis muscle in a deep upper eyelid laceration may result in ptosis. Consult an Ophthalmologist for all deep upper eyelid lacerations.

There are at least six published variations on the techniques described for repair of the eyelid margin with less than one-third of tissue loss measured horizontally, yet there is no literature comparing outcomes.[7,13–19] The experience and skill of the practitioner are vital. Each minor variation aims for precise apposition to avoid malalignment or notching of the eyelid margin. Each technique varies the sequence, number, or type of margin sutures or the order of margin sutures (final or temporary) versus tarsal suture placement and closure (if required).

A recently published edition of a major Emergency Medicine text maintains that only Ophthalmologists or Oculoplastic Surgeons should close marginal lacerations. Consult an Ophthalmologist prior to repairing any marginal lacerations. Repair requires considerable experience, the use of magnification, and the placement of deep sutures.

Eyelid lacerations without marginal involvement are considered "superficial." Approximate these lacerations with interrupted 6-0 nonabsorbable sutures (e.g., nylon or Prolene), which should remain in place for 3 days.[10] The skin and orbicularis muscle may be closed in one layer. Consult an Ophthalmologist or Oculoplastic Surgeon for lacerations involving the tarsal plates.

Eyelid lacerations with tissue loss require individualization.[13,20] Wound edge loss of less than 25% of the horizontal length of the eyelid can often be closed primarily. Approximate the wound edges with a toothed forceps to evaluate wound tension. Freshen ragged edges without loss of tissue. Avoid penetration to the conjunctival surface to avoid contact with the cornea. Accurate repair of the

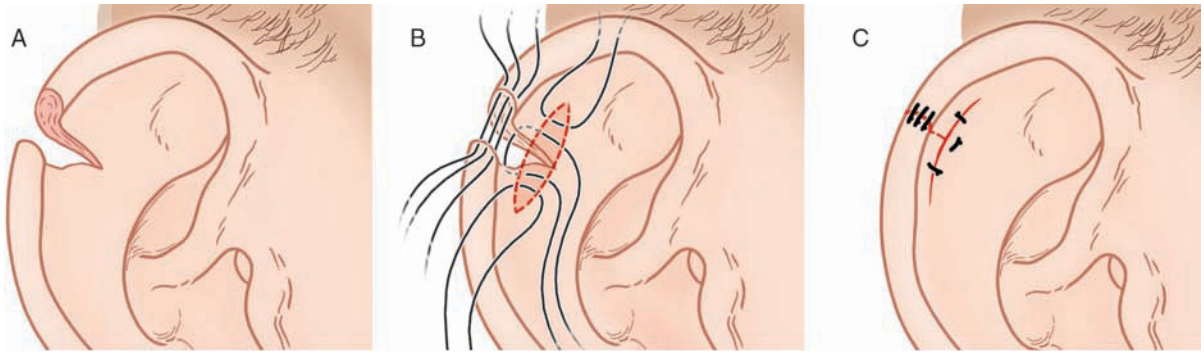

FIGURE 96-1. The wedge excision and repair technique for auricular lacerations. **A.** Excise a full-thickness triangle of tissue. **B.** Place interrupted nonabsorbable sutures through the skin and perichondrium. **C.** Approximate the wound edges by tying the sutures.

tarsus is vital because it forms the skeleton of the eyelid. Remove sutures in 5 days. Tissue loss of greater than 25% may require a canthotomy, cantholysis, or a tissue flap. Refer these injuries to an Ophthalmologist or Oculoplastic Surgeon. Older patients with skin laxity may be able to tolerate a greater than 25% loss with adequate cosmesis.[13,20]

Some eyelid lacerations without eyelid margin involvement may involve the levator muscle. Evaluate horizontal lacerations of the upper eyelid for levator interruption. Visible fat indicates orbital septum penetration and raises the suspicion of levator involvement. These lacerations should be repaired with fine absorbable suture to avoid ptosis.[10,13] **An eyelid crease and/or minimal levator function suggests an intact levator.[13]**

The orbital septum lies deep to the orbicularis oculi muscle. The levator palpebrae muscle lies deep to the orbital septum. The septum is rigidly attached to the orbit and does not move on traction with a forceps. Grasp the levator muscle with a forceps and instruct the patient to look up. A brief pull will be felt as the muscle contracts. It is crucial to distinguish between the levator apparatus and the orbital septum. Injuries involving the orbital septum carry a higher risk of globe injury, intraorbital foreign body, and orbital cellulitis. **The septum must not be included in a repair of the levator, as it will restrict movement of the levator.** Consult an Ophthalmologist or Oculoplastic Surgeon for deep extramarginal lacerations with suspected levator muscle involvement, in addition to a computed tomographic scan to evaluate for potential transorbital fascia/septal involvement.[21]

Complications associated with eyelid repair include malalignment, missed canalicular lacerations with attendant tearing dysfunction, missed foreign bodies, corneal abrasions, missed globe injury, missed canthal interruption, and missed fractures with entrapment. Unless an Emergency Physician has adequate familiarity with the techniques, referral to an Ophthalmologist or Oculoplastic Surgeon is recommended.

EAR LACERATIONS

Ear lacerations can result from blunt or sharp trauma to the auricle. The primary goals are to preserve the normal contours of the auricle, to prevent chondritis, and to prevent hematoma formation.[22,23] The skin of the ear is extremely vascular. The underlying auricular cartilage is avascular and receives its nourishment from the overlying skin. **Minimize any debridement of the auricular soft tissues to ensure that the repair covers all exposed cartilage.** Auricular laceration repair follows the same principles as other laceration repair techniques. Differences to be appreciated include the importance of debriding as little soft tissue as possible, always covering exposed cartilage, splinting the ear appropriately after the repair, and recognizing the indications for consulting a Plastic Surgeon (cartilage defects > 5 mm, inability to cover exposed cartilage, and amputation injuries).

Examine the area for signs of an acute hematoma or other associated traumatic injuries, (e.g., hemotympanum or Battle's sign).[10] Clean, prepare, and anesthetize the auricle. Refer to Chapter 168 regarding the techniques of auricular anesthesia.[24] Consider local infiltration for small, isolated wounds without cartilage involvement or an auricular block for complicated or extensive lesions. Use only a local anesthetic agent without epinephrine to prevent potential complications. Close simple lacerations primarily with interrupted 6-0 nonabsorbable suture (e.g., nylon or Prolene).

Wounds involving soft tissue and cartilage loss of less than 5 mm should be closed with a wedge excision and repair technique (**Figure 96-1**). The auricular skin does not stretch to allow coverage of defects. Thus, the wedge excision technique allows a primary closure that would otherwise have been difficult to achieve without distortion or buckling the anatomy of the auricle due to the underlying cartilage.

Excise a full-thickness triangle of tissue in the antihelix with a #15 scalpel blade (**Figure 96-1A**). **Approximate the skin on the anterolateral surface followed by the posterior surface** with interrupted 6-0 nonabsorbable sutures (e.g., nylon or Prolene). **Carefully approximate the ridges and valleys to minimize the cosmetic defect. Place the sutures through the skin and perichondrium, not the cartilage.** The skin and underlying cartilage are so adherent to each other that it is not necessary to close the cartilage separately. A preferred technique by some, who believe that the cartilage fragments will be drawn together and heal much better, is to place numerous interrupted sutures through the skin and perichondrium on either side of the wound (**Figure 96-1B**) and then approximate the wound edges (**Figure 96-1C**).

Auricular lacerations can involve one or all layers without any loss of tissue. The cartilage may protrude into the wound further than the overlying skin (**Figure 96-2A**). This type of wound is difficult to close primarily without debridement as the skin does not stretch to cover the cartilage. Use a #15 scalpel blade to carefully trim the cartilage back to the level of the skin or so that the skin overhangs the cartilage by 1 mm (**Figure 96-2B**). This allows the skin edges to be everted when closed. Approximate the skin and perichondrium with interrupted 6-0 nonabsorbable sutures (e.g., nylon or Prolene).

Extensive lacerations of the auricle are managed in a similar manner. Trim any protruding cartilage as described above. Place interrupted 6-0 absorbable sutures (e.g., Vicryl or Dexon) through the perichondrium to approximate the cartilage at important landmarks

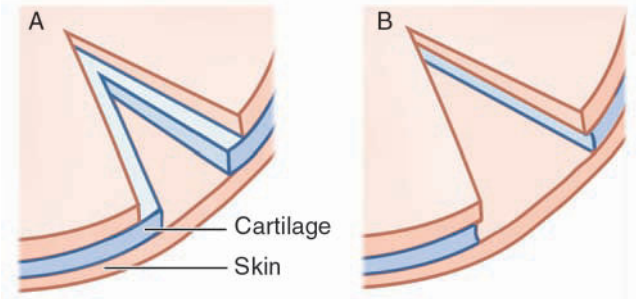

FIGURE 96-2. Repair of an auricular laceration. **A.** The skin has retracted and the cartilage protrudes into the wound. **B.** Trim the cartilage so that it is level with the skin or so that the skin overhangs the cartilage by 1 mm.

and remove tension from the wound edges. Approximate the skin and perichondrium with interrupted 6-0 nonabsorbable sutures (e.g., nylon or Prolene).

Lacerations of the external auditory canal require repair only if the underlying cartilage is exposed. This is done in an attempt to prevent a chondritis. Otherwise, pack the external auditory canal with a nonabsorbent wick (e.g., petrolatum gauze wrapped around a cotton ball) to approximate the wound edges and speed the healing process.

Consult a Plastic Surgeon for wounds with tissue loss of greater than 5 mm, wounds with exposed cartilage that cannot be covered without sacrificing greater than 5 mm of cartilage, complete or almost complete ear avulsion injuries, and injuries with obvious devitalization of the auricle. **Care for the avulsed auricle as an "amputated part" to preserve viability should the consultant desire to pursue reimplantation.**

Uncomplicated wounds not involving the auricular cartilage require local wound care and suture removal in 4 to 5 days. Larger wounds and those involving the auricular cartilage require oral antibiotics to cover skin flora and a dressing that conforms to the anatomic configuration of the auricle. The dressing will provide support and prevent an auricular hematoma from forming. Refer to Chapter 168 regarding the details of placing this dressing. Sutures should be removed in 3 to 5 days in children, 4 to 5 days in adults.[22]

The complications following ear laceration repair are similar to those occurring after all wound repairs. Specific problems include the development of a chondritis, which is much more likely if the auricular cartilage is left exposed. Deformities can be due to the injury itself, poor repair techniques, or the development of an auricular hematoma secondary to poor ear splinting. Antistaphylococcal antibiotic coverage is recommended in cases where cartilage has been exposed or a hematoma has been drained. Hematomas that have been drained should be rechecked in 24 hours to evaluate for reaccumulation.[22] Refer to Chapter 168 for a complete discussion of these complications.

NASAL LACERATIONS

Important points to note in dealing with nasal lacerations are the extent of the laceration and the structures involved. Cartilage involvement increases the likelihood of developing a subsequent infection. Lacerations are difficult to close because the skin is inflexible and lacks redundancy. Associated injuries, such as nasal fractures and septal hematomas, must also be managed. Suturing back a totally avulsed nose is unnecessary as it will most often fail.[25]

The repair of nasal lacerations requires local anesthesia, which can be achieved using an infraorbital nerve block (Chapter 126), a nasal block (Chapter 170), or direct infiltration of local anesthetic solution without epinephrine. The nasal mucosa can be anesthetized using cocaine-soaked pledgets (Chapter 170).

Lacerations limited to the outer aspect of the nose (i.e., skin lacerations and not through-and-through lacerations) can be repaired as simple lacerations. Minimize any debridement, as the lack of redundancy of nasal skin can result in disfiguring scarring.[26]

Lacerations involving the nasal cartilages require a thorough cleansing, minimal if any debridement, and a multilayered closure. **Do not place stitches through the avascular nasal cartilages, as this increases the chances of a postrepair infection.** Approximation of the nasal mucosa, subcutaneous tissues, and skin will appose the cartilage edges. **It is crucial to have proper alignment of the alar rim and columella in order to achieve good cosmetic results[25] and to avoid the postrepair complication known as "notching."** The repair proceeds from inside outward. Approximate the nasal mucosa with interrupted 5-0 or 6-0 absorbable sutures (e.g., Vicryl, Dexon, or gut). Approximate the subcutaneous tissues with interrupted 5-0 or 6-0 absorbable sutures (e.g., Vicryl or Dexon). Approximate the skin with 5-0 or 6-0 nonabsorbable sutures (e.g., nylon or Prolene).

ORAL MUCOSAL LACERATIONS

Lacerations of the oral mucosa generally heal without intervention. Wounds requiring repair are those large enough to trap food particles (greater than 2 to 3 cm) and wounds with a tissue flap that falls between the occlusive surfaces of the teeth. Some physicians prefer to place 4.0 silk sutures, as they are not irritating to the patient and do not tempt the patient to "play" with them with their tongue or bite through them. The disadvantage of silk sutures is that they require a return visit for removal. Absorbable sutures (e.g., plain gut or chromic gut) are thus preferable, especially in children to avoid the task of suture removal.[25] However, the choice of using absorbable versus silk sutures remains physician-dependent. Tissue flaps that fall between the occlusal surfaces of the teeth may be approximated or excised. A diet of soft foods and liquids is recommended for the first 2 to 3 days after the repair. The mouth should be rinsed gently two or three times a day and after meals with chlorhexidine solution. Some authors recommend the use of prophylactic antibiotics although this practice is controversial.[27]

LIP LACERATIONS

Attention to detail is essential for attaining a good cosmetic result in repairing lip lacerations, as they can result in devastating cosmetic defects if not repaired properly. Malalignment of the vermilion border or the "white line" (the border between the skin of the face and the red part of the lip), by as little as 0.5 to 1 mm will be easily noticeable.

Anesthetize the lip using a nerve block to avoid tissue distortion and allow proper tissue apposition (Chapters 126 and 176). Avoid using epinephrine with anesthesia, as this will blunt the vermilion border landmark.[28] Close the vermilion border first, using 6-0 nonabsorbable sutures (e.g., nylon or Prolene) (**Figure 96-3A**). Close the orbicularis muscle layer next using 5-0 plain gut or chromic gut suture (**Figure 96-3B**). Close the mucosal border with the same type of suture. Close the skin with interrupted 6-0 nonabsorbable sutures (e.g., nylon or Prolene) (**Figure 96-3C**).

Adhering to this plan will allow the best cosmetic result possible. Other anatomic areas that require careful approximation to attain good cosmesis include the mucosal border (separating the intraoral and extraoral portions of the lip) and the orbicularis oris muscle. Through-and-through lip lacerations often violate all three of these structures. In these cases, consider debridement of irregular borders.[28]

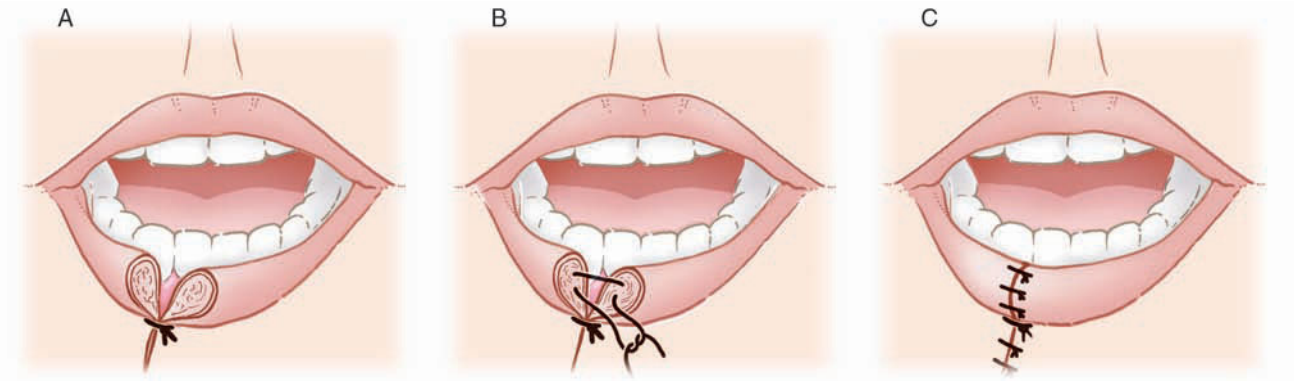

FIGURE 96-3. Lip laceration repair. **A.** Always approximate the vermillion border first. **B.** Approximation of the orbicularis oris muscle. **C.** Approximation of the mucosal surface and the skin.

The aftercare for a sutured lip laceration is much the same as for oral mucosal lacerations. Instruct the patient to avoid bringing excessive pressure to bear on the suture line. Remove the skin sutures in 4 to 5 days to avoid scarring. Parents should be instructed to distract their children from biting the sutures off while they are still anesthesized.[28]

TONGUE LACERATIONS

The majority of tongue lacerations are the result of oral trauma and tongue biting, and heal well without intervention.[29] Lacerations that do not require repair are generally small, linear, and superficial lacerations located in the central tongue region or small flaps on the edge of the tongue that can be excised. The tongue's generous blood supply allows these wounds to heal well, yet can also cause serious hemorrhage and potential airway compromise.[29] Therefore, patients who have tongue lacerations that require repair should also be evaluated for potential airway problems, and the need for procedural sedation or possibly general anesthesia (especially in children).[28] Some wounds require closure and can be very challenging to repair.[30–33] These may include large lacerations (>1 cm), gaping wounds, actively bleeding lacerations, U-shaped lacerations, wounds that bisect the tongue, and large flaps on the tongue edge. The main problem is not the repair itself but achieving control of the area to facilitate the repair.

Anesthetize the tongue via local wound infiltration or a lingual nerve block for the anterior two-thirds of the tongue (Chapter 176). These can be supplemented with procedural sedation techniques (Chapter 129). Instruct an assistant to gain control of the tongue. Grasp the anesthetized tip of the tongue with a towel clip, a suture through the tip of the tongue, or a gauze square. Consider inserting a bite block to further protect the patient and the Emergency Physician from injury during the repair process. Thoroughly irrigate the wound. Close the laceration using absorbable 4-0 plain gut or chromic gut sutures. Take large bites that include the mucosal and muscular layers of the tongue. Buried or deep sutures are not required when taking large bites. Multiple well-secured sutures are preferred to prevent the untying of suture material with tongue motion.[34]

Extensive complex tongue lacerations are at a greater risk for infection and should be treated with prophylactic antibiotics that cover normal oropharyngeal flora.[34] Children with tongue lacerations may chew off the stitches, and so parents should be made aware of this and be instructed to distract the child until the local anesthesia wears off.[28] Aftercare instructions are similar to those for oral mucosal lacerations.

GINGIVAL LACERATIONS

Gingival lacerations differ from other lacerations in that there is often no subcutaneous tissue available to anchor the flap. Small gingival lacerations tend to heal well without intervention because of the extensive blood supply in this area. Repair wounds that are large, actively bleeding, gaping open, or that fall onto the occlusive surface of the teeth.

Flap lacerations exposing the alveolar ridge and tooth roots pose a special problem, as there is no subcutaneous support to anchor the mucosa. The technique requires the placement of a 4-0 or 5-0 absorbable suture that first runs circumferentially around and then is tied posterior to the tooth.[35] Place the suture 2 to 3 mm proximal to the gingival margin (**Figure 96-4A**). Place the suture through the gingiva so that it passes circumferentially around the tooth to secure the flap (**Figure 96-4B**). Loosely tie the suture on the inner aspect of the tooth so that the knot does not irritate the lip or strangulate the tissues (**Figure 96-4B**). The aftercare is the same as described under "Tongue Lacerations" in this chapter.

SUTURING THROUGH HAIR

It is inadvisable to shave hair bordering the edges of a laceration, as this only serves to increase the likelihood of a wound infection.[36] Instead of shaving the hair, brush it aside or mat it down using petroleum jelly or antibiotic ointment prior to wound repair. **It is of particular importance never to shave eyebrows or eyelashes, as they will take months to grow back if they grow back at all.** Always debride an eyebrow laceration oblique to the hair follicles

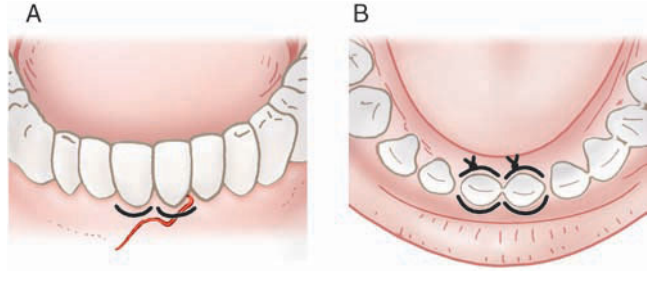

FIGURE 96-4. Gingival laceration repair. **A.** Place the suture 2 to 3 mm proximal to the gingival margin. **B.** Place the suture through the gingiva and circumferentially around a tooth to secure the flap.

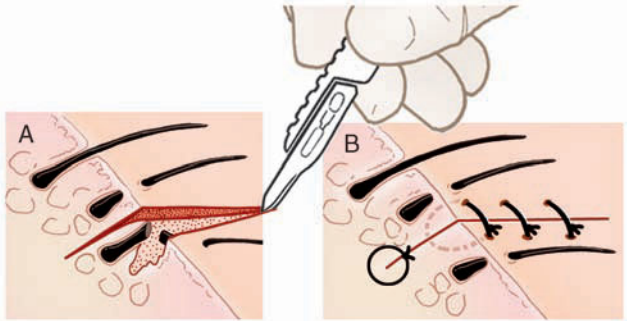

FIGURE 96-5. Repair of eyebrow lacerations. **A.** Debride the wound edges obliquely and parallel to the hair follicles and not perpendicular to the wound edges. **B.** Approximate the wound edges.

and not perpendicular to the skin edge (**Figure 96-5**). This will reduce the loss of hair follicles.

MUSCLE LACERATIONS

The repair of muscle lacerations begins with a careful assessment of the extent of injury and the level of contamination prior to repair. Large and/or grossly contaminated muscle injuries require operative management. All other muscle injuries may be managed in the Emergency Department. Treatment should focus on repair or reconstruction of a muscle using its long tendons of origin and insertion to anchor the repair, as the muscle tissue alone is inadequate for suture repair.[37]

Lacerations of the fascia surrounding a muscle are common. Thoroughly cleanse the area and debride any devitalized tissue. Approximate small violations of the muscle fascia with interrupted 3-0 or 4-0 absorbable sutures (e.g., Vicryl or Dexon). Closing small rents will prevent symptomatic herniation of muscle tissue through them in the future. Do not repair large violations of the muscle fascia. Anecdotal reports of muscle compression and compartment syndromes after such repairs abound.

Lacerations through the muscle require a thorough cleansing and debridement of any devitalized tissue. Repair the laceration with 3-0 or 4-0 absorbable sutures (e.g., Vicryl or Dexon). **Place horizontal mattress stitches to close the laceration.** Interrupted sutures are not effective, as they tend to pull through the muscle fibers and not hold.

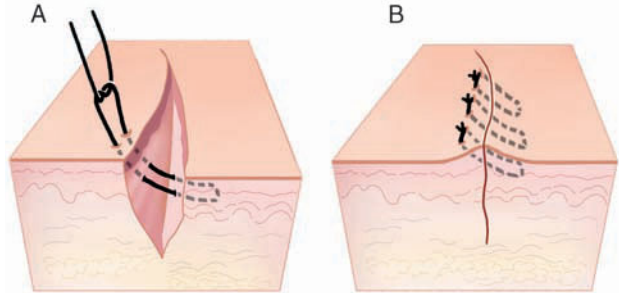

FIGURE 96-6. Closing a wound with edges of unequal thickness using half-buried horizontal mattress sutures.

INCOMPLETE LACERATIONS

Lacerations involving the epidermal and superficial papillary layers of the skin but sparing the deep papillary layer are referred to as incomplete lacerations. Excise the loose epidermal pieces of skin. Cover the wound with petrolatum gauze and a pressure dressing.

WOUNDS OF UNEQUAL THICKNESS

Wounds of unequal thickness are not suited for repair with simple interrupted sutures. Unequal tissue loss on each edge of a wound creates a thick edge–thin edge wound. **The depressed edge must be elevated to the level of the nondepressed edge in order to attain proper wound apposition and cosmesis.**

There are two techniques to repair wounds with edges of unequal thickness. The first technique utilizes a half-buried horizontal mattress suture (**Figure 96-6**).[38] Place the suture through the thick edge of the wound, across the wound and buried into the subcutaneous tissue of the thin edge, and back out the skin of the thick edge (**Figure 96-6A**). Apply traction to the suture and tie it to approximate the wound (**Figure 96-6B**). Apply an ointment-based compressive dressing.

The second technique requires undermining both wound edges at the same depth in the subcutaneous tissue plane (**Figure 96-7**).[39] Make an incision in the subcutaneous tissues of both wound edges and at the same level (**Figure 96-7A**). Undermine the area to free the tissue flaps (**Figure 96-7B**). Grasp the subcutaneous tissue flap from the thicker side and insert it under the thinner side beneath the undermined area (**Figures 96-7B & C**). Place a buried

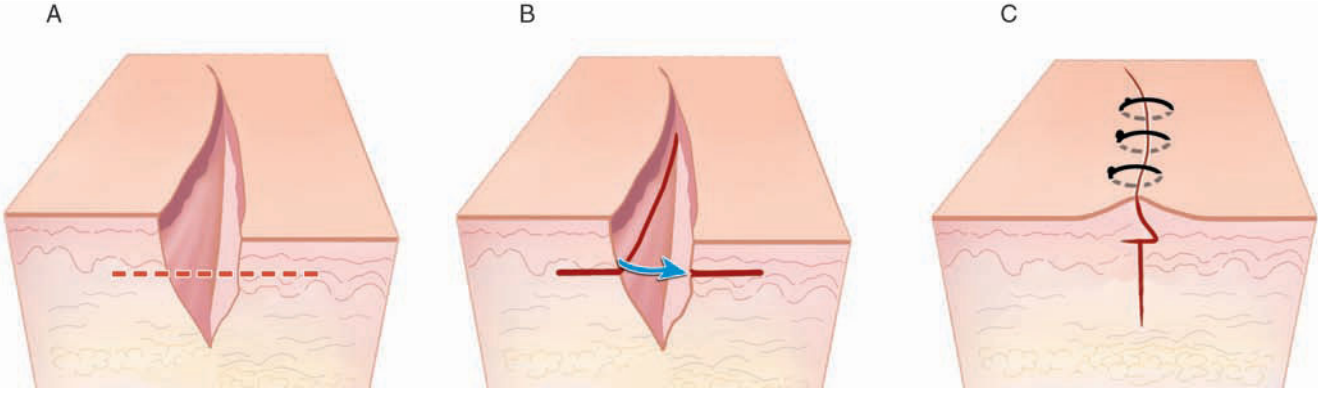

FIGURE 96-7. An alternative technique to close a wound with edges of unequal thickness. **A.** Make an incision in the subcutaneous tissue of both wound edges. **B.** Undermine the edges. Transpose the subcutaneous tissue of the thicker side into the undermined area of the thinner side (*arrow*). **C.** Approximate the wound edges using interrupted sutures.

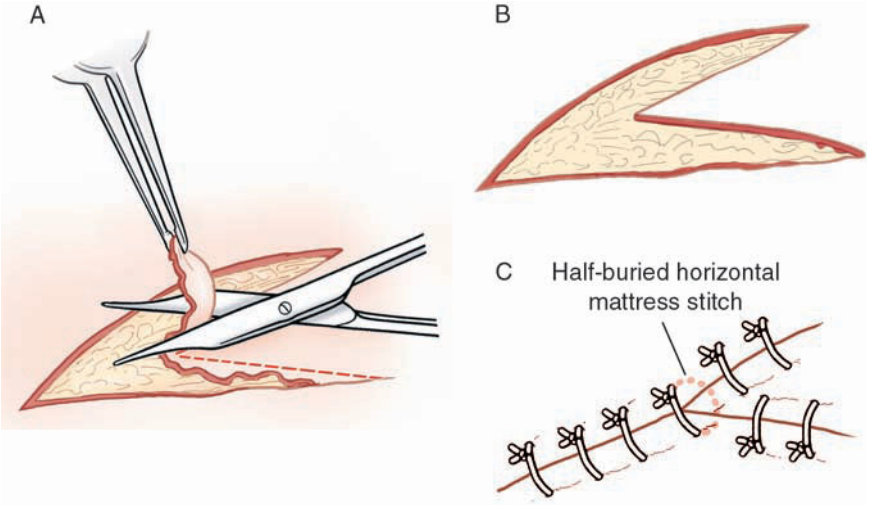

FIGURE 96-8. Repair of a flap laceration. **A.** Sharply debride the edges. **B.** The resultant defect. **C.** Approximation of the wound edges. First place a half-buried horizontal mattress suture to close the tip of the flap. Approximate the remaining wound edges with interrupted sutures.

horizontal mattress suture to maintain the flaps in position. This "flap" elevates the depressed wound edge and facilitates appropriate wound approximation (**Figure 96-7**).[39] Place interrupted sutures to approximate the wound edges (**Figure 96-7C**).

Tangential flap lacerations over thin skin, such as the dorsum of the hand or the pretibial area, where there is very little subcutaneous tissue can be approximated with a specially placed simple interrupted suture. Insert the needle through the tip of the thin edge, across the wound, into the dermis of the thick edge, and out the skin of the thick edge. Apply traction to the suture to pull the thick edge up to meet the thin edge, producing good approximation rather than overlap of the edges. Apply an ointment-based compressive dressing.

FLAP LACERATIONS

Flap lacerations occur when shearing forces to the skin tear the dermis from the underlying subcutaneous tissues. This type of laceration is problematic. The flap is now separated from its blood supply except for the blood entering through the base. This makes the flap susceptible to necrosis and infection. As a general rule, a flap will remain viable if the base of the flap is three times its length.[40] Flaps with a ratio of less than 3:1 are less likely to survive intact; therefore, alternative methods of closure should be entertained.

A flap can easily be repaired primarily if it has viable edges and meets or exceeds the 3:1 ratio of base to length. Anesthetize, clean, and prepare the area. Trim the excess fatty tissue from the underside of the flap. This will improve the chances of healing. Place a half-buried horizontal mattress suture as the first stitch to close the corner or the tip of the flap. Approximate the sides of the flap with interrupted sutures or half-buried mattress sutures.

Some viable flaps have nonviable edges that must be debrided prior to closure to ensure proper cosmesis and survival of the tissue. Debride the nonviable edges sharply with a #15 scalpel blade or an iris scissors (**Figures 96-8A & B**). Place a half-buried horizontal mattress suture as the first stitch to close the corner. This is necessary to close the flap, as the debridement has left the flap too small to close the wound. Approximate the sides of the flap with simple interrupted sutures, mattress sutures, or half-buried mattress sutures.

Some flaps may be too small after debridement or be under too much tension to stretch across the wound. These flaps can be closed by forming a Y-shaped closure instead of a v-shaped closure (**Figure 96-8C**). Place a half-buried horizontal mattress suture to close the tip of the flap. Approximate the base and arms of the Y with interrupted sutures.

A flap laceration may present difficulties. It may not be possible to revise and repair it or it may be obviously nonviable. It is often possible to "ellipse" the flap (**Figure 96-9**). Excise the tissue defect to form a circle. Excise a surrounding ellipse of tissue centered about the circle (**Figure 96-9A**). The ellipse must be 2½ to 3 times as long as its greatest width. Undermine the edges of the ellipse. Approximate the center of the resulting defect using a locked vertical mattress stitch, which allows approximation of the remainder of the wound with minimal extrinsic tension. Approximate the remainder of the resulting defect with deep sutures, if required, and cutaneous sutures (**Figure 96-9B**).

In some cases, there is simply not enough tissue to cover the defect, no matter what technique is attempted. These wounds may be left to heal by secondary intention if small or referred to a Plastic Surgeon for skin grafting. The only complication unique to the repair of flap lacerations is the possibility that the flap may not survive, requiring referral and revision or skin grafting.

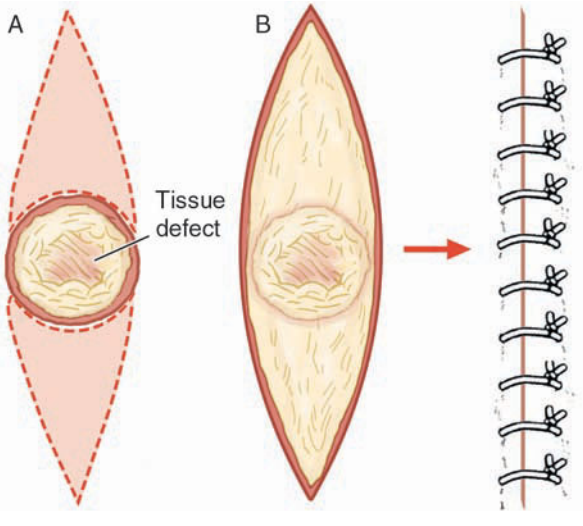

FIGURE 96-9. Closure of a tissue defect. **A.** Excise the defect and a surrounding ellipse. **B.** Approximation of the wound edges with deep and cutaneous sutures.

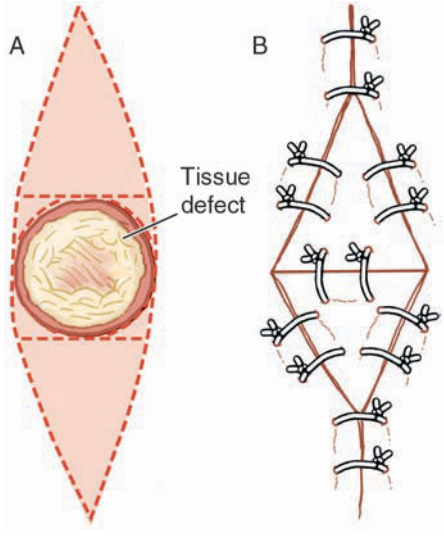

FIGURE 96-10. The double V-Y closure to repair a tissue defect. **A.** Create an ellipse centered about the tissue defect. Remove the tissue defect and form straight edges at the bases of the triangular flaps. **B.** Approximate the bases of the triangular flaps followed by the arms and bases of the Y's, using interrupted sutures.

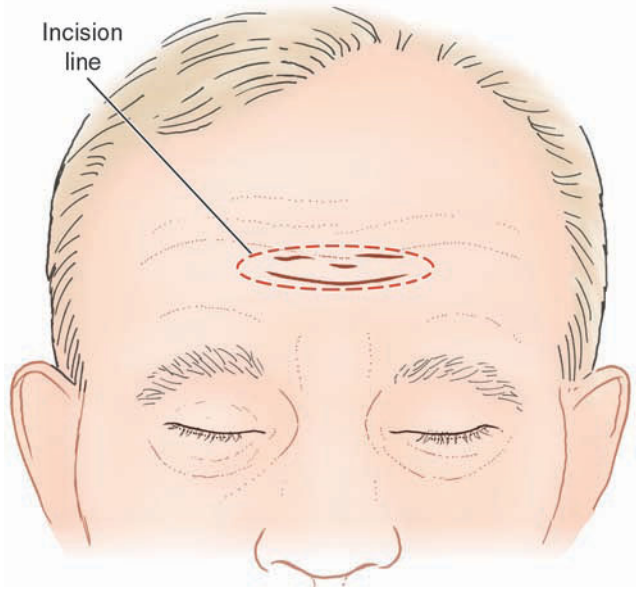

FIGURE 96-11. Repair of multiple small lacerations. Excise the lacerations as a group to form a single wound that can be closed primarily.

AVULSION INJURIES

The treatment of tissue avulsion injuries varies depending on the amount of tissue lost and its depth. Allow full-thickness defects less than 1 to 2 cm^2 to heal by secondary intention after debridement. Full-thickness defects greater than 2 cm^2 require a different approach utilizing skin grafts, flaps, or converting the wound to one that can be closed primarily. Treat avulsed tissue as an "amputated part" that may be used in the repair process. Consider consulting a Plastic Surgeon for a large avulsion that cannot be closed primarily or to convert it into a wound that can be closed primarily.

Some defects can be closed primarily. Examples include circular defects or triangular defects that are converted to ellipses (**Figure 96-9**).[41] This technique is described above under "Flap Lacerations."

Larger defects require the use of a double V-Y closure, which converts the flap to a different shape prior to the repair and thus increases the chances of successful primary closure (**Figure 96-10**).[41] Create two sliding pedicle flaps with a #15 scalpel blade. **Incise the skin and dermis, but not the underling subcutaneous tissue,** to form an ellipse centered about the tissue defect (**Figure 96-10A**). Remove the tissue defect and debride the tissues at the base of the flaps to form two straight edges (**Figure 96-10A**). Gently undermine the edges of the ellipse. **Do not undermine the triangular tissue flaps, so that their vascular supply is preserved.** Slide (advance) the flaps on their subcutaneous pedicles until the bases are touching. Approximate the base of one flap to the other using simple interrupted nonabsorbable sutures (e.g., nylon or Prolene) (**Figure 96-10B**). Approximate the arms and bases of the Y using interrupted nonabsorbable suture (e.g., nylon or Prolene).

MULTIPLE SMALL SKIN FLAPS

Numerous small skin flaps that are bunched up, as commonly seen when a patient's forehead shatters a windshield, are difficult to repair individually. Excise them as a group to form a single laceration that can be repaired primarily (**Figure 96-11**). Larger and more "spread out" groups of flap lacerations can be repaired in a manner similar to that described under "Multiple Forehead Lacerations," above.

DISTAL FINGERTIP AMPUTATIONS

Injuries of the distal fingertip rank among the most frequently injured parts of the hand.[42] Amputations of the fingertip are defined as loss of the tissues distal to the insertions of the extrinsic flexor and extensor tendons on the distal phalanx, distal to the level of the lunula. These injuries may include skin, pulp, bone, the nail matrix, or the nail plate.[42] Treatment options have evolved remarkably over the past 30 years, though change in clinical practice has lagged. Multiple treatment modalities exist and depend on whether the amputated part was retrieved, its condition, the character of the injury, the patient's preference and underlying health status, as well as the availability and sophistication of consultants.

For amputations with pad loss of less than 1 cm, with and without bone exposure, conservative nonsurgical management with serial dressing changes of nonadherent gauze is appropriate.[43,72] Nonoperative open management has been shown to be at least as effective as primary closure, local and distant tissue-transfer flap procedures, and grafts.[44–51,73] Conservative management is advocated in children less than 12 years of age, as they have greater regenerative potential than do adults.[42] Anatomic classification schemes for the level of injury are multiple and make literature comparisons problematic. Therefore, it is best to describe injuries related to anatomic landmarks.

Amputations proximal to the lunula are less common. Those who address the issue specifically recommend shortening and primary closure without discussion or data. These injuries require emergent consultation for possible re-implantation. Injuries from the flexor digitorum profundus insertion to approximately the level of the mid-nail can be replanted if the amputated part is available.[52–54] The purpose of replantation is the restoration of cosmesis and function. The patient's perception may be that replantation will restore functional and cosmetic normality. Inform the patient that this is doubtful.

Conservative therapy usually provides acceptable preservation of contour and better salvage of two-point discrimination than grafts, is cheaper than replantation, is associated with a virtual absence of postsurgical infections, and limits joint stiffness. It is equivalent to other techniques in terms of functional use, preservation of length, and time absent from work. Moreover, eventual patient satisfaction may be even greater than with surgical techniques. Patients may have to be convinced that closure by secondary intention is both rational and, in fact, optimal. A set of photographs demonstrating this is often helpful.

Clean, prep, and anesthetize the finger. Fingertip amputations tend to bleed profusely. Achieve hemostasis with direct pressure using a nonadherent dressing while the hand is raised above heart level for several minutes. Do not remove the dressing if this is successful. Consider the application of sterile compression sponge covered with a nonadherent dressing and the application of pressure if the bleeding continues. Attempts at cauterizing bleeding vessels are usually unsuccessful because of the tissue's vascularity. Apply a sterile Penrose drain as a tourniquet, without excessive constriction, to provide a dry field if debridement of devitalized tissue is required.

The presence of protruding bone poses several treatment options. Some physicians rongeur any significantly protruding bone until it is flush with the wound surface and thereafter continue open treatment. There is no published evidence supporting rongeuring of protruding bone in adults. Anecdotal statements supporting this technique exist in texts.[45,51] Published reports support not shortening protruding bone in children under the age of 12.[49,55] Consider trimming the nail bed back to the bone margin if a remnant overhangs or is not supported by adequate bone.

Dress the wound with either a bulky hand dressing or tube gauze and a four-pronged disposable (metal or plastic) splint. There is no documented benefit for the use of topical or oral antibiotics. Refer all patients to a Hand Surgeon or primary care provider in 24 to 48 hours. Inform all patients of the 30% to 50% incidence of sensory impairment (i.e., diminished sensation, cold intolerance, and dysesthesia), impaired function, or cosmetic deformity.[44,46,50,51,56] Document this in the medical record. The possibility of a wound infection is very small with conservative treatment.[48,74] Healing may be prolonged if protruding bone is not debrided or if it is debrided at a later time.

ANIMAL BITES

Animal bites must be carefully explored to rule out underlying fractures, retained teeth, penetrated joints, tendon injuries, nerve injuries, and/or vascular injuries. Consideration must also be given to prevention or treatment of local bacterial infection, and prevention, recognition, and management of subsequent systemic illness.[57] Infections following a bite wound are polymicrobial. The most frequent bacteria isolated from infected dog and cat bites are *Pasteurella*, staphylococci, streptococci, and anaerobes. Human bites result in infections due mainly to anaerobes and less commonly staphylococci, streptococci, and *Eikenella corrodens*.[58,59]

Any bites to the hand, especially clenched-fist injury human bites, are the most likely to be complicated by infection. Human bites in other locations do not have higher rates of infection than other types of lacerations. *E. corrodens* is isolated from a significant percent of clenched-fist injury human bites, may cause a septic arthritis or osteomyelitis, and can be resistant to several commonly prescribed antibiotics (e.g., clindamycin and penicillinase-resistant penicillin).

Severe infections occasionally develop after bite wounds.[59] Consider the presence of *Capnocytophaga canimorsus* infection in dog bites, *E. corrodens* in human bites, and *Bartonella henselae* in cat bites with persistent lymphadenopathy and/or drainage. There are no prospective studies confirming the indications for repairing bite wounds. Primary closure with subsequent antibiotic therapy of head and neck wounds from dogs, cats, and humans have low infection rates in studies of small numbers of patients. Suturing head and neck lacerations within 6 hours of a dog bite, following a meticulous debridement and irrigation protocol, was successful without subsequent antibiotic use.[60] Therefore, some bite wounds can be safely closed primarily while others are left open for delayed primary closure (**Table 96-1**). The issue of closure applies only to wounds of cosmetic significance. Allow wounds without notable cosmetic significance to be left open for delayed primary closure or healing by secondary intention. **Do not primarily close puncture wounds, hand wounds, human bites, extremity wounds, wounds less than 2 cm in size, facial wounds more than 12 to 24 hours old, or nonfacial wounds more than 6 to 12 hours old. Limit the use of buried sutures, as they can increase the infection rate of a repaired bite wound.**

Preparation of the wound for closure is of the utmost importance. Obtain radiographs of the bite wound if there is the possibility of a fracture, a retained tooth, or penetration of a joint. Debride any devitalized tissue, compromised tissue, or dirty wounds. Gently scrub the surrounding skin, and not the wound, with povidone iodine, chlorhexidine solution, or soap and water. **Copiously irrigate the wound. Antibiotic coverage is no substitute for meticulous wound cleansing.** Refer to Chapter 92 for a complete discussion of wound irrigation principles and techniques. Some studies report

TABLE 96-1 The Repair of Laceration-Type Bite Wounds

Foot	DPC	DPC	DPC

Key: PC, primary closure; DPC, delayed primary closure.

lower infection rates when wounds have been irrigated with a topical antibiotic.[61] However, this cannot be recommended as standard practice.

Bites to the hand require radiographs to rule out a fracture, retained teeth, or air in the joint cavity. Bite wounds, especially human bite wounds, involving a joint cavity or tendon require operative debridement and parenteral antibiotics. Bite wounds not involving a joint or tendon can be cleaned, debrided, splinted, watched expectantly on an outpatient basis, and treated with oral antibiotics.[62] Instruct the patient to keep the hand elevated and return in 12 to 24 hours for a reevaluation.

The use of antibiotics for an infected bite wound is beneficial. However, there is little concurrence regarding the routine use of prophylactic antibiotics. Data demonstrating effectiveness are limited. Differences in wound care, antibiotic regimens, and the severity of wounds make comparison of studies problematic. Prophylactic treatment should ideally allow infection rates to be less than 5%.[63] The only significant benefit that has been shown was for dog or cat bites of the hands.[57] As a result there is a trend toward benefit for the prophylactic antibiotic treatment of hand wounds and bites presenting more than 8 hours after the injury.[59,62,64]

High-risk wounds include puncture wounds (as opposed to laceration-type wounds), cat bites, bites to the hands, severe crush injuries, wounds in immunocompromised patients, and bites requiring surgical repair. The relative risk of infection can be reduced with prophylactic antibiotics (**Table 96-2**). Dog bites have the lowest associated infection rate of all bite wounds (5%-6%) which is similar to the rate found with lacerations from non-bite mechanisms.[57,59,62,64] Higher rates of infection in cat bites (60%-80%) may be due to the fact that a greater proportion of cats have narrower, sharper teeth than dogs, and thus the ability to deliver infectious agents deep into a small-bore puncture wound.[57] It is unclear whether all cat bites require prophylactic antibiotic treatment. It may eventually be proven that superficial laceration-type cat bites may not require treatment beyond irrigation and debridement.[65] Recommended treatment regimens for prophylaxis are 5 to 7 days for all bites with a beta lactam–beta lactamase inhibitor antibiotic (i.e., amoxicillin/clavulanate). Penicillin or ampicillin provides adequate coverage for *Pasteurella multocida* infections, and thus is a logical lower cost option for prophylaxis of cat bites. Penicillin-allergic patients can receive doxycycline or cefuroxime for cat bites, and clindamycin plus a fluoroquinolone for dog bites. Cephalexin, dicloxacillin, erythromycin, and clindamycin do not cover *Pasteurella* species and therefore should not be used alone.[57]

Immunoprophylaxis may be required. Administer tetanus immune globulin and tetanus toxoid as indicated. With any animal bite, consider rabies postexposure prophylaxis. In North America, bites from bats, raccoons, skunks, and foxes carry a special risk. Consult the local public health department for guidelines and the incidence of rabies in your community.

The discharge instructions are just as important as the Emergency Department management. Provide the patient with a written copy of a wound care sheet, regardless of whether the wound was closed primarily. Instruct the patient to elevate any involved extremity, even with antibiotic treatment.[66] Arrange follow-up within 24 to 48 hours for a reevaluation of the wound. Physical therapy following a hand infection may be required and initiated 3 to 5 days after the infection resolves.[59]

TABLE 96-2 Indications for Prophylactic Antibiotic Therapy for Bite Wounds

	Dog bites	Cat bites	Human bites
Puncture wound	Yes	Yes	Yes
Hand bites	Yes	Yes	Yes
Facial bites	No	Consider	No
Non-hand-laceration-type bites	No	Consider	No
Immunocompromised patients*	Yes	Yes	Yes
Surgical closure	Yes	Yes	Yes
Severe crush	Yes	Yes	Yes

*Immunocompromised includes patients with age > 50, diabetes, alcoholism, asplenia, and patients with any other illness associated with an impaired immune status.

DEBRIDEMENT OF GUNSHOT WOUNDS

The lack of primary literature on this subject makes it a controversial area. Wounds created by low-velocity bullets tend to cause damage only along the bullet track. Debridement is unnecessary for wounds created by bullets with muzzle energy of less than 400 foot-pounds, as many consider bullets to be sterile.[67] Devitalized and contaminated tissue are more likely to result from shotgun wounds and high-velocity bullets.[68] The shock wave created by the bullet damages tissue distant from the track of the bullet.[68] Consider these wounds for debridement.[68] The debridement of gunshot wounds requires exposure of the entire bullet track and treatment as a delayed closure, followed by referral for skin grafting if needed.

Clean, prep, and anesthetize the skin overlying the path of the bullet (or shotgun blast). Incise the wound with a #11 scalpel blade to expose the area. Sharply debride any devitalized and contaminated tissue. Repeated staged exploration should be undertaken at 24 and 48 hours to remove necrotic or devitalized tissues.[69] Treat with prophylactic antibiotics; cefazolin, 1 g intravenously every 8 hours, is satisfactory.[69] Treat the area with delayed closure techniques, giving priority to reestablishment of bony relationships, followed by soft tissue coverage.[69] Consider skin grafting for large areas of tissue destruction for adequate closure.

ABRASIONS

An abrasion is a skin wound created by tangential trauma to the epidermis and dermis. The skin is forced against an abrasive surface in a rubbing fashion and the resultant injury resembles a thermal burn. The goals of managing an abrasion include the prevention of infection, promotion of healing, and prevention of "tattooing" with retained foreign bodies. Large and heavily contaminated abrasions are best managed in the operating room, as the volume of local anesthetic required to achieve anesthesia would likely exceed toxic limits.

Prepare the wound. Anesthesia may be required prior to wound management. EMLA cream, which contains lidocaine and prilocaine, produces anesthesia of the intact skin but it must be in place for about 60 minutes in order to provide significant benefit.[70] Perform a field block or regional nerve block (Chapter 126) as appropriate. Large abrasions may be anesthetized by applying 5% lidocaine gel topically for 5 to 10 minutes. Remove any dirt or debris, using a sterile scrub brush and surgical soap (or saline). Consider imaging (i.e., plain radiographs) to evaluate for potential foreign bodies.[28] Use the tip of a #11 scalpel blade to remove deeply embedded and larger particles from the wound. Apply petroleum jelly or antibiotic ointment to remove embedded tar.[71] Apply an antibacterial ointment to the wound.

Instruct the patient to cleanse the wound three to four times a day. The wound may also be covered with petrolatum gauze and sterile gauze. Instruct the patient on how to properly cleanse the wound and reapply the bandage. Provide the patient with wound care supplies prior to discharge from the Emergency Department.

97 Subcutaneous Foreign Body Identification and Removal

Samuel J. Gutman and Michael B. Secter

INTRODUCTION

Wounds with retained foreign bodies are a frequent presenting complaint to Emergency Departments. Up to 38% of embedded objects are missed on the initial assessment.[1] Identification and removal of debris and foreign bodies promote optimal healing of traumatic wounds. **The presence of an unrecognized foreign body can lead to complications that include infection, pain, loss of function, joint injury, tenosynovitis, tendon rupture, and osteomyelitis.[2–5] Patients presenting with chronic, recurrent, or delayed skin infections should be assessed for the presence of an unrecognized foreign body.** Failure to diagnose and treat a foreign body is a common cause of litigation against Emergency Physicians. **The presence of a foreign body may not be obvious. A high index of suspicion and careful methodical examination, including appropriate imaging, must be undertaken to identify a foreign body.**

It is important to be familiar with the characteristics of different types of foreign bodies and the interactions they may have with a host patient. This information is crucial in determining the urgency or necessity of removal (not all implanted objects require removal), the appropriate imaging techniques, the approach to removal, and whether specialty referral is required. The removal of foreign bodies from subcutaneous tissue can be a frustrating and time-consuming endeavor when it is ill conceived. **The successful removal of a foreign body requires a directed history and physical examination, appropriate imaging, adequate light, anesthesia, exposure, hemostasis, patient cooperation, an uninterrupted time period for attempted removal, appropriate wound care, and assured postprocedural follow-up.**

ANATOMY AND PATHOPHYSIOLOGY

Only a small percentage of wounds actually contain concealed foreign bodies.[6] The mechanism of injury may give some idea of the likelihood of a retained object.[1] Crush wounds and puncture wounds, especially those involving the sole of the foot, as well as wounds deeper than 5 mm involving adipose tissue are associated with a higher incidence of foreign bodies that are often difficult to find.[6] Wounds caused by objects that shatter, splinter, or break in the process of causing injury have a higher risk of having a retained foreign body.[7] Lip or facial lacerations associated with dental fractures must be explored for pieces of teeth. Thorns, spines, or slivers tend to penetrate deeply and break. Broken-off needles are common foreign bodies in injection drug users. Objects greater than 4.5 mm in diameter that penetrate the skin may push fragments of epidermis deep into the wound producing an epidermal inclusion cyst, which can act as a foreign body.[8]

Depending upon the type of material retained and the physical form of the foreign object, excess inflammation may result. This can delay healing or destroy surrounding soft tissues. Retained organic foreign bodies trigger the most severe inflammatory reactions and can lead to chronic granulomatous reactions, periosteal reactions, osteolytic lesions, or severe infections such as necrotizing fasciitis.[8–10] The presence of soil in wounds markedly lowers the concentration of bacteria required to cause an infection by its interaction and interference with white blood cells.[11] Wounds tend to be resistant to antibiotics when a foreign body is present[2,3,12] and it may be impossible to eradicate the infection until the foreign body is removed.[2,3,12] Metals that oxidize may cause mild to moderate inflammation. Some retained foreign bodies, like lead, have the potential to produce systemic effects, especially when in contact with pleural, peritoneal, cerebrospinal, or joint fluid.[13] Inert objects with smooth, nonporous surfaces like glass or plastic elicit minimal tissue reaction. Retained foreign bodies that are not dissolved or extruded by the body's defenses become encapsulated, after which the inflammation will subside.[13]

HISTORICAL AND PHYSICAL ASSESSMENT

Patients presenting after an injury require a focused history including the details of the incident, the wounding agent, and the mechanism of injury. This information may suggest the presence of a retained foreign body and direct which imaging study is required.[14,15] Historical features that may signal unusual circumstances or difficult wound healing and management include diabetes, renal failure, immunosuppression, lymphedema, or peripheral vascular disease.[16] Past anesthetic history and the potential for aspiration should be assessed if procedural sedation is to be considered.[17] Medications and allergies should be queried. Assess the patient's tetanus immunization status. Provide booster doses and tetanus immune globulin as needed (**Table 92-2**).

A directed physical examination should begin with a brief inspection and documentation of the distal neurovascular status and function. An injured extremity must be carefully examined through a full range of motion to ensure the integrity of the tendons. Discoloration of the skin may suggest a foreign body.[8] Palpation may reveal superficial foreign bodies. Sharp localized pain with palpation over a puncture wound may suggest a retained foreign body. Adequate anesthesia, lighting, and good hemostasis are required to allow a thorough examination of the wound. **The examiner must avoid probing only superficially since the subcutaneous tissue can reapproximate and give the appearance of a superficial wound.** The wound edges should be extended with a scalpel to facilitate inspection if there is concern regarding a retained foreign body and direct visualization is difficult.

A retained foreign body can be ruled out with a negative predictive value of 96% for wounds less than 5 mm deep if the bottom of the wound is visible.[6] **Never insert a gloved finger to probe the wound cavity, as this can result in injury from sharp foreign bodies.** Gentle blind probing with a hemostat is an acceptable and preferred alternative. A grating sensation that can be appreciated by the examiner is produced if the probe strikes a metallic or glass foreign body. **Avoid blind grasping within a wound with a hemostat.** Direct visualization is preferable when examining wounds of the face, feet, or hands.

RADIOLOGIC ASSESSMENT

Imaging is indicated in most cases where a retained foreign body is suspected but not found during wound exploration, when thorough exploration of the entire wound cavity is not possible, or if the patient feels that there is a retained foreign body.

PLAIN RADIOGRAPHY

Most foreign bodies missed during the initial clinical examination can be seen on plain radiographs.[14] Plain radiographs are readily available. Some authors suggest radiographic evaluation of nearly any penetrating wound involving an extremity.[1,4,18] Standard anteroposterior and lateral radiographs should be performed using an underpenetrated "soft-tissue technique" to increase the contrast between the foreign body and the surrounding tissue.[3] Visibility of foreign material in

soft tissues is dependent upon its composition, relative density, configuration, size, and orientation.[19,20] Oblique and other views can be added to avoid superimposition of the object over bony structures. Radiopaque foreign bodies may be invisible if they are projected over or impacted within bone.[21] Metal, bone, teeth, pencil graphite, certain plastics, gravel, sand, and aluminum are all visible on plain radiographs.[3,20,22] Glass fragments have been thought to require lead or heavy metal content to be visible. However, glass fragments as small as 0.5 mm appear on two-view plain radiographs if not obscured by bone fragments; and glass fragments as small as 2 mm appear in the presence of overlying bone regardless of lead content.[23,24]

Organic materials and plastics are not reliably detected on plain radiographs. They may be indirectly shown as a radiolucent filling defect when the object is less dense than the surrounding tissue, making plain radiography worthwhile even in cases of suspected nonradiopaque foreign bodies.[25,26]

It is important to examine the entire radiograph for the appearance and location of an unexpected foreign body.[27] The evaluation can be terminated after adequate wound exploration and plain radiographs for a known radiopaque foreign body, if nothing is found. Other imaging modalities are required if there is a strong suspicion for a retained foreign body of the type that is not usually demonstrated on plain radiographs.

The advantages of plain radiographs include their universal availability, low cost, and familiarity to most Emergency Physicians. The disadvantages include the inability to resolve objects with densities similar to body tissues. Plain films do not demonstrate anatomic structures that may be intervening between the skin and foreign body along the planned surgical approach. It may be difficult to accurately judge the depth of a foreign body using two-dimensional radiographs.[8] Despite these drawbacks, standard radiographs remain the most clinically practical means of screening for foreign bodies.[19]

ULTRASOUND

Radiography alone is not sufficient to detect nonradiopaque foreign bodies. Bedside ultrasound has become available in many Emergency Departments. The lack of radiation exposure or harm to patients and its ease of use dictates an assessment with bedside ultrasound by the Emergency Physician as a screening tool when foreign bodies are suspected or not found on plain radiography.[28]

Many recent studies have shown ultrasonography to have a higher sensitivity for nonradiopaque foreign bodies than plain radiography.[28,29] High-resolution real-time ultrasound using a 7.5 MHz or greater linear array probe or transducer, in the hands of a skilled and experienced operator, can detect radiolucent superficial foreign bodies with a similar radiographic density as the surrounding tissue.[8,30–34] This can include wood, small glass fragments, fish bones, sea urchin spines, and other vegetative material.[8,34–38] Wood foreign bodies can act as a source for infection and should be evaluated with ultrasound in patients where radiographs are negative.[35] This is especially important in the Emergency Department where wood foreign bodies make up as much as 34% of all foreign bodies and plain radiographs have a sensitivity as low as 7.4% for organic material.[36] Patient perception of a retained foreign body and the use of bedside ultrasound can localize a retained object with a sensitivity of 88.9% and a specificity of 76.5%.[37] One study showed that the accuracy of detection was above 80% for radiolucent objects by ultrasound technologists, Radiologists, and Emergency Physicians.[38]

Ultrasound has the ability to localize a foreign body within three dimensions, thus helping to establish its relation to adjacent bone, muscle, tendons, and tendon sheaths.[32] Preoperative ultrasound results in less damage to the surrounding tissues, reduced operative time, and reduced postoperative morbidity.[32,39]

FIGURE 97-1. A sonographic image of a subcutaneous thorn. The foreign body is hyperechoic (white) with an acoustic shadow deep to it.

The procedure for locating a subcutaneous foreign body with ultrasound begins with selecting the highest available transducer frequency.[40] Higher frequency transducers have better resolution for superficial structures. The use of a standoff pad or gel filled glove (with the air and talc carefully removed) can act as a dead zone for objects that would normally be too superficial to fall within the focal zone of the transducer.[41,42] Adjust the focus to the required depth and proceed to scan the field in two orthogonal planes.[40] The scanning beam must be oriented parallel to the long axis of a hemostat, which can be directed toward the long axis of the foreign body.[31] Please refer to Chapter 98, Ultrasound-Guided Foreign Body Identification and Removal, for more complete details.

The sonographic appearance of foreign bodies is related to the surface characteristics and not its composition.[43,44] Metals and needles are often hyperechoic with reverberation artifact or comet tails. Gravel is usually hyperechoic and shows dense posterior acoustic shadowing. Organic materials such as wood have a characteristic appearance and are ideal for ultrasonographic evaluation. Wood is most often hyperechoic with a posterior acoustic shadow (**Figure 97-1**). Furthermore, the foreign body is often surrounded by a hypoechoic halo[37,42,44] (**Figure 97-2**). This is

FIGURE 97-2. A sonographic image of several shards of glass in the palm. Note the hyperechoic (white) foreign bodies surrounded by an echo-poor (black) signal consistent with either a hematoma or edema.

frequently a zone of edema, granulation tissue, or abscess.[40] While this hypoechoic halo can represent an inflammatory response, it may not be visible within 24 hours of the wound.[35] Doppler ultrasound shows a hypoechoic (black) ring around a hyperechoic (white) foreign body. Doppler also shows marked hyperemia around the periphery of a foreign body, something considered to be a reliable secondary sign.[45]

Once a foreign body has been located on ultrasound, both ends of the object should be marked.[46] This is often done by inserting paperclips between the skin and the transducer and connecting both ends with a marked dotted line. Meticulously scan along the entire length of the suspected object and also visualize the foreign body perpendicular to the transducer.

There are several disadvantages when using ultrasound, including the level of skill required for its use in diagnosing musculoskeletal foreign bodies.[46–49] Studies assessing the accuracy of ultrasound have shown a sensitivity of 30% to 100% and a specificity of 70% to 90%.[49] These values have been mostly demonstrated in referred patients studied by Radiologists and certified technicians.[50,51] Ultrasound by Emergency Physicians has a specificity of only 59% under conditions that replicate a typical Emergency Department situation.[51] Another disadvantage is that false positives can occur with tendons, old scar tissue, calcifications, fresh bleeding, sutures, air in wounds, sesamoid bones, ossified cartilage, or keratin plugs.[8,35,42] Ultrasound localization may also be difficult if the object is close to bone or deep to subcutaneous gas.[43] **As such, Emergency Physicians with a high suspicion for a retained subcutaneous foreign body not identified by bedside ultrasound should request a formal diagnostic imaging study.**

COMPUTED TOMOGRAPHY (CT) SCAN

CT imaging should be requested in cases where radiography and ultrasonography have failed to demonstrate suspected foreign bodies such as nonradiopaque material or those that cannot technically be located by ultrasound due things like overlying bone or gas.[52] CT is valuable because it is more sensitive in differentiating densities and thus is capable of detecting more types of foreign bodies.[14,53–56] The modality can also be used in high-risk wounds when there is potential for infection or joint involvement. CT images can be created in multiple planes and can demonstrate the relationship of a foreign body to important anatomic structures.[53,57] CT-guided percutaneous placement of a catheter or needle can guide surgical dissection to a foreign body, aiding in the subsequent removal.[53,57] The disadvantages of CT scanning include its higher cost, radiation dosage, the need for patient cooperation, and availability. Additionally, organic foreign bodies become less visible over time due to absorption of body fluids.[28]

MRI

MRI appears to be more accurate than any other modality for identifying wood, glass, plastic, spines, and thorns.[14,53] It is superior to CT scanning in detecting the presence and extent of edema, hemorrhage, and infection surrounding foreign bodies.[14,53] Wood foreign bodies often show linear hypointensity with an associated surrounding inflammatory response.[28] MRI's other advantages include the high resolution and contrast between adjacent tissues. It allows the precise localization of foreign bodies in three dimensions to aid in surgical planning and assessment of the need for advanced exploration, debridement, and irrigation. It does not expose the patient to any radiation.[58]

The disadvantages of MRI include its lack of availability and high cost. Patients must be assessed to rule out a magnetic foreign body due to the risk of movement of the foreign body during MRI scanning.[59] Prior history of an ocular or other metallic foreign bodies must also be sought prior to MRI scanning to prevent iatrogenic injury. This requires a thorough screening history and plain radiographs prior to MRI scanning. Gravel and ferromagnetic substances produce significant artifact.[14] Differentiating scar tissue, tendons, and calcifications from an actual foreign body can be challenging.[60] MRI is better suited to evaluate the complications of foreign bodies and is not used routinely in the Emergency Department.

INDICATIONS

Every effort should be made to identify foreign bodies, even if they are not likely to be removed. It must be decided whether a foreign body needs to be removed immediately, electively, or at all once identified. Factors that influence the decision to proceed with attempted removal include the size and reactivity of the foreign body, its proximity to vital structures, and associated injuries. These must be weighed against the potential for further tissue damage and contaminating the wound.

A foreign body requires immediate removal if it is likely to provoke significant tissue inflammation or injury.[3,61,62] Contaminated objects such as teeth, soil, or foreign bodies located in the presence of an established infection should be immediately removed.[3,11] Allergenic foreign bodies, toxic foreign bodies, or those causing hemorrhage or ischemia should be immediately removed.[3,62] Foreign bodies interfering with sensory or motor function, or having the potential for migration, should be urgently removed.[3] Foreign bodies in the hands and feet usually require removal as they may cause persistent pain and can sever nerves or tendons much later.[5] The foreign body may require removal for cosmetic or psychological reasons in some cases.[1]

CONTRAINDICATIONS

The foreign body should be urgently removed under ideal conditions by an appropriate Surgeon when it is associated with a neurovascular injury or is located near tendons, nerves, or blood vessels.[1,3] Deep exploration of the hands or feet should be avoided to prevent injuring the intricate structures. Large, deep, and impaled foreign bodies are assumed to be tamponading hemorrhage, should initially be left in place, and urgently removed in the Operating Room.[27] Foreign bodies associated with fractures or located within a joint require prompt surgical debridement to prevent osteomyelitis or septic arthritis.[62] Urgent surgical intervention is required for all high-pressure injection injuries. These injuries may initially appear innocuous but often cause extensive damage and carry a significantly high risk of complications.[62] Consider referral based on one's own experience, anticipated problems related to the foreign body's location or depth of penetration, the duration of retention, or other patient factors likely to complicate the procedure or follow-up.

A deeply embedded, inert object not near any vital structures can be left in place. The difficulty of removal is usually not worth the potential tissue damage. These patients can be referred for elective removal, if necessary.[1,62] **If the decision is made not to remove a foreign body, the patient must be informed and the issues discussed including the potential for migration and infection. Document this discussion in the medical record.**

EQUIPMENT

- 18 gauge needles
- 27 gauge needles
- 10 mL syringes
- Povidone iodine or chlorhexidine solution

- Lidocaine (1%) with and without epinephrine
- Topical 4% liposomal lidocaine
- Depilatory wax, rubber cement, or hardening facial gel
- #11 scalpel blade on a handle
- #15 scalpel blade on a handle
- Nylon suture, 1-0 or 2-0
- Methylene blue
- Paper clips
- Wire grid
- Eye magnet
- Hemoclips
- Hemoclip applier
- Fluoroscopy unit
- Hemostats, two sizes
- Forceps
- 22 gauge needles for foreign-body localization
- Magnification eye loupes
- Normal saline
- 19 gauge blunt-tip needle or angiocatheter
- 35 mL syringe
- Blood pressure cuff or Penrose drains
- 4 × 4 gauze squares
- Adhesive tape
- Bedside ultrasound with high frequency transducer
- Standoff pad or gel filled glove

PATIENT PREPARATION

Foreign body removal can be frustrating and time consuming, even when performed under ideal conditions. It is appropriate to set a time limit that is reasonable based upon the staffing and volume of the Emergency Department. Approximately 10 to 30 minutes is appropriate to find and remove an embedded foreign body. Inform the patient of the planned time limit at the outset. The search should be discontinued and the patient referred to a Surgeon after expiration of the predetermined time.

Apply povidone iodine or chlorhexidine to the skin site surrounding the wound. Avoid spilling the solution into the wound cavity as both are toxic to wound defenses and may increase the incidence of a subsequent wound infection.[12] Obtain a bloodless field for the examination. Place a blood pressure cuff proximal to the injury. Elevate the extremity for at least 1 minute and then inflate the cuff to a pressure greater than the patient's systolic blood pressure. Although it will cause some discomfort, this is safe for up to 2 hours.[63] A local vasoconstrictor can be used with the anesthetic to control localized capillary bleeding if no contraindications exist. A 0.25 to 0.50 in. Penrose drain can be wrapped tightly around a finger or toe and secured in place with a hemostat.

Adequate anesthesia is crucial to the procedure. A field block or regional nerve block, depending upon the location of the foreign body, best accomplishes anesthesia without distorting the wound further by local infiltration.[64] Consider using topical anesthetics in the pediatric population. Liposomal lidocaine (4%), for example, has a very fast onset and is associated with higher success rates, reduced procedure time, and less pain.[65,66] The techniques of topical and regional anesthesia are described in Chapters 124 through 127. Procedural sedation (Chapter 129) or general anesthesia may be required, especially in children where cooperation may not be otherwise possible.

TECHNIQUES

SUPERFICIAL WOOD OR ORGANIC SPLINTER REMOVAL

Very fine foreign bodies can be difficult to visualize. One method to help localize them is to spread soft soap very lightly over the skin.[67] Only superficial organic splinters and foreign bodies should be pulled out with forceps as they often come apart leaving a fragment that is more difficult to remove.[3,68] Occasionally, cactus spines or wood splinters lie superficial and parallel to the skin surface. Make an incision parallel to the long axis of the foreign body and then lift it out of the wound. Enlarge the skin entrance wound with a scalpel so that the foreign body can be grasped and withdrawn with a hemostat under direct visualization if it is lodged in the subcutaneous tissue.

Small cactus spines may be difficult to locate and remove directly. Application of a depilatory wax, rubber cement, or a water-soluble facial gel with a brush can successfully aid in the removal of small fine spines.[61] Apply the wax, rubber cement, or facial gel over the skin containing the protruding spines. Apply a layer of gauze over the wet substance. Allow the substance to dry onto the skin and the gauze. Remove the gauze to lift off the dried substance and attached spines. Repeat this process as required to remove the remaining spines.

PUNCTURE WOUNDS

Puncture wounds of the foot are commonly seen in Emergency Departments. Punctures frequently, drive pieces of clothing, shoes, or other debris deep into the wound resulting in an infection rate of approximately 10%.[69,70] Although technically difficult, puncture wounds in the distal foot may profit from debridement and irrigation.

Puncture wounds can be trimmed or ellipsed to remove contaminated and/or embedded foreign bodies (**Figure 97-3**).[3] This

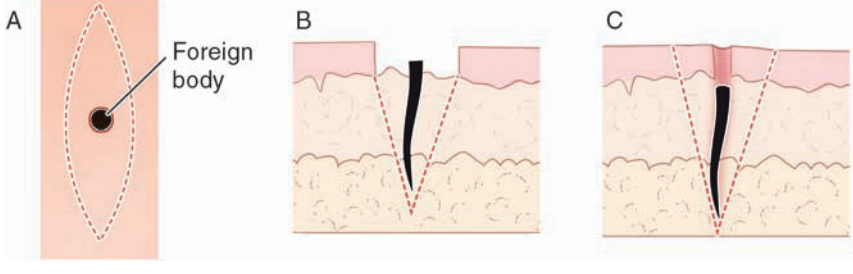

FIGURE 97-3. Creating an ellipse to remove a contaminated or embedded foreign body. **A.** An ellipse is made in the skin surrounding the foreign body. **B.** The epidermis is removed to expose the foreign body. A block of subcutaneous tissue (dotted line) can be removed if the foreign body is difficult to visualize. **C.** The skin, the subcutaneous tissue, and the foreign body can be removed en bloc.

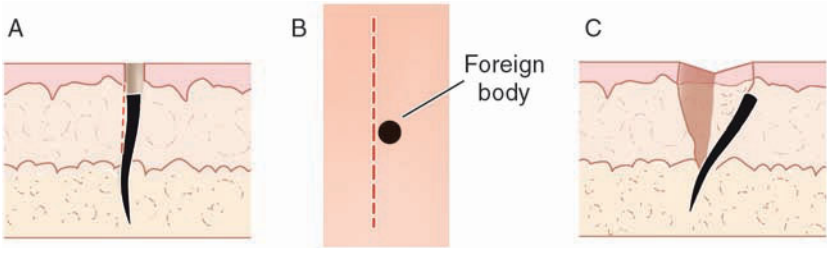

FIGURE 97-4. Removal of a foreign body embedded perpendicular to the skin. **A.** The embedded foreign body. The dotted line represents the proposed incision line. **B.** A linear incision is made 1 mm lateral to the foreign body. **C.** The incision is spread open to visualize and remove the foreign body.

technique also works well for foreign bodies that are difficult to localize. Make an ellipse in the skin surrounding the foreign body with a #15 scalpel blade (**Figure 97-3A**). Lift up the ellipse of skin and separate it from the underlying dermis (**Figure 97-3B**). The foreign body may be visible. Grasp it with a hemostat or forceps and remove it from the tissue.

If unable to exactly localize the object, the foreign body and the ellipsed puncture wound can both be extracted in a block of tissue (**Figure 97-3B**, dotted line).[64] **First ensure that no nerves, blood vessels, or tendons will be injured.** Alternatively, make the skin ellipse and extract the block of tissue containing the foreign body without dissecting the skin from the subcutaneous tissue (**Figure 97-3C**). Both techniques allow for the removal of foreign bodies and better cleaning of the wound. Puncture wounds of the foot require careful follow-up due to the risk of infection.

There are several alternative techniques if removing an ellipse of skin and/or tissue is contraindicated or if the Emergency Physician is not comfortable with this technique (**Figures 97-4 & 97-5**). A foreign body may be embedded perpendicular to the skin (**Figure 97-4A**). Make a linear incision that passes 1 mm to the side of the puncture wound with a #15 scalpel blade (**Figures 97-4A & B**). Spread the incision open. Visualize the foreign body, grasp it with a hemostat, and remove it.

The final technique of removing a foreign body from a puncture wound involves making a superficial skin incision and manually expressing the foreign body (**Figure 97-5**). Make an elliptical incision surrounding the foreign body or a linear incision over the foreign body (**Figure 97-5A**). Remove the ellipse of skin or spread the linear incision. Undermine the subcutaneous tissues surrounding the foreign body (**Figure 97-5B**). Apply digital pressure over the undermined areas to displace the foreign body into the center of the wound and upward (**Figure 97-5B**). Grasp the foreign body with a hemostat and remove it.

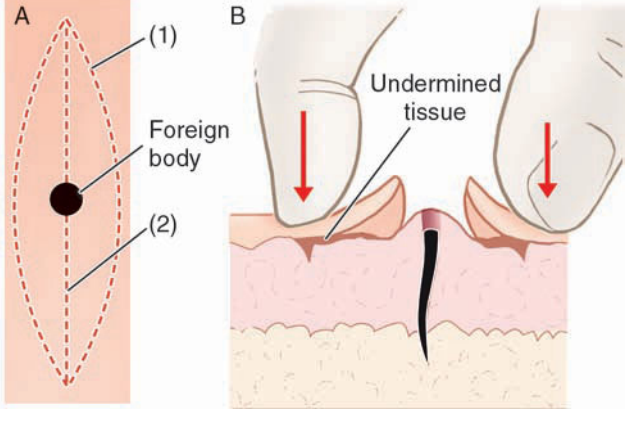

FIGURE 97-5. An alternative technique to remove a foreign body from a puncture wound. **A.** Incise and remove an ellipse of epidermis (1). Alternatively, make a linear incision centered over the foreign body (2). **B.** Undermine the subcutaneous tissue surrounding the foreign body. Apply digital pressure (*arrows*) to visualize and express the foreign body.

NYLON SUTURE LOCALIZATION

One technique described for use in fresh wounds involves the localization of a foreign body by marking its entry tract with a nylon suture.[71] Grasp a piece of 1-0 or 2-0 nylon suture between the thumb and index finger. Rotate the suture while pushing it into the wound so that it follows the tract made by the foreign body. It is reported that the foreign body is easily felt when the nylon contacts the foreign body.[71] Leave the suture in the wound tract. Open the wound tract by cutting alongside the nylon suture until the foreign body is reached, at which time it is removed. A 92% success rate up to 48 hours after the time of injury has been reported with this technique.[71]

GEOMETRIC APPROACH FOR A NEEDLE IN THE FOOT

A technique that is useful for the removal of a needle in the plantar surface of the foot involves the use of standard anterior, posterior, and lateral radiographs to identify the cutaneous site corresponding to the location of the needle.[72] The incision site is determined by bisecting the midpoint of the needle, as seen in each projection, by a line drawn at right angles to the long axis of the needle. The ideal plane of dissection is perpendicular to the needle's midpoint, which is correlated with the surface anatomy of the foot.

Prepare and anesthetize the skin after determining the dissection plane. Make a 0.5 to 1.0 cm skin incision in the plane perpendicular to the needle in its midpoint. Advance an iris scissors into the incision and along the dissection plane with the blades slightly open. Advance the scissors 1 to 2 mm and close the blades. Withdraw the scissors slightly. Open the blades of the scissors, advance them 1 to 2 mm, and close the blades. **Care must be taken to avoid cutting the flexor tendons, although they are located deep and in close association to the bones of the foot.** Continue this process of advancing and closing the blades until the needle prevents closure of the scissors. Advance a hemostat into the wound and over the blades of the scissors. Grasp and secure the needle. Pull the hemostat out of the wound to simply back the needle out of its entry tract. This procedure is reported to have a 100% success rate and takes approximately 10 minutes.[72]

DYE LOCALIZATION

Methylene blue may be used to track the location of a foreign body.[73] Identify the presence of a needle or foreign body on plain radiographs. Clean and prepare the skin. Sterilely inject 0.1 to 0.2 mL

of methylene blue very gently through the entrance wound of the foreign body. The dye will travel along the path of least resistance, that is, the path of the foreign body. Make an A-, U-, V-, or Y-shaped incision from the point of entry and raise a flap of tissue. The blue dot of dye serves as a guide to the location of the foreign body. This procedure is often complicated by seepage of dye and is therefore of limited value.

PAPER CLIP X-RAY LOCALIZATION

Simple paper clips may be used to locate a foreign body.[74,75] Obtain plain radiographs to demonstrate the presence of a radiopaque foreign body. Bend two or more paperclips into different shapes. Place the ends over the wound entry site. Secure the paper clips in position with tape. Obtain two plain radiographs taken at right angles to each other. Examine the radiographs to determine the cutaneous location of the foreign body in relation to the paper clips and note its depth from the skin surface. Mark the exact cutaneous location of the foreign body on the patient's skin with a permanent ink pen. Remove the paper clips.

Clean, prepare, and anesthetize the skin. Make a stab incision at a 90° angle to the middle of the foreign body, taking the shortest distance between the skin and the foreign body, and following the method discussed for the geometric approach for a needle in the foot. Insert a small hemostat into the incision. Advance the hemostat allowing localization of the object with minimal probing. Grasp and remove the foreign body.

WIRE GRID LOCALIZATION

This technique follows a similar approach to the paper clip method.[76] Place a wire grid over the skin. Obtain radiographs in two planes to locate the object within the grid system. Mark the skin and remove the grid. Remove the foreign body as discussed for the paper clip technique.

NEEDLE GRID LOCALIZATION

The grid principle may also be used to remove superficial and nonlinear radiopaque foreign bodies after they have been identified on plain radiographs. Clean, prep, and anesthetize the skin. Insert three 25 gauge, 1.5 in. needles into the skin near the estimated location of the foreign body and at right angles to each other. Obtain two orthogonal plain radiographs. This process can be repeated, each time moving the needles slightly until one is superimposed on the foreign body. Determine the cutaneous position of the foreign body by noting its position within the needle grid. Mark this position on the skin. It must be remembered that this technique does not provide a true three-dimensional image since divergence and parallax distortion of images occur on the radiographs.[3]

The Emergency Physician must recall that tendons and other structures may block the planned path to the object.[7] Make a 0.5 to 1.0 cm incision in a plane perpendicular to the long axis of the foreign body to an appropriate depth or dissect along the path of the closest needle.[27] Identify and remove the foreign body. A drawback of this technique is the potential for dislodging of the needles with attendant repeated trips to the Radiology Department. The use of a portable fluoroscopy unit will prevent this problem.

Another similar technique involves the placement of three to four needles of different gauges at 90° to each other in the anesthetized subject.[77] Obtain repeat radiographs to identify which needle is closest to the object. Remove all but the closest needle. Make an incision down to the estimated depth where the foreign body is located. Identify and remove the foreign body.

EYE MAGNET

Another technique reported to have a good success rate in removing metallic foreign bodies utilizes a hand-held eye magnet.[78] Confirm the presence of a radiopaque foreign body with plain radiographs. Prepare, drape, and anesthetize the area. Slightly enlarge the entry wound to permit entrance of the magnet tip. Apply a sterile ultrasound probe cover or glove over the magnet. Gently probe the wound track with the magnet until a "click" is appreciated. Withdraw the magnet with the foreign body attached to the magnet. Perform further and more directed wound exploration with the magnet if resistance is met. This technique is likely of limited value.

TAGGED HEMOCLIPS

It can be difficult to find foreign bodies once the dissection actually begins since the tissues may be distorted by retraction, edema, or local anesthesia; even with the most elaborate marking system using grids or needles. The tagged Hemoclip method was developed to address this problem.[79] It requires a skin incision and dissection down to where the physician believes the foreign body to be, based as observed on plain radiographs. Prepare two or three Hemoclips with a long silk suture attached to each one. Place them into the Hemoclip applier. Dissect down to where the foreign body is believed to be located. Place two or three Hemoclips into the depths of the wound. Obtain repeat radiographs to show the relationship of the foreign body to the Hemoclips. Remove all but the closest Hemoclip. Dissect towards the Hemoclip and the foreign body. Identify and remove the foreign body. Remove the Hemoclip. If the foreign body is not readily found, repeat the procedure after placing two or three additional Hemoclips. Follow the trail of Hemoclips to the foreign body.

ULTRASONOGRAPHIC REMOVAL

There are a multitude of different approaches to the ultrasound-guided removal of subcutaneous foreign bodies.[37,40–42,46,80] A detailed working knowledge of the pertinent anatomy is essential. Locate and mark the location of the foreign body. Clean, prep, and anesthetize the skin. Insert a needle under ultrasonographic guidance. The ultrasound monitor screen will display a hyperechoic linear object with posterior reverberation effect. Guide the needle under ultrasound until it touches the foreign body. Make a skin incision down to the foreign body. The addition of a second needle in a perpendicular plane can enhance the objects localization.[41] Inset a closed hemostat to approach the foreign body.[41,80] Ideally, the hemostat should be inserted along the plane of the foreign body. Open the jaws of the hemostat under sonographic guidance to reveal two echogenic structures, the jaws of the hemostat, with posterior reverberation effect. Once the object is within the hemostat's grasp, it can be removed under sonographic guidance. Always rescan the area after the foreign body is removed in order to ensure that no additional fragments remain. Patients should be instructed to return if there are any signs of infection.[46] A more detailed description of ultrasound-guided foreign body removal is available in Chapter 98.

FLUOROSCOPIC TECHNIQUES

Fluoroscopy offers an excellent aid in the removal of radiopaque foreign bodies.[81] Make an incision over the foreign body as judged from plain radiographs. Localize the foreign body under fluoroscopy. Guide a curved hemostat to the foreign body with brief intermittent exposures of the fluoroscopy unit.[82] Grasp and remove the foreign body. This procedure exposes the operator's hands to radiation and may risk damaging structures in the wound by blind manipulation of the hemostat.[83]

The grid and needle localization techniques described previously can be applied under fluoroscopy. Rotate the site of injury under the fluoroscope to visualize the foreign body between the markers. This may improve the ability to judge the location of the foreign body in three dimensions and aid in its removal. Intermittent exposure with a fluoroscope can allow repositioning of the needles until the foreign body is localized between two needles or at the tip of a single needle. Make a small incision carried down to the foreign body and remove it.[83,84]

Additional techniques using fluoroscopy and neurosurgical stereotactic devices have been described.[3] The cost, availability, and practicality make these approaches unattractive in the Emergency Department and are therefore not discussed further.

AFTERCARE

It is often prudent to take postextraction radiographs to ensure complete removal of the foreign body, especially if multiple objects are involved or if there is concern about the object fragmenting.[77] Carefully irrigate and debride the wound of all epidermal fragments.[3] The most effective form of wound preparation and cleansing is jet lavage irrigation with normal saline to decrease the bacterial load in the wound and the risk of developing infection.[85] This can be performed with a commercially available device or a 35 mL syringe armed with a 19 gauge angiocatheter or blunt needle.[12] Studies of simple pediatric wounds has found that using drinkable tap water to irrigate wounds is a good alternative to saline, as it shows similarly low infection rates.[86] The quality of mechanical cleaning is important to wound prognosis.[1] Clean, thoroughly irrigated, and debrided wounds with a good blood supply do not require antibiotics and may be sutured closed after removal of the foreign body. Patients should be followed up in 5 to 7 days for suture removal.

If complete cleansing of the wound is not assured or if the wound is at significant risk for infection for other reasons, delayed primary closure or healing by secondary intention should be considered.[12,87] Delayed primary closure involves packing the wound open for 4 to 5 days, after which it is reassessed and closed primarily if the edema has resolved, no infection is present, and exudate has been removed. This technique results in minimal tissue damage. It is especially useful in clean contaminated and contaminated wounds, achieving a 90% success rate in appropriate patients.

Antibiotic therapy may be considered in those with wounds that are at significant risk for infection. **But, antibiotics are not a replacement for proper wound care.** Infection rates for traumatic wounds range from 4.5% to 6.3%. Those patients who are immunocompromised, have puncture wounds, crush injuries, open fractures, bites, burns, frostbite, or wounds that involve tendons and cartilage as well as those wounds contaminated with feces, soil, saliva should be considered high risk and should be considered for antibiotic therapy.[88,89] Close follow-up is especially important in these patients. Prophylaxis for endocarditis is not recommended unless foreign body removal is undertaken through an area of an established infection.[90] Splint the involved extremity if the foreign body is near a joint, a highly mobile region, or a vital structure to prevent injury and/or migration of the foreign body if the patient is referred for delayed removal.[8] A more complete discussion on wound cleansing, wound irrigation, and the general principles of wound management can be found in Chapter 92.

TETANUS PROPHYLAXIS

Tetanus prophylaxis must be considered for wounds involving foreign bodies. Wounds contaminated with feces, soil, or saliva, puncture wounds, avulsions, and wounds resulting from missiles, crushing, burns, and frostbite are considered to be tetanus prone. Recent studies have found that up to 26% of those patients reporting they were up to date with tetanus vaccination were confirmed not to be, while a further 30.2% were indeterminate.[91] In the Emergency Department, it is vital to investigate a patient's tetanus status and vaccinate according to the accepted guidelines.[40,92] For patients who have had three or more doses, those who received their previous dose within 5 to 10 years presenting with a nonclean and minor wound should receive the Tdap booster (preferred over the Td booster). Those patients who have gone more than 10 years since their last dose should also receive the booster regardless of wound type. All patients who have fewer than three doses or an uncertain vaccination history should receive the vaccine booster. Of these patients, those with complicated or contaminated wounds (such as those due to a puncture) should receive the tetanus immunoglobulin (TIG) in addition to the vaccine booster.[92] Please refer to Chapter 92 for more complete details regarding tetanus prophylaxis.

COMPLICATIONS

The removal of embedded foreign bodies is relatively free of complications if properly conceived. **Care must be taken to document the functional and neurovascular status prior to and after any significant manipulations.** Appropriate referral of complicated cases, including those with foreign bodies located deep in the hands, the feet, or near vital structures will lessen the risk of unfavorable outcomes. Infection remains the most common complication of a retained foreign body, even when the object itself is not contaminated. Aseptic technique and avoidance of excessively prolonged manipulation and searching for embedded foreign bodies are important to prevent introducing infection into a previously sterile area. In cases where the foreign body cannot be found, it may be necessary, although less than ideal, to wait for abscess formation in order to pinpoint the location of an object at a later time.[3] Referral for additional imaging and removal may be appropriate. The patient must be advised in detail of the likely course, and follow-up must be assured and documented.

SUMMARY

Virtually all embedded subcutaneous foreign bodies should be identified and located with rigorous assessment of each and every traumatic wound and a high index of suspicion. The history and physical examination should guide the search for retained foreign bodies and the approach to locating them. The majority of foreign bodies are visible on plain radiographs. Wounds for which a radiopaque foreign body may be retained should be imaged with standard radiographs utilizing a soft tissue technique. Bedside ultrasound should be utilized to assist in the identification and removal of subcutaneous foreign bodies. Additional diagnostic imaging with CT, ultrasound, or MRI may be indicated if the suspected foreign body is likely to be radiolucent or is not adequately identified. Once identified and located, several techniques are available to aid in localization and removal. A decision must be made regarding the necessity of immediate or urgent removal in the Emergency Department or by referral to a specialist. Inert foreign bodies that are unlikely to cause long-term complications may be left in situ with information provided to the patient explaining the reasoning behind this conservative approach. Appropriate wound care is crucial to satisfactory healing, and postprocedure follow-up must be assured.

98 Ultrasound-Guided Foreign Body Identification and Removal

Daniel S. Morrison

INTRODUCTION

Retained foreign bodies are associated with up to 1.9% of all wounds.[1] The presence of a foreign body in a wound increases the incidence of a wound infection.[2] Retained foreign bodies are also a major cause of litigation against Emergency Physicians.[3,4] A high index of suspicion for a retained foreign body must be maintained whenever there is the potential for a foreign body in a wound.[5,6] This chapter focuses on ultrasound-guided identification and removal of subcutaneous foreign bodies.

Foreign bodies may be small, leave no skin entry marks, and consist of many different types of material. Almost any object (solid, liquid, or gas) can become a foreign body and present itself in a location where it should not reside. Standard radiographs and fluoroscopy are good at identifying radiopaque objects such as metal, gravel, and glass.[7–13] The ability of these techniques to identify a foreign body varies by the size and composition of the foreign body.[9] MRI and CT are useful to detect foreign bodies.[12,14,15] These are expensive imaging modalities and the images vary depending upon the length of time the foreign body has been present.[15] Certain foreign bodies may produce artifacts that diminish the MRI and CT image qualities.[12] Plastic, hair, vegetative material, and rubber are not radiopaque and are not routinely identified on radiographs.[6–8,10–13,16–18] Ultrasound (US) is able to identify radiopaque foreign bodies. US can also detect foreign bodies that are not radiopaque due to their different echotextures in relation to surrounding structures.[6,8,14–30]

ANATOMY AND PATHOPHYSIOLOGY

Foreign bodies can be present in almost any part of the body. Foreign bodies can be detected with US even when they are found in nontraditional places. They have been identified in the eye,[31] esophagus,[29] and tongue[32] with US. Foreign bodies isolated to small spaces, such as in the web spaces of the hand, may not be identified due to the size of the US probe footprint and the difficult anatomic location to scan.[26]

Not diagnosing foreign bodies can be dangerous for the patient and lead to an increased risk of complications. Legislation to introduce an aluminum penny into circulation in the United States in 1973 was defeated in part by Pediatricians and Pediatric Radiologists concern that these new coins would not be easily identified on radiographs.[33] Patients with retained lead foreign bodies can have statistically significant elevated blood lead levels as compared with matched controls.[34]

Foreign bodies have specific US characteristics. Smooth and flat surfaces typically produce a dirty shadowing or reverberation artifact.[35,36] Irregular surfaces with a small radius or curvature produce a more clean shadow (**Figure 98-1**). Glass and metal typically produce a ring-down or reverberation artifact[11,23,28,29,35,37] (**Figure 98-2**). A wood foreign body produces a bright echogenic reflection with a strong acoustic shadow[6,11,29,38] (**Figure 98-3**). Foreign bodies residing in soft tissue longer than 24 hours can cause an inflammatory reaction, which creates a hypoechoic rim around the echogenic foreign body (**Figure 98-4**).[35]

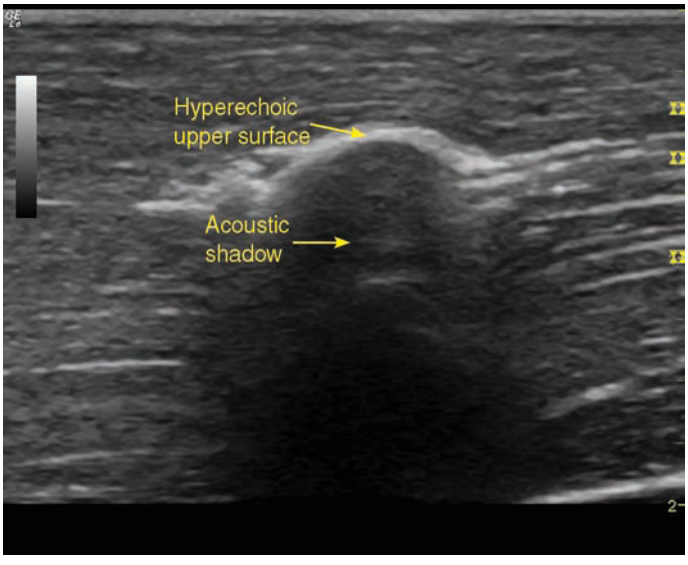

FIGURE 98-1. US image of a subcutaneous pebble. Notice the hyperechoic short radius and tight curvature. The pebble casts a strong acoustic shadow as it blocks transmission of the US beam.

INDICATIONS

Patients with a foreign body sensation or soft tissue mass should be considered to have a foreign body until ruled out.[5,16] Foreign bodies can migrate great distances from the original insertion site requiring the Emergency Physician to maintain a high index of suspicion for a foreign body.[39] Any patient in which the Emergency Physician has any index of suspicion for a foreign body should have additional investigations. Wood, thorns, spines, vegetative foreign bodies, dirt, clothing, and heavily contaminated foreign bodies should be removed immediately, as should those with potential for migration or entrance into the systemic circulation. It is generally believed that glass, metal, and plastic are inert and can be removed electively as they tend to be encysted by scar tissue. Their removal is dependent on the specific situation, physician preference, and patient characteristics. Patients who have

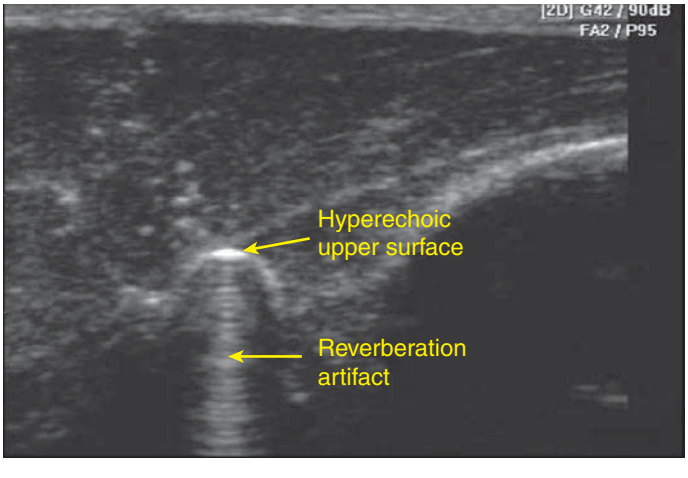

FIGURE 98-2. US image of a subcutaneous metallic BB. The BB is hyperechoic and produces a reverberation artifact.

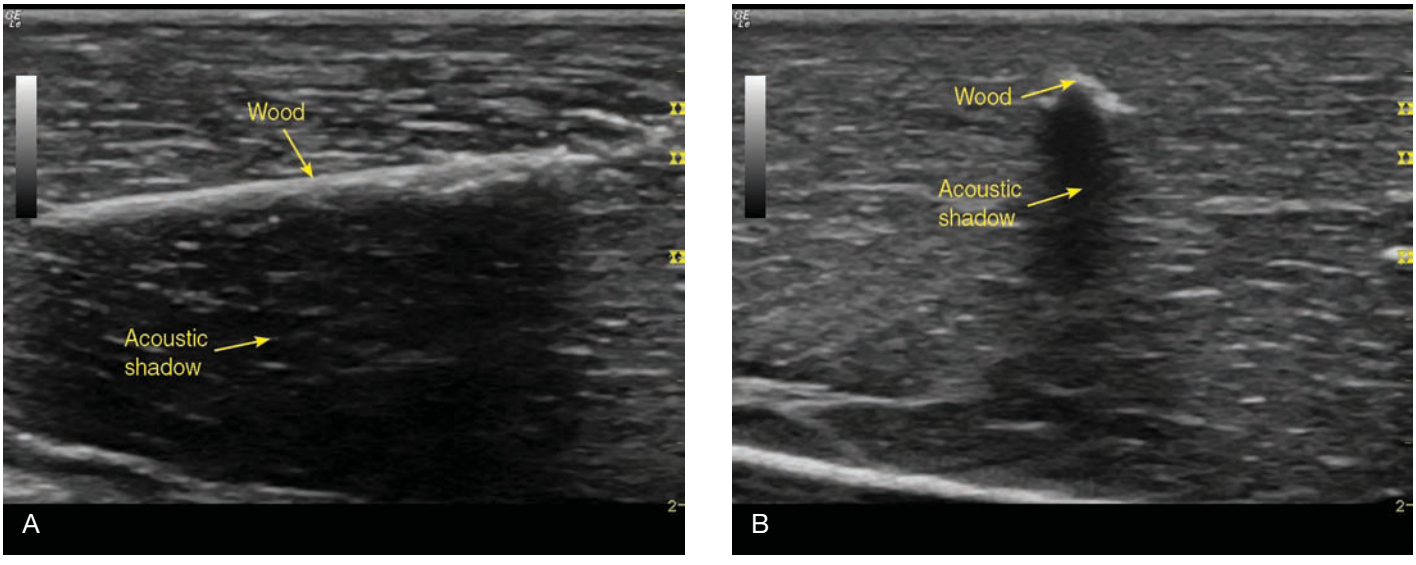

FIGURE 98-3. US image of a subcutaneous wood foreign body. The wood produces a strong hyperechoic reflection and a hypoechoic acoustic shadow. **A.** Long axis US view. **B.** Short axis US view.

persistent pain, neuropraxia, impairment of function, limitation of range of motion of a joint, or psychological distress should have the foreign body removed. Foreign bodies adjacent to bone can cause osteomyelitis and should be removed within 96 hours.[40] Any patient in whom a foreign body, especially wood, was removed should have a further investigation to ensure there are no additional foreign bodies or a fragment of the removed foreign body present.[18]

CONTRAINDICATIONS

US is a safe imaging modality without any known ionizing radiation. There are no known contraindications to using US to identify and remove a foreign body.

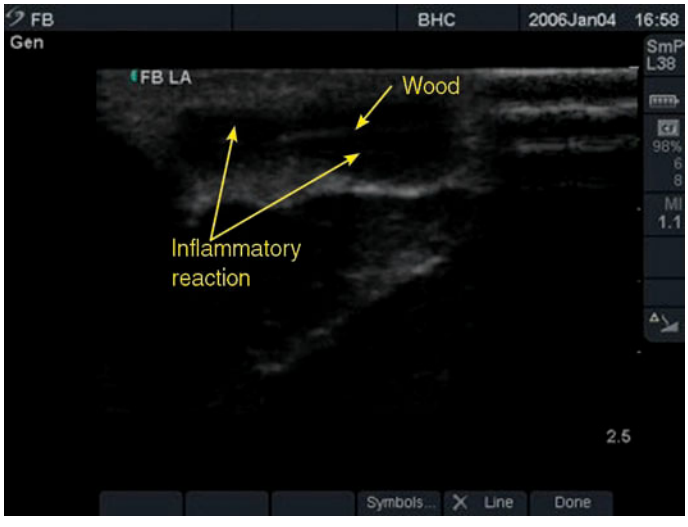

FIGURE 98-4. US image of a subcutaneous wood foreign body that has been in place for over 24 hours. The inflammatory reaction forms an anechoic rim around the foreign body (Courtesy of James W. Tsung, MD, MPH).

EQUIPMENT

- US machine
- High frequency linear US probe
- Sterile US probe cover or glove
- Skin cleansing solution (chlorhexidine or povidone iodine)
- Sterile US gel (or other type of sterile gel, i.e., Surgilube)
- #11 scalpel blade
- Suture kit or individual components (sterile drape, gauze pads, hemostat, and forceps)
- Local anesthetic solution, usually lidocaine
- 5 mL syringes
- 27 gauge needles
- 18 gauge needle to draw up local anesthetic solution
- Skin marking pen
- Paperclips
- Stand-off pad (or a 50 mL or 100 mL saline bag)

PATIENT PREPARATION

Obtain informed consent in which the risks, benefits, and any alternative treatment modalities are discussed. Cleanse the skin of any dirt and debris. Apply a liberal amount of US gel over the area in which the foreign body is suspected. Use a high frequency linear US probe to search for the foreign body. Look for signs of the foreign body such as reverberation artifact, comet-tail artifact, acoustic shadowing, a hypoechoic rim surrounding an echogenic structure, or any other signs associated with foreign bodies.

Foreign bodies may be very superficial. It may be necessary to change the focal zone on the US machine. An acoustic interface may assist in locating a superficial foreign body. Apply a stand-off pad over the site of the foreign body. This can be either a commercially available stand-off pad, a small saline bag in which the air is removed, or a glove filled with saline or US gel.[17,41] The water bath technique works well for the hands and feet. Place the body part

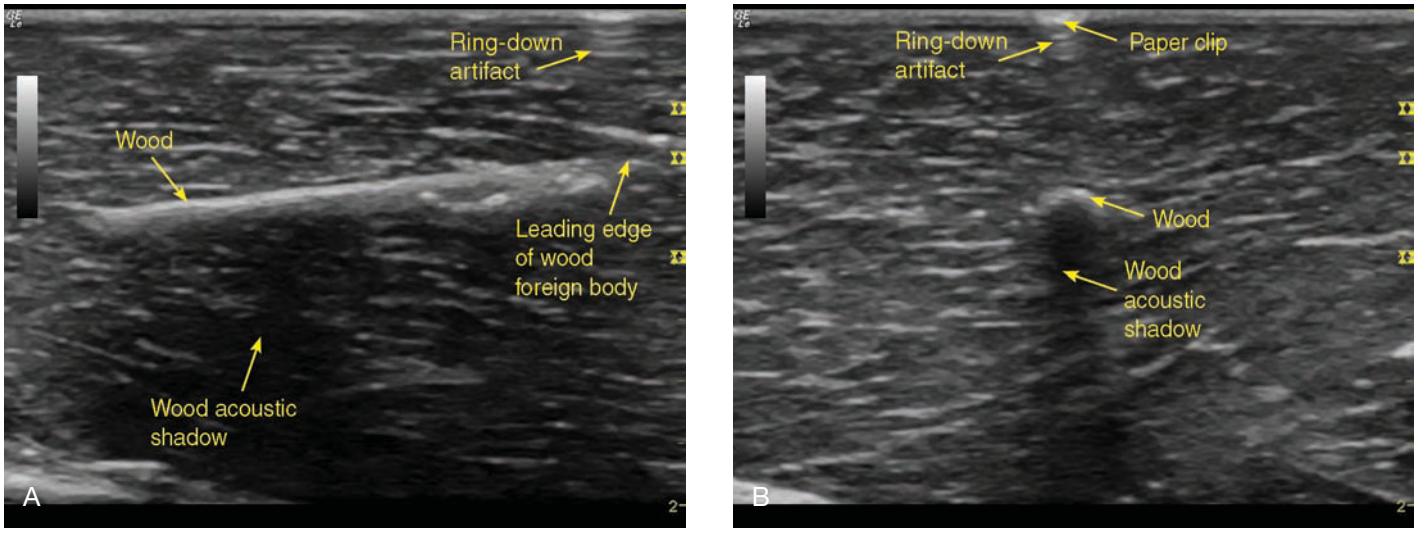

FIGURE 98-5. Paper clip localization of a foreign body. The wood foreign body has a bright echogenic reflection and casts an acoustic shadow. The paper clip casts a ring-down or reverberation artifact that is lined up over the leading edge or most superficial aspect of the foreign body. **A.** Long axis US view. **B.** Short axis US view.

in a water-filled container. Place the US probe in the water-filled container without actually contacting the patient's skin. Identify the presence of a foreign body. Once identified, it must be localized to make removal easier for the patient and the Emergency Physician.

TECHNIQUE

PAPER CLIP LOCALIZATION AND REMOVAL

Since the foreign body is located under the skin, its location should be marked on the patient's skin. It is helpful to use a metal foreign body, such as a paper clip, to create a shadow to locate the foreign body. The metal paper clip will cast a distinct shadow.

Identify the foreign body on US. Place the US probe on the patient's skin above the foreign body. Turn the US probe so its long axis is aligned with the long axis of the foreign body. Insert the tip of an unfolded paper clip between the US probe and the skin surface. Slowly advance the paper clip until the shadow it casts aligns with the leading edge (the most superficial aspect) of the foreign body (**Figure 98-5**). Use a skin marker to mark this location on the patient's skin. Rotate the US probe 90° to visualize the short axis or cross-sectional view of the foreign body. Insert the tip of the unfolded paper clip between the US probe and the patient's skin. Mark the location on the patient's skin where the shadow cast by the paper clip aligns with the leading edge of the foreign body. The intersection of these two lines is where the leading edge of the foreign body resides under the skin.

Prepare to remove the foreign body. Prepare a 5 mL syringe with a 27 gauge needle and local anesthetic solution. Cleanse the patient's skin with chlorhexidine or povidone iodine solution and allow it to dry. Apply sterile drapes to form a sterile field. Inject local anesthetic solution subcutaneously around the skin markings over the leading edge of the foreign body.

Prepare the US probe. Apply US gel to the footprint of the US probe. Apply a sterile probe cover or a sterile glove over the US probe. Squeeze any air out of the space between the US probe and the cover. Apply sterile US gel on the probe cover.

The Emergency Physician should don sterile gloves. The use of a hat, face mask, and sterile gown is not necessary for this procedure. Grasp the US probe with the nondominant hand. Align the long axis of the US probe along the long axis of the foreign body, and approximately 3 to 4 mm proximal to the skin markings. Aim the syringe containing the local anesthetic solution downward and in the direction of the foreign body. Slowly insert and advance the needle through the skin mark under US guidance while slowly injecting a small volume of local anesthetic solution. The injection of local anesthetic solution around the foreign body creates a hypoechoic halo that helps with the identification of the foreign body. Stop advancing the needle when the tip reaches the foreign body. Remove the needle without moving the US probe.

Use a #11 scalpel blade to make a small skin incision just proximal to the skin mark and in an area that has been previously anesthetized. Insert the jaws of a closed hemostat or the arms of a closed alligator forceps into the skin incision. Advance the instrument under US guidance and bluntly dissect down to the foreign body. Align the tip of the instrument with the leading edge of the foreign body (**Figure 98-6**). Open the instrument, grasp the foreign body, and remove it.

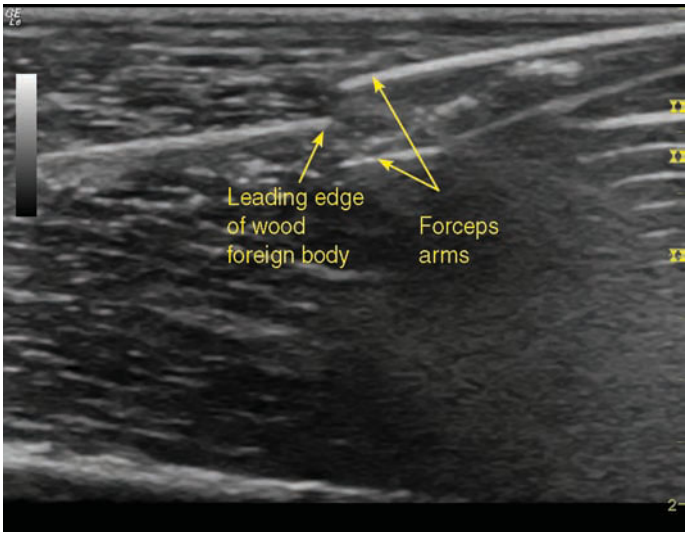

FIGURE 98-6. Retrieval of the foreign body. US image of the forceps approaching a wood foreign body. Note that the arms of the forceps are open and in line with the foreign body.

NEEDLE LOCALIZATION AND REMOVAL

Identify the foreign body using US. Cleanse the skin, apply sterile drapes, prepare the syringe, and prepare the US probe as described above. Infiltrate local anesthetic solution subcutaneously in the area overlying the foreign body. Align the long axis of the US probe with the long axis of the foreign body. Insert a 27 gauge needle in front of the US probe. Slowly advance the needle under US guidance until its tip is against the foreign body. Release the needle with the dominant hand and grasp a #11 scalpel. Insert the #11 scalpel blade along the needle until the tip of the blade is at the tip of the needle. Remove the scalpel blade and needle without moving the US probe. Insert a forceps, hemostat, or alligator forceps along the incision track under US guidance. Open the instrument, grasp the foreign body, and remove it.

ASSESSMENT

It is important to rescan the area after removal of the foreign body to ensure there is no additional foreign body or a retained piece of the original foreign body which needs to be retrieved. Foreign bodies may not be removed in their entirety. A second foreign body may be present in an injury and not visible on the initial US scans.

AFTERCARE

Ensure that the foreign body is completely removed. There are many different thoughts on the care of wounds. Copiously irrigate the area. A review of the Cochrane Database indicates that there is no evidence that using tap water to cleanse acute wounds in adults increases infection; while some evidence suggests that it reduces infection rates.[42] There is no strong evidence that cleansing wounds per se increases healing or reduces infection.[42] Close any lacerations from the wound itself or from the procedure to remove the foreign body. There is no strong evidence to support the use of antibiotics in simple non-bite wounds.[43] Wounds associated with foreign bodies are at an increased risk for infection. Instruct the patient to be aware of the signs and symptoms of an infection. In one review, 44.4% of all subjects with a foreign body removed were prescribed antibiotics.[44] However, when consultants were utilized in the care of these patients, this number rose to 84.4%.[44] A short course of antibiotics may be appropriate to prevent iatrogenic septic complications or sequelae caused by mobilization of the foreign body.[45]

COMPLICATIONS

Foreign bodies, as well as the procedures to remove them, have been associated with infections (e.g., flexor synovitis, cellulitis, gas gangrene, abscesses, osteomyelitis, fungal infections, and lymphangitis), laceration of adjacent structures (e.g., nerves and tendons), neuropraxia, inclusion cysts, fractures, arthritis, and even an angiosarcoma.[13,23,40,46,47] Even though attempts are made to identify and remove all foreign bodies, some of them may be missed. A retained foreign body can lead to similar symptoms at a later time.[48] **Therefore, it is important to investigate and remove foreign bodies in a timely manner.**

SUMMARY

Foreign bodies are a major source of physician litigation. They are often not detected on standard radiographs and can be associated with complications. A high index of suspicion must be maintained when the patient has a laceration, soft tissue mass, or foreign body sensation. US can be used to identify and guide the removal of foreign bodies in the Emergency Department.

99 Tick Removal

Zach Kassutto

INTRODUCTION

Ticks are blood-feeding external parasites (**Figure 99-1**). Ticks are a significant infectious disease problem in the United States as well as worldwide. They have been implicated as vectors in the transmission of many diseases including Lyme disease, ehrlichiosis, babesiosis, Rocky Mountain spotted fever, tularemia, tick paralysis, and tick-borne relapsing fever. Disease transmission is postulated to occur when stomach contents and saliva from the tick are introduced into the host during the blood-feeding process. There is significance in how long a tick has been attached and how quickly a feeding tick can be removed to the transmission of tick-borne diseases. Early removal is felt to limit the transmission of disease. For example, current entomological thinking suggests that the tick must be attached for at least 24 hours in order to transmit *B. burgdorferi*, the spirochete responsible for Lyme disease.[1]

ANATOMY AND PATHOPHYSIOLOGY

There are two main families of ticks.[2] Hard body ticks belong to the Ixodidae family. Soft body ticks belong to the Argasidae family. Hard body ticks are responsible for the transmission of the majority of human diseases and will be the focus of this chapter. Hard ticks pass through four life cycle stages from birth (egg, larva, nymph, and adult). They require a blood meal in order to progress into the next stage of their development.

The bite of a tick is painless and often goes unnoticed unless the tick is found attached to the skin. Ticks are often encountered in the late spring, summer, and early fall. Ticks are more prevalent in rural and wooded areas. They like to feed in dark (covered) and moist areas of the body such as the axilla, groin, or scalp.

Ticks have specialized mouthparts that make their removal difficult (**Figure 99-2**).[2] They screw their mouthparts into the skin in a clockwise direction. Mouthparts include the palps, the chelicerae, and the hypostome. The chelicerae are used to cut through the host's epidermis and allow passage of the tick's hypostome, through which the feeding takes place. Ticks attach themselves to their host by inserting the rod-like hypostome into the skin. The hypostome

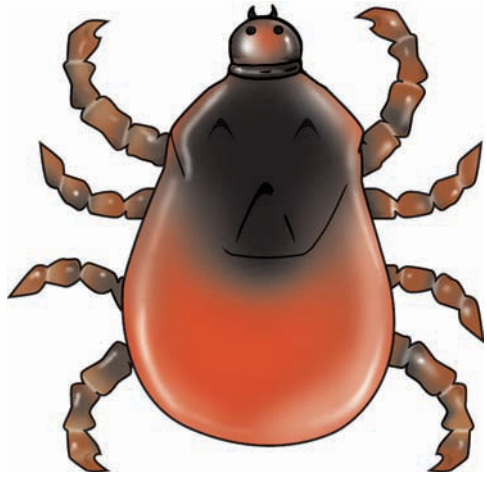

FIGURE 99-1. The tick.

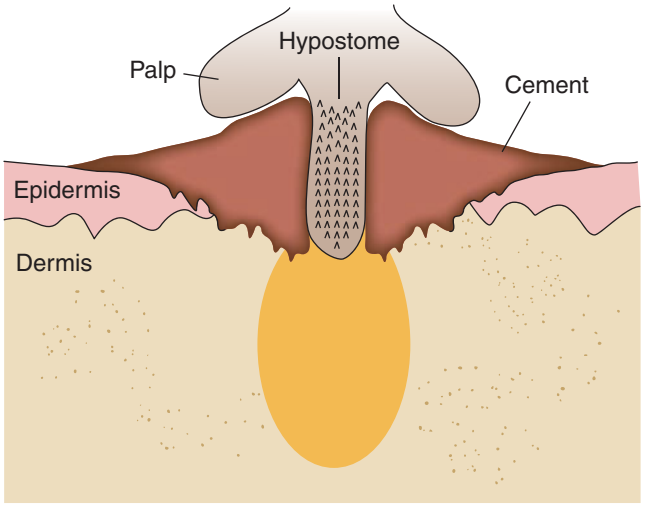

FIGURE 99-2. The specialized mouthparts of the tick.

has many backward pointing sharp barb-like projections that prevent it from being pulled out. Additionally, some ticks secrete a cement-like material around the hypostome to secure its attachment to the host while it feeds. The longer the tick is attached, the more difficult it becomes to remove it intact. The tick releases its mouthparts from the host after the meal is complete. It can take anywhere from hours to days for an adult tick to finish its blood meal and detach from its host.[4]

INDICATIONS

Any tick found attached to the skin should be removed. Transmission of bacteria, spirochetes, viruses, or other infectious agents is directly related to length of time of attachment. Ticks attached less than 24 hours are very low risk for transmission of disease.[3]

CONTRAINDICATIONS

There are no absolute or relative contraindications to the removal of a tick.

EQUIPMENT

Required Equipment

- Povidone iodine solution, chlorhexidine solution, or isopropyl alcohol swabs
- Gloves
- Fine forceps or mosquito hemostat

Optional Equipment

- Magnifying headlamp
- 18 gauge needle
- Local anesthetic solution
- 3 mL syringe with a 27 gauge needle
- Skin biopsy punches
- #15 surgical scalpel blade on a handle
- 5-0 nylon suture
- Specimen container with isopropyl alcohol
- Commercial tick removal device[10]

PATIENT PREPARATION

Explain the risks and benefits of the procedure to the patient and/or their representative. Risks include failure to remove all tick parts and infection. Obtain an informed consent for the procedure. Clean any dirt and debris from the skin. Apply povidone iodine or chlorhexidine solution to the skin surrounding the tick and allow it to dry. An alcohol swab can be used as a substitute.

TECHNIQUE

Direct mechanical removal of the tick is the only recommended technique.[4] Grasp the tick tightly with a fine forceps or mosquito hemostat at the tick's head or mouthparts, as close to the patient's skin as possible (**Figure 99-3A**). **Do not crush, puncture, squeeze, or tear the ticks' abdomen.** Apply firm and upward pressure to remove the tick (**Figure 99-3B**). **Carefully examine the skin for any remaining portions of the tick's mouthparts.** Gently grasp and remove any retained parts of the tick with a fine forceps or tease them out with the tip of a sterile needle.

Direct traction is the preferred method, although some have suggested that a rotary counterclockwise movement combined with the firm pull may be more effective.[4] Another technique that has been described suggests first rotating the tick two complete revolutions around its axis to loosen its attachment prior to pulling it away from the skin.[5] The premise is that the twisting action will disengage the tick's mouthparts. There is not enough information to recommend or refute these methods.

ALTERNATIVE TECHNIQUES

Some Emergency Physicians prefer a surgical technique to remove the tick and its attachment to the skin to ensure that no fragments of the tick mouthparts remain within the patient. Clean and prep the skin. Inject 0.25 to 0.50 mL of local anesthetic solution subcutaneously immediately underneath the tick's mouthparts. Apply povidone iodine or chlorhexidine solution to the skin and allow it to

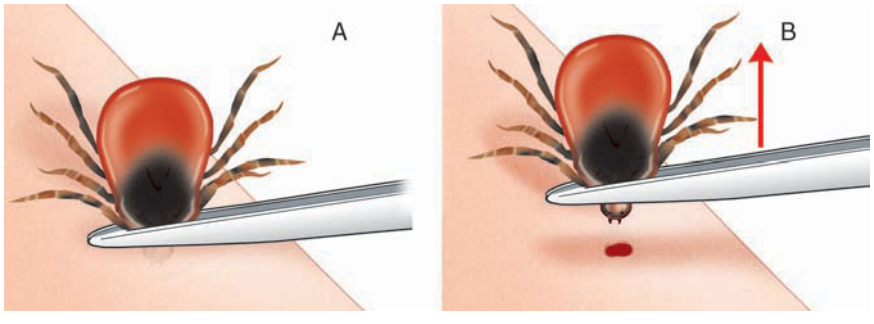

FIGURE 99-3. Removal of the tick. **A.** The tick is grasped as close to the skin as possible. **B.** Firm upward pressure is applied to remove the tick.

dry. Stretch the skin on each side of the tick with the nondominant hand. Apply the skin biopsy punch perpendicular to the skin. Make sure that the tick is centered within the skin biopsy punch. Advance the skin biopsy punch downward using a twisting (clockwise–counterclockwise) motion until a loss of resistance is felt. The loss of resistance indicates that the skin biopsy punch is through the epidermis and at the level of the dermis. Remove the skin biopsy punch. Grasp and lift the punched skin plug with a forceps. Cut the plug at the dermal-epidermal junction with an iris scissors or a #15 scalpel blade. Alternatively, remove the tick and skin with a #15 surgical scalpel blade. At the Emergency Physician's discretion, close the skin site with a single 5-0 nylon suture or leave it open to granulate and heal.

Patients or their family members may use variety of folk/home therapies in their efforts to either passively or actively remove ticks. Techniques that involve coating the tick with noxious materials such as kerosene, lidocaine, or nail polish to cause the tick to voluntarily withdraw its attachment have not been shown to be successful.[4,6] Techniques that attempt to suffocate the tick with petroleum jelly are also not felt to be useful due to the low respiratory rate of 3 to 10 breaths per hour in a feeding tick.[5] The use of a heated object, e.g., a match tip or piece of metal, applied to the abdominal surface of the tick has not been shown to effect rapid tick detachment and presents a risk of burning the patient. Subcutaneous injection of local anesthetic solution at the attachment site was studied and was found to be ineffective in stimulating tick detachment.[7] There are specific devices that are commercially available and advertised to aid in manual tick removal. Some of these devices have been tested and are not felt to offer any advantage over forceps removal.[8–10]

ASSESSMENT

After removing the tick, carefully inspect the bite site to ensure no foreign material has been retained. Ticks can usually be discarded as testing of the tick is usually not indicated. If testing is desired, place the tick in a specimen container with isopropyl alcohol until testing can be performed by a laboratory or the local public health department.

AFTERCARE

Cleanse the area with a mild disinfectant or soap and water. Administer tetanus prophylaxis if the patient's immunization history is not up-to-date. The appearance of any rash or the occurrence of any febrile illness 2 to 12 days after a documented tick exposure should prompt further medical follow-up. Provide the patient information regarding the signs and symptoms of Lyme disease and/or other tick-borne diseases seen in your specific geographical area. The patient should inspect the site twice a day for signs of an infection. They should return to the Emergency Department or their Primary Care Physician if they develop redness, tenderness, swelling, a discharge, or a rash at the bite site.

A detailed discussion identifying the types of ticks or the indications for prophylactic antibiotic therapy is beyond the scope of this chapter. Consult the current medical literature or an Infectious Disease Specialist regarding these questions. The use of prophylactic oral antibiotics to cover typical skin flora or Lyme disease is not routinely recommended. If antibiotics are prescribed, options include 5 to 7 days of: doxycycline (100 mg bid), tetracycline (500 mg qid), amoxicillin-clavulanate (400 to 875 mg bid), levofloxacin (500 mg qd), or erythromycin (125 to 500 mg qid). Do not prescribe doxycycline, tetracycline, or levofloxacin in children and pregnant women to avoid associated complications.

Patients should be educated about ticks and preventative measures to avoid tick bites. Prevention is the best protection. When outdoors, patients should be advised to wear clothes to cover their arms, legs, and torso; tuck the cuffs of pants into boots; apply a repellent (chemical or botanical in origin) or an insecticide to clothes and exposed skin; and physically check for the presence of ticks at the end of the activity or the end of the day.

COMPLICATIONS

The major complication of the direct removal technique is the separation of the tick body from the embedded head. Leaving foreign material in the wound can serve as a site for subsequent infection.[5] Any remaining pieces of the tick should be removed using an 18 gauge needle, a skin biopsy punch, or sharp dissection with a #15 scalpel blade.

Inadvertent crushing of the tick may allow stomach contents or saliva from the tick to enter the wound. It is theorized that grasping the tick too distal to its head, across its thorax/abdomen, could induce regurgitation of stomach contents into the wound and increases the risk of disease transmission.[5]

Local complications include bleeding and infection. The application of direct pressure will control any bleeding. A cellulitis presents a few days after the bite and is often due to the ticks feeding process, skin contamination entering the bite site, or retained mouthparts. Carefully inspect the bite site to ensure there are no retained mouthparts. If unsure, use a skin biopsy punch to remove the bite site. Treat the cellulitis with oral antibiotics that cover typical skin flora.

SUMMARY

Ticks are a vector for numerous serious diseases and should be removed from the skin as soon as they are identified. Disease transmission is felt unlikely if the tick has been attached less than 24 hours. The only recommended technique for tick removal is manual detachment using forceps.

100 Fishhook Removal

Eric F. Reichman and Renee C. Hamilton

INTRODUCTION

Depending on practice location and season of the year, the presentation of a fishhook embedded in the subcutaneous tissue can be common. The patient or a well-meaning bystander will often have already attempted removal that was prevented by the hook's barb. The ensuing tissue trauma and patient anxiety can complicate the task for the Emergency Physician. Removal can be difficult as a fishhook is designed not to pull out of a fish's mouth. Several methods of removal have been described.[1–9] The method chosen depends on the type and size of the hook, the depth of penetration, and the anatomical location of injury.

ANATOMY AND PATHOPHYSIOLOGY

Most fishhooks become embedded in the skin and subcutaneous soft tissue. The anatomy of a fishhook is simple (**Figure 100-1**). The long, straight section is known as the shaft. The proximal end of the shaft has a closed circle, the eyelet, where the fishing wire attaches. The distal end of the shaft curves in a semicircle known as the belly of the fishhook. The belly tapers into a sharp point with a barb. The

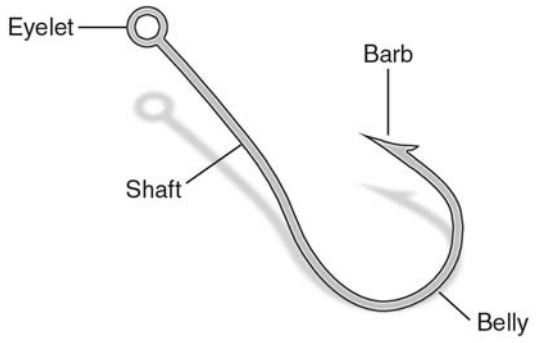

FIGURE 100-1. Anatomy of a fishhook.

barb is usually located on the inner surface of the hook, pointing away from the tip. The barb, once pierced through the skin, becomes embedded within the tissue and prevents removal of the fishhook. Additional barbs may be located along the shaft of the fishhook.

INDICATIONS

Any embedded fishhook must be removed from the body. There is no reason a fishhook should not be removed by the Emergency Physician if no contraindication exists.

CONTRAINDICATIONS

There are no absolute contraindications to fishhook removal. Occasionally, the procedure should be referred to a consultant. Globe perforation or laceration requires emergent consultation with an Ophthalmologist. Place the patient supine with a shield, not a patch, over the eye. Please see Chapter 161 for the complete details regarding eye patching and eye shields. **Penetration of, or near, vital structures (e.g., the neck, groin, or major neurovascular structures) should be given consideration for the appropriate surgical consultation prior to removal of the fishhook.**

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Local anesthetic solution without epinephrine
- 3 mL syringe armed with a 25 gauge needle
- Wire cutter
- Needle driver
- Hemostat
- 18 gauge needle
- #11 scalpel blade on a handle
- String, fishing line, or a strong silk tie, at least 50 cm in length
- Tongue depressors
- Safety glasses/goggles or a face mask with an eye shield

PATIENT PREPARATION

Explain the risks and benefits of the procedure to the patient and/or their representative. Ask the patient to describe the type of fishhook embedded, especially in regards to the number and location of the barbs. Ask the patient to draw a picture of the fishhook or provide you with a similar one to examine. The number and location of the barbs will help in determining the appropriate removal technique. Obtain a signed consent form prior to beginning the procedure. Cleanse the skin of any dirt and debris. Apply povidone iodine or chlorhexidine solution to the skin surrounding the embedded fishhook and allow it to dry. **The Emergency Physician should wear eye protection when removing a fishhook to prevent injuring themself.** At minimum, wear safety glasses or goggles. If available, a face mask with an eye shield is preferred.

TECHNIQUES

PULL-THROUGH TECHNIQUE

This is the traditional method that is used for larger sized hooks embedded in the soft tissue with the barb near the skin surface. This is the preferred technique for fishhooks embedded in the ear, a joint, or in the nasal cartilages. Experienced fishermen often perform this technique in the field, as they would hate to lose prime fishing time to go to the Emergency Department.

Identify the barbed end of the fishhook, located under the skin surface. Inject 0.5 to 1.0 mL of local anesthetic solution into the subcutaneous tissue overlying the barbed end of the fishhook to raise a skin wheal (**Figure 100-2A**). Allow 3 to 4 minutes for the local anesthetic solution to take effect. Grasp the shaft of the fishhook with a needle driver (**Figure 100-2B**). Advance the fishhook until the barbed end protrudes through the anesthetized skin (**Figure 100-2B**). **Securely clamp a hemostat over the barb.** This

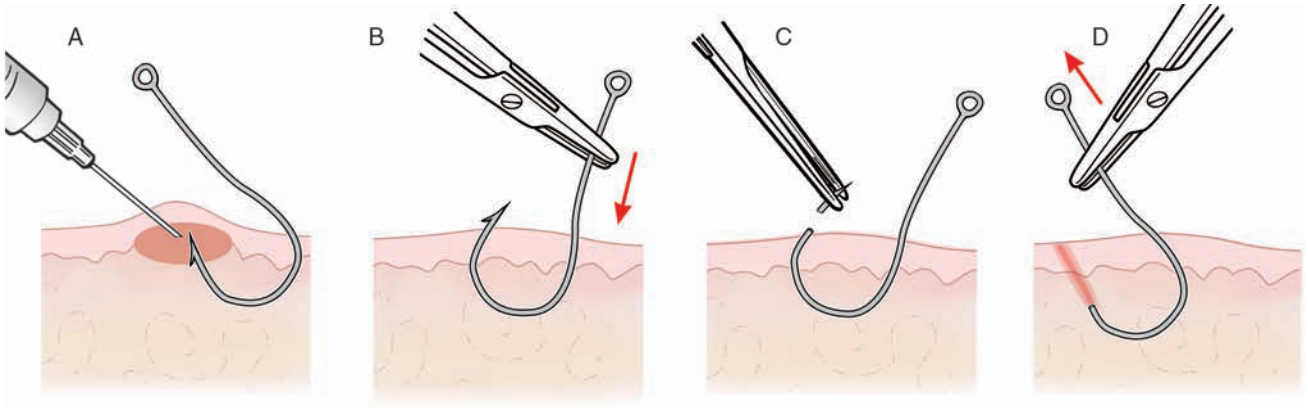

FIGURE 100-2. The pull-through technique for fishhook removal. **A.** Subcutaneous anesthetic is placed over the barb. **B.** The fishhook is advanced until the barb protrudes from the skin. **C.** A hemostat is placed over the barb before it is cut off with wire cutters. **D.** The fishhook is removed.

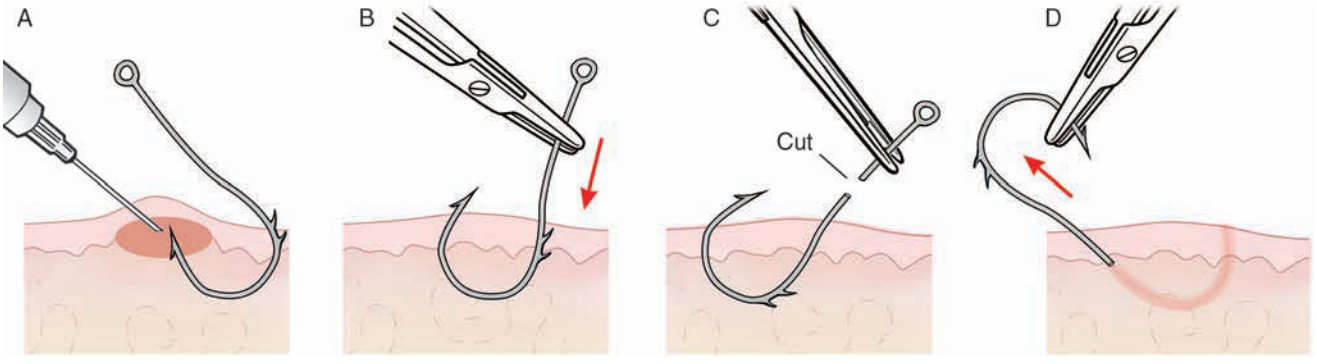

FIGURE 100-3. An alternative pull-through technique for the removal of a multibarbed fishhook. **A.** Subcutaneous anesthetic is placed over the barb. **B.** The fishhook is advanced until all of the proximal barbs are under the skin. **C.** The shaft is cut. **D.** The fishhook is removed.

will prevent it from becoming a projectile when cut and injuring someone. Cut the belly of the fishhook just proximal to the barbed end with a wire cutter (**Figure 100-2C**). Grasp the shaft of the fishhook with the needle driver and withdraw it along its direction of entry (**Figure 100-2D**).

Occasionally, fishhooks may have additional barbs on the shaft or the belly (**Figure 100-3**). Inject 0.5 to 1.0 mL of local anesthetic solution into the subcutaneous tissue overlying the barbed end of the fishhook (**Figure 100-3A**). Allow 3 to 4 minutes for the local anesthetic solution to take effect. Grasp the shaft of the fishhook with a needle driver (**Figure 100-3B**). Advance the fishhook until the barbed end protrudes through the anesthetized skin (**Figure 100-3B**). Continue to advance the fishhook until all the barbs on the belly and shaft are below the skin surface (**Figure 100-3B**). Securely clamp a hemostat over the proximal shaft of the fishhook (**Figure 100-3C**). Cut the shaft of the fishhook at the level of the skin with a wire cutter (**Figure 100-3C**). Grasp the fishhook just proximal to the barbed end with the needle driver and pull the remainder of the fishhook out of the tissues (**Figure 100-3D**).

BARB-SHEATH TECHNIQUE

This method is reserved for small fishhooks embedded near the skin surface. This technique should not be used for fishhooks in the ear, nose, or a joint cavity. Inject 0.5 to 1.0 mL of local anesthetic solution to form a wheal subcutaneously around the area where the fishhook enters the skin. Insert an 18 gauge needle along the entrance wound and aimed toward the barb (**Figure 100-4A**). The bevel of the needle should face the barb with the goal being to engage and cover the barb. Advance the needle and engage the barb in the core of the needle (**Figure 100-4B**). Gently twist and pull the hook back through the entrance wound while the needle covers the barb (**Figure 100-4C**).

An alternative method is to insert a #11 scalpel blade parallel to the shaft of the fishhook at the site it enters the skin. Advance the scalpel blade until it is adjacent to the barb. Withdraw the fishhook and scalpel through the tract. The barb will be resting against the scalpel blade and not get embedded in the subcutaneous tissues. This method is not recommended due to the blind insertion of a scalpel blade into the soft tissues and the potential for secondary injury.

STRING-YANK TECHNIQUE

This method has been extensively described and is often performed by experienced fishermen in the field. It is rapid, effective, easy to perform, and relatively painless. This technique should not be used for fishhooks in the ear, nose, or a joint cavity. **The Emergency Physician should take caution for themselves, the patient, and bystanders. The hook often forcibly flies out of the patient. Ensure the suspected path of the fishhook is clear. Eye protection is recommended with this technique for both the Emergency Physician and the patient.**

Place the body part that the fishhook entered firmly on a flat surface. Local anesthetic solution can be infiltrated, at the Emergency Physicians discretion, into the area where the fishhook enters the skin. Wrap the midpoint of a long string around the belly of the fishhook at the site it enters the skin (**Figure 100-5A**). The string ends should be firmly wrapped around and secured to the index and middle fingers of the Emergency Physician's dominant hand. Use the gloved nondominant thumb or index finger to firmly depress the shaft of the fishhook against the skin, until slight resistance is met (**Figure 100-5B**). The shaft should be parallel to the skin and touching the skin. This will disengage the barb from the soft tissues. Quickly and firmly jerk the string (**Figure 100-5C**). This maneuver will release the fishhook from the subcutaneous tissues and pull it out through the entry wound.

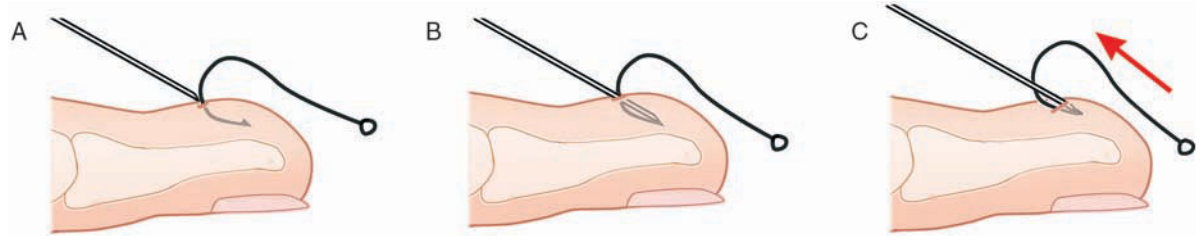

FIGURE 100-4. The barb-sheath technique for fishhook removal. **A.** Insert the needle through the entrance wound and aimed toward the barb. **B.** Advance the needle through the entry site to catch the barb in the core of the needle. **C.** The needle and fishhook are removed as a unit.

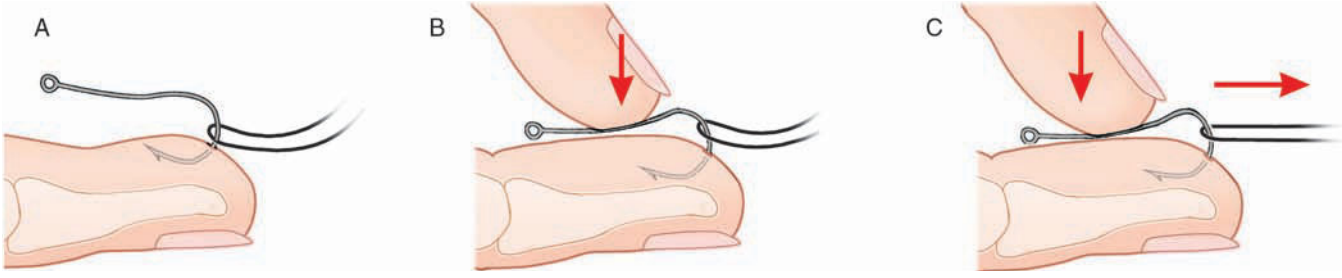

FIGURE 100-5. The string-yank technique for fishhook removal. **A.** A string is wrapped around the belly of the fishhook. **B.** The shaft of the fishhook is depressed until resistance is encountered. The shaft should be parallel to the skin and touching the skin. **C.** A quick tug on the string will remove the fishhook.

Alternatively, the Emergency Physician may use two tongue depressors to provide secure traction to the string. Wrap each end of the string around one tongue depressor. Instruct an assistant to gently depress the fishhook shaft against the skin while the Emergency Physician jerks the string.[6]

AFTERCARE

The wound should be cleaned of any blood and a dry dressing applied. Administer tetanus prophylaxis if the immunization history is not up-to-date. A radiograph is indicated if there is any suspicion of a retained foreign body. Acetaminophen or nonsteroidal anti-inflammatory drugs will provide any required analgesia. Instruct the patient to clean the area with warm soapy water three times a day and to keep the wound covered until healed. Instruct the patient as to the signs of infection. They should return to the Emergency Department, or their physician, if signs of an infection develop. Routine follow-up is often not required unless the fishhook penetrated the ear, nose, or a joint.

Antibiotic prophylaxis remains controversial.[1,2] The use of antibiotics is left to the discretion of the Emergency Physician and should include consideration for the anatomic site of injury, depth of penetration, evidence of gross contamination, and factors that may compromise the patient's immunity (e.g., diabetes mellitus, HIV infection, steroid use, or malignancy). If antibiotic prophylaxis is chosen, prescribe a broad spectrum antibiotic such as trimethoprim-sulfamethoxazole or doxycycline. These will provide good coverage against gram-negative organisms typically associated with water recreation injuries, as well as some coverage against MRSA and other community acquired infections.[7] Adding ciprofloxacin for pseudomonas coverage may also be considered, as pseudomonas and its subtypes are commonly found in soil and freshwater.[6]

COMPLICATIONS

Complications include infection or damage to the surrounding tissue. Infection is often due to either the contaminated fishhook inoculating the tissues or the fishhook penetrating contaminated skin. Using proper removal techniques will minimize, but not eliminate, any damage to the soft tissues.

Use caution when extracting fishhooks to avoid secondary injury to bystanders, the patient, or the Emergency Physician. Protective eyewear should be worn with all three techniques of fishhook extraction. Ocular injury has been reported to occur during this procedure.[2] Fishhooks have been surgically extracted from the hypopharynx and the intestine.[8,9] A surgical face mask with a face shield is another mode of protection that we recommend. When using the pull-through technique, clamping a hemostat to the exposed portion of the fishhook that is to be cut off will prevent flying shrapnel.

SUMMARY

Fishhook removal can be accomplished by one of several simple techniques. It can be performed in the Emergency Department, the office, or the field with minimal supplies. Almost painless removal is possible in most cases. This procedure is gratifying both for the patient and the Emergency Physician.

101 Ring Removal

Steven H. Bowman

INTRODUCTION

The need to remove a ring is not uncommon in the Emergency Department. Patients may present with an initial primary complaint that they can no longer remove a ring or that a ring has become painful. A variety of conditions may necessitate the urgent removal of a ring, including swelling from extremity trauma, infections or burns, increases in total volume status, and allergic reactions. Swelling of the digit can rapidly progress, causing the ring to become a constricting band and compromise blood flow to the digit. Critically ill patients undergoing admission to intensive care settings or emergency surgery may need to have rings removed urgently. **The Emergency Physician's goal is to remove the ring in a timely manner and not cause additional injury.** The information in this chapter applies to rings on the fingers and toes.

ANATOMY AND PATHOPHYSIOLOGY

The second through fourth digits receive their blood supply through four vessels: the palmar radial digital arteries, the palmar ulnar digital arteries, the dorsal radial digital arteries, and the dorsal ulnar digital arteries. The thumb receives its blood supply from the dorsalis pollicis and princeps pollicis arteries. Blood returns from the digits via the dorsal digital veins. When the digit is compressed for prolonged periods by a tight-fitting ring, which acts as a tourniquet, venous return is impeded and swelling ensues. The swelling results in greater compression and further propagation of this cycle. In theory, the increased swelling will eventually impede the arterial supply to the digit.

The greatest circumference of the finger is at the proximal interphalangeal (PIP) joint. Rings usually become entrapped proximal to the PIP joint. Skin breakdown and tissue necrosis occur if the constricting ring is not removed. Left untreated, the digit is at risk

for infections such as cellulitis, tenosynovitis, and osteomyelitis. In severe cases, the digit's viability may be threatened. There are several case reports of rings that have become embedded in the soft tissue of the digits.[1–5]

Most patients will experience pain and seek medical attention prior to the development of severe complications. Patients with an altered mental status, psychiatric illness, peripheral neuropathies, peripheral vascular disease, or other chronic disability may present later with complications.[1,2,4,5]

INDICATIONS

Rings are usually removed to prevent ischemia of a digit. Remove a ring if the digit shows any signs of neurovascular compromise such as decreased capillary refill, decreased pulse wave on pulse oximetry, mottling, paleness, paresthesias, or diminished sensation. Rings should be removed whenever patients complain that a ring is causing pain. Generally, even a tight-fitting ring will not be painful. Rings must be removed from any injured digit where edema is a possible consequence. Examples include sprains, contusions, fractures, lacerations, crush injuries, and burns. Rings should be removed from all digits on the involved side for any extremity injury above the digits and where edema of the distal extremity is a possible consequence. Other nontraumatic conditions that may necessitate emergent ring removal include infections of the upper or lower extremity, acute increases in volume status, and allergic reactions. A patient may present and request a ring be removed that is tight and can no longer be taken off. Consider the need for urgent ring removal with markedly decreased levels of consciousness and in all critically ill patients, particularly those being admitted to intensive care settings or undergoing emergent surgery.

CONTRAINDICATIONS

There are no absolute contraindications to removing a ring. It is important to note that certain techniques may be more applicable than others, depending on the individual patient.

EQUIPMENT

Metacarpal Block

- Povidone iodine or chlorhexidine solution, or an isopropyl alcohol swab
- 3 mL syringe
- 25 or 27 gauge needle, 1 in. long
- 3 to 5 mL local anesthetic solution without epinephrine

Lubricant and Caterpillar Techniques

- Lubricant (K-Y jelly, Surgilube, petrolatum, mineral oil, or liquid soap)

String Technique

- String (1-0 silk suture, cotton umbilical string, tracheal tape, Penrose drain, or intravenous tourniquet)
- Mosquito hemostat

Rubber Band Technique

- 3 to 4 mm wide rubber band
- Lubricant (K-Y jelly, Surgilube, petrolatum, mineral oil, or liquid soap)
- Mosquito hemostat

Glove Technique

- Rubber gloves
- Lubricant (K-Y jelly, Surgilube, petrolatum, mineral oil, or liquid soap)
- Mosquito hemostat
- Scissors

Ring Cutter Technique

- Ring cutter, manually operated or battery-powered
- Steinman pin cutter if a ring cutter is not available
- Two large hemostats or needle drivers
- Pliers (optional)

Vice-grips Pliers Technique

- Medium size vice-grip pliers

Miscellaneous Supplies

- Ice water
- Penrose drain or IV tourniquet
- Basin or zip-lock bag for ice water

PATIENT PREPARATION

Place the patient sitting upright or in a semi-recumbent position. Position their hand on a bedside procedure table. Explain the procedure to the patient and/or their representative. A signed informed consent is not required for the removal of a ring. Analgesia should be provided in the form of a metacarpal block for patients who are complaining of pain. Refer to Chapter 126 for the complete details regarding a metacarpal block.

The removal of a tight ring should be considered a two-step process: first reduce the edema in the finger, then remove the ring.[6] Instruct the patient to elevate the affected hand or foot to reduce edema prior to any attempts at ring removal. Use a finger trap to elevate the affected extremity if the patient has difficulty or cannot keep the extremity elevated. Consider soaking the hand or foot in ice water for 5 to 10 minutes to reduce edema. A Penrose drain, piece of tape, gauze, or elastic bandage can be wrapped around the finger, from distal to proximal, to further reduce swelling.

The simplest and most effective way to remove a ring from a finger is simply to cut the ring using a ring cutter. Reassure the patient that cut rings can be repaired by a jeweler. However, patients may still be reluctant to have expensive rings or rings with sentimental value removed in such a way. The practitioner must consider time, the individual circumstances regarding the entrapment, and which alternative techniques may be effective.

TECHNIQUES

LUBRICANT TECHNIQUE

This technique works for mild cases of ring entrapment with minimal swelling and without significant trauma. Many patients will attempt to remove the ring using some type of lubricant at home prior to presenting to the Emergency Department. Despite this, the same technique may also be tried in the Emergency Department prior to attempting other techniques. Liberally apply a lubricant (e.g., K-Y jelly, Surgilube, petrolatum, mineral oil, or liquid soap) to the digit and beneath the ring. Attempt to advance the ring over the PIP joint with steady traction.

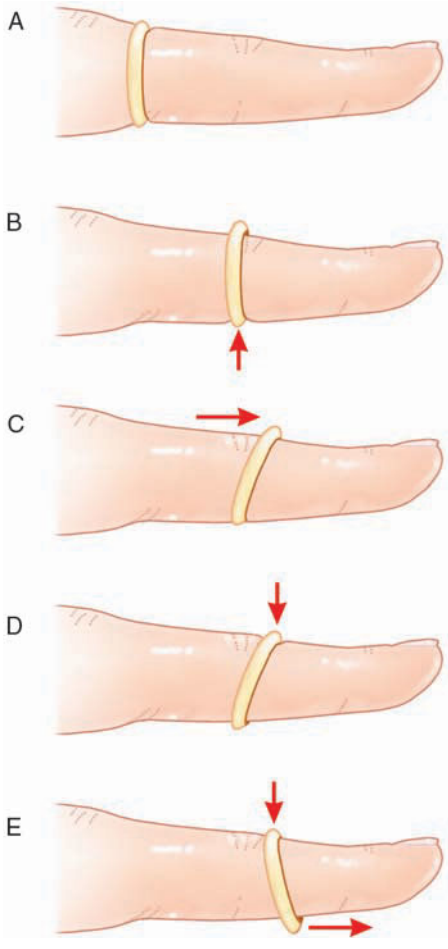

FIGURE 101-1. The caterpillar technique. **A.** The entire finger is lubricated. **B.** The ring has been pushed down the proximal phalanx until it reaches the PIP joint. Push the bottom of the ring up firmly while maintaining pressure. **C.** Swing the top portion of the ring distally over the joint while maintaining upward pressure. **D.** Push down firmly while maintaining downward pressure. **E.** Swing the bottom portion of the ring proximally over the joint and remove the ring.

CATERPILLAR TECHNIQUE

This recently described technique is useful in that it requires no additional materials other than lubricant (**Figure 101-1**).[7] Liberally apply a lubricant to the finger (**Figure 101-1A**). Slide the ring down the proximal phalanx and just proximal to the PIP joint. Apply and maintain upward pressure on the bottom of the ring (**Figure 101-1B**). Simultaneously swing the upper portion of the ring distally (**Figure 101-1C**). Pull the top of the ring over the PIP joint. Apply and maintain downward pressure on the top of the ring (**Figure 101-1D**). Simultaneously swing the lower portion of the ring distally to free it (**Figure 101-1E**). Remove the ring from the finger. This "caterpillar motion" allows the ring to be slowly advanced distally and ultimately removed.

STRING TECHNIQUE

Several authors have extensively described the string technique and its modifications[5,6,8,17] (**Figure 101-2**). This technique consists of using a "string" to compress the edematous tissue, exsanguinate the digit, and then facilitate the passage of the ring over the PIP joint. This technique should be avoided if the patient has an associated finger laceration, finger fracture, or an embedded ring.[8,9]

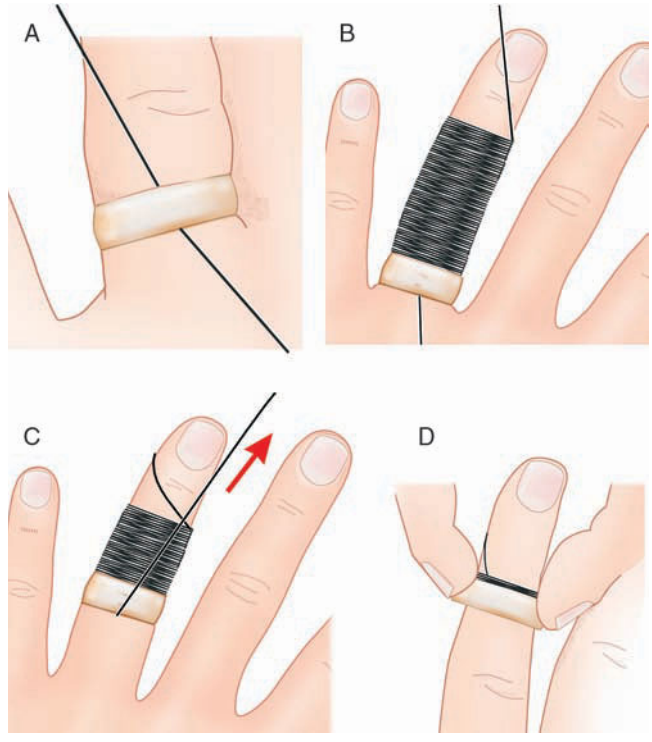

FIGURE 101-2. The string technique. **A.** A string is passed between the ring and the finger. **B.** The string distal to the ring is wound tightly around the finger and continued distally to the level just below the PIP joint. **C.** The string proximal to the ring is slowly unwound and moves the ring distally. **D.** When the ring passes the PIP joint, it usually comes off without effort.

Pass a length of 1-0 silk suture or a piece of string underneath the ring (**Figure 101-2A**). Avoid monofilament sutures and smaller-size sutures as they may break or inadvertently cut the patient if wound too tightly. Passage of the string or suture may be facilitated with the use of a mosquito hemostat.[8–10] Wind the distal portion of the suture tightly around the digit in a closed spiral (**Figure 101-2B**). **There should be no interposition of skin between the turns of the suture material so as to ensure even compression of the skin and soft tissue.** Continue the spiral distally to just beyond the PIP joint. Grasp the proximal end of the suture. Unwind the suture while maintaining traction in the distal direction (**Figure 101-2C**). The ring will be pushed distally as the suture unwinds. The ring is easily removed once it clears the PIP joint (**Figure 101-2D**).

Other materials—such as umbilical tape, cotton gauze, rubber intravenous tourniquets, or Penrose drains—have also been used.[6,11,12] These materials have certain practical advantages. Since they are wider than sutures, shorter lengths and fewer turns are required to encircle the finger. It is easier to wind these materials around the digit without interposition of the skin between the turns (**Figure 101-3**).

Insert the umbilical tape under the ring, from distal to proximal, with the aid of a mosquito hemostat (**Figure 101-3A**). Pull 6 to 7 cm of the umbilical tape proximal to the ring (**Figure 101-3B**). Wind the distal portion of the umbilical tape tightly around the digit in a closed spiral (**Figure 101-3C**). There should be no interposition of skin between the turns of the umbilical tape. Continue to spiral distally to just beyond the PIP joint (**Figure 101-3C**). Grasp the proximal end of the umbilical tape. Unwind the proximal end of the umbilical tape while maintaining traction in a distal direction

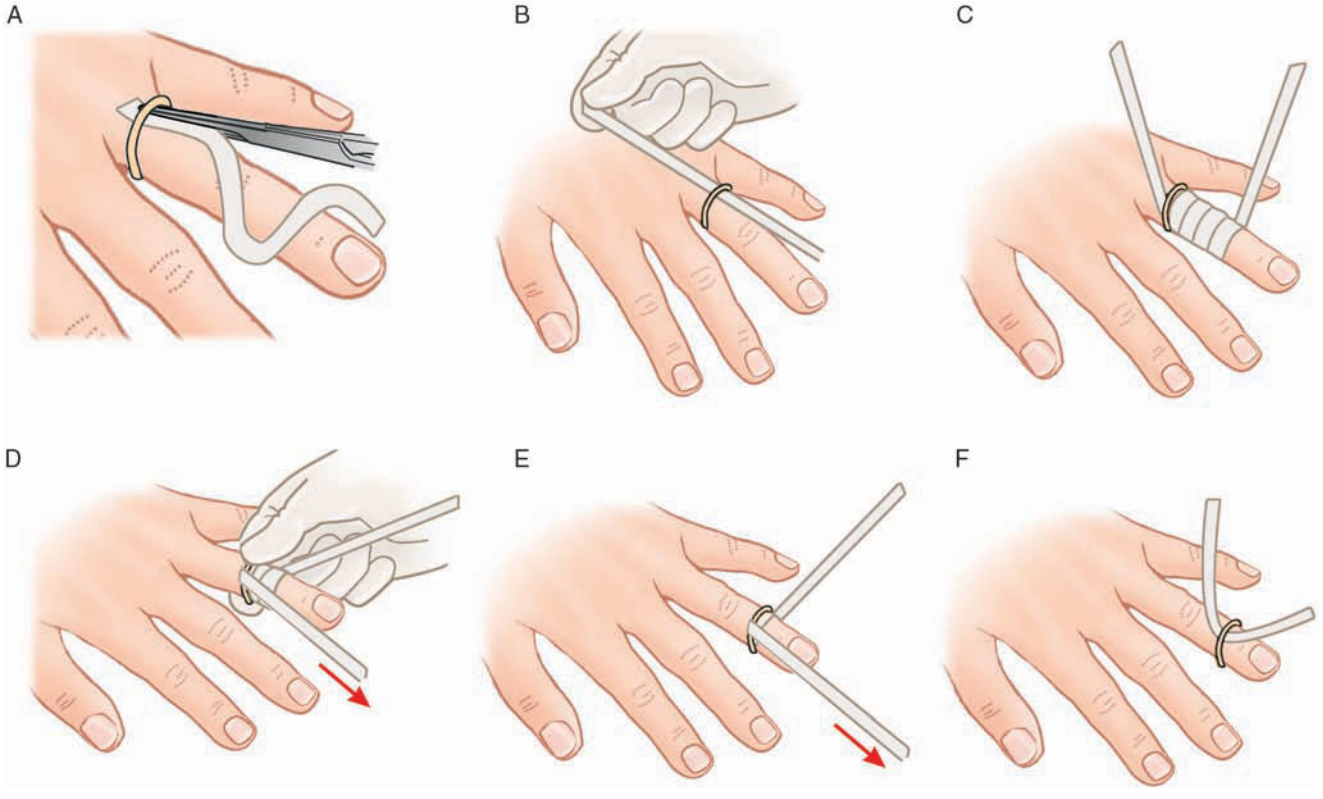

FIGURE 101-3. The string technique with umbilical tape. **A.** The umbilical tape is inserted under the ring with a mosquito hemostat. **B.** The umbilical tape is pulled through to the other side of the ring. **C.** The umbilical tape distal to the ring is wound tightly around the finger to the level just below the PIP joint. **D.** The umbilical tape proximal to the ring is slowly unwound and moves the ring distally. **E.** The ring passes the PIP joint. **F.** The ring is free and usually comes off without effort.

(**Figure 101-3D**). Continue to unwind the umbilical tape until the ring passes the PIP joint (**Figure 101-3E**). The ring is easily removed once it clears the PIP joint (**Figure 101-3F**).

RUBBER BAND TECHNIQUE

This technique utilizes a 3 to 4 mm wide rubber band, which is used to apply traction on the ring to facilitate its passage over the PIP joint[10] (**Figure 101-4**). Though success has been reported using rubber bands, this technique should be reserved for less severe ring entrapments. Avoid this technique if the patient has a laceration, a fracture, or an embedded ring.

Lubricate the finger liberally, as described above. Pass the rubber band beneath the ring using a mosquito hemostat (**Figures 101-4A & B**). Position the rubber band so that equal lengths are on each side of the ring (**Figure 101-4C**). Insert a finger through both loops of the rubber band (**Figure 101-4D**). Pull the loops of the rubber band distally while simultaneously moving them circumferentially between the ring and the finger (**Figure 101-4D**). Continue the motion until the ring is removed (**Figure 101-4E**).

GLOVE TECHNIQUE

This technique has been advocated for use in patients with underlying soft tissue injury to the finger.[13,14] Its success is anecdotal. The glove technique uses a finger cut from an appropriately sized rubber glove (**Figure 101-5**). The glove finger provides mild compression, acts as a barrier to protect damaged soft tissue, and provides a "leading edge" to guide the ring over the damaged tissues. Despite these theoretical advantages, the glove technique may be no more effective than any other in cases of severe finger edema.

Choose a glove that fits the patient snugly. Use the patient's other hand to aid in choosing the right size glove. Cut the finger from a glove to match the finger of the patient (**Figure 101-5A**). Cut off the tip of the finger of the glove to create a cylinder (**Figure 101-5A**). Slide the cylinder onto the patient's finger. Advance the proximal portion of the cylinder beneath the ring using a mosquito hemostat (**Figure 101-5B**). Lubricate the cylinder and the ring with K-Y jelly, Surgilube, petrolatum, mineral oil, or liquid soap. Pull the proximal edges of the latex cylinder distally, with your fingers or mosquito hemostats, to advance the ring distally (**Figure 101-5C**). Continue to pull on the proximal cylinder until the ring moves past the PIP joint and falls off the finger.

RING CUTTER TECHNIQUE

The definitive method for ring removal is cutting the ring. The ring should be cut if the patient presents with an underlying injury, severe swelling, an embedded ring, or entrapment with nonjewelry items. Cutting a ring is generally rapid and safe. A ring cutter can be used to cut rings made of gold, plastic, platinum, silver, stainless steel, and titanium.

Many devices will cut rings. The standard rotary ring cutter should be available in every Emergency Department (**Figure 101-6**). The ring cutter's blade should be periodically inspected and it should be sharp. Battery-powered ring cutters are also available (**Figure 101-7**) (Mooney & Co., Ashland, OR). The advantage of the powered ring cutters is that they are easy to use, lightweight, fast, powerful, can easily cut nonjewelry items, and do not rely on the strength of the healthcare provider to use them. In the absence of a ring cutter, another medical device that has been used successfully to cut rings is the Steinman pin cutter.[15] Our

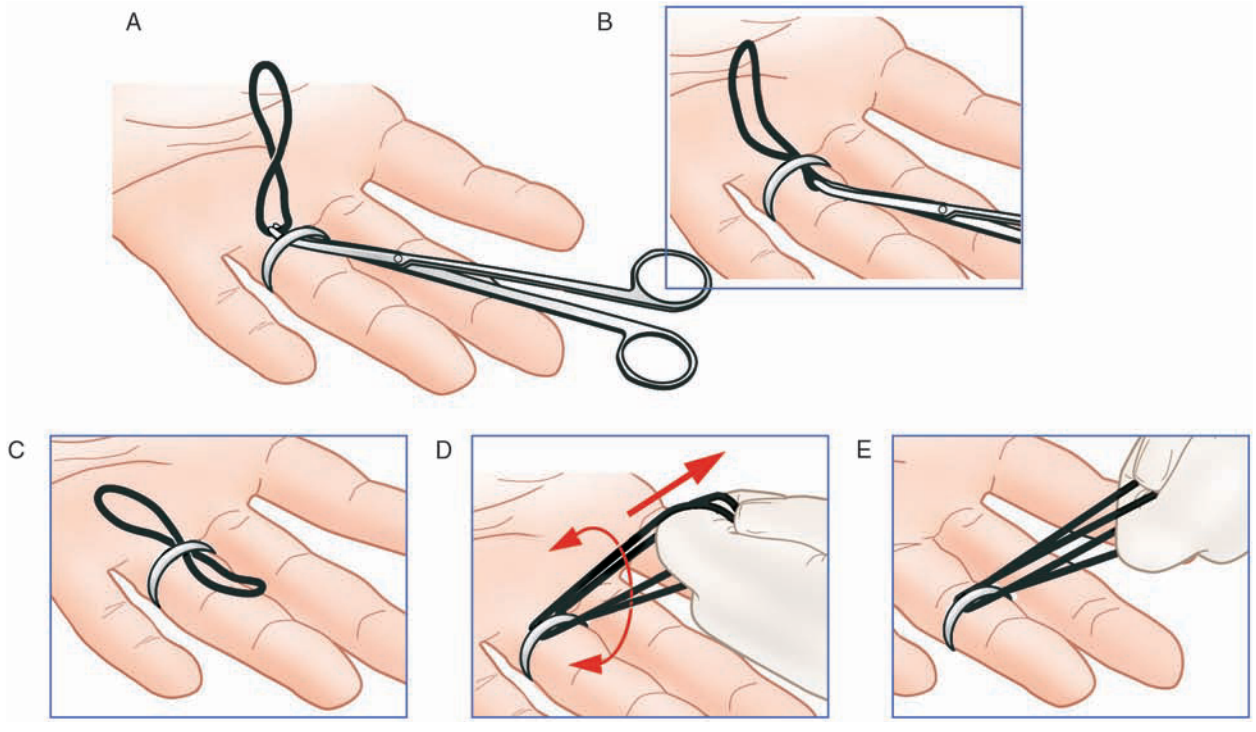

FIGURE 101-4. The rubber band technique. **A.** A mosquito hemostat is passed below the ring and grasps the rubber band. **B.** The rubber band is pulled beneath the ring and out the other side. **C.** The rubber band is positioned with equal lengths of loop on each side of the ring. **D.** Both loops of the rubber band are grasped and pulled distally while it is simultaneously rotated circumferentially. **E.** When the ring passes the PIP joint, it usually comes off without effort.

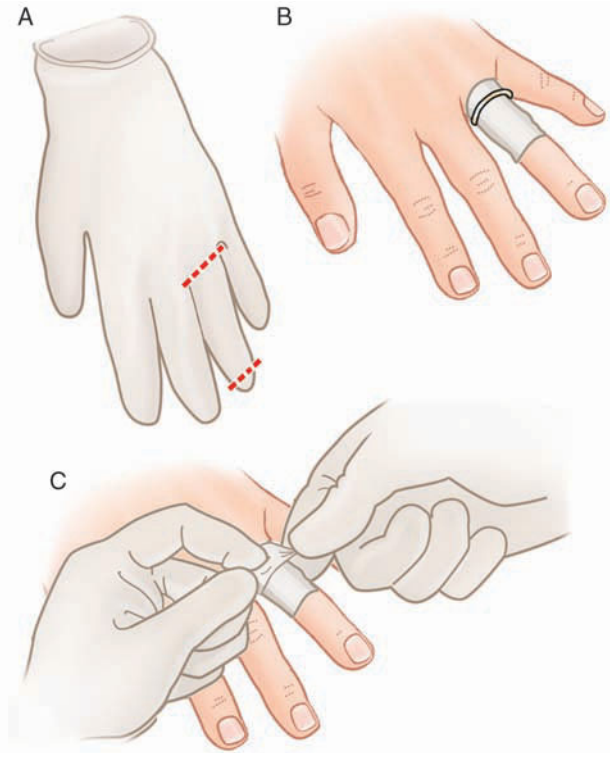

FIGURE 101-5. The latex glove technique. **A.** The finger matching the one on which the ring is lodged is cut from an examination glove. **B.** The latex cylinder is put on the finger. The proximal edges of the cylinder are pulled under and proximal to the ring using a mosquito hemostat. **C.** The proximal edges of the latex cylinder are slowly pulled distally to roll the ring off the finger.

Emergency Department also maintains a sharp pair of diagonal pliers that can be effective at cutting small rings.

Pass the finger guard of the ring cutter between the ring and the digit at the thinnest part of the ring (**Figure 101-8**). Care should be taken to place the ring cutter correctly and avoid additional injury. The ring may be squeezed using a heavy needle driver, hemostat, or pliers to change its shape from round to oval to facilitate passage of the finger guard (**Figure 101-9**). This additional distortion of the ring will not further exacerbate the entrapment.[15] Lower the cutting blade onto the ring. Turn the turn key to rotate the blade while maintaining pressure on the ring. Continue turning the turn key until the blade completely cuts through the ring. Pry the ring open with two hemostats or needle drivers once it is completely cut through and remove the ring. An alternative to one cut and prying the ring open is to make two cuts on opposite sides of the ring so that it falls apart in two pieces.

If an open wound is present, it should be irrigated with normal saline to remove any small metal fragments that may result from the cutting process. There has been a case report of a foreign body granuloma caused by metal particles left in a finger wound in a patient following ring removal.[16]

VICE-GRIP PLIERS TECHNIQUE

Many rings cannot be removed with the previously described techniques. These rings can be of a material that also cannot be cut with a carbide, diamond, or metal cutting disk on a ring cutter. This includes rings made of ceramics, natural stone (e.g., jade or onyx), and tungsten carbide. These rings can be removed by cracking them into pieces in a controlled fashion using a vice-grip pliers.

A medium-sized vice-grip pliers is usually appropriate for most ring sizes. Open the jaws of the vice-grip pliers. Adjust the

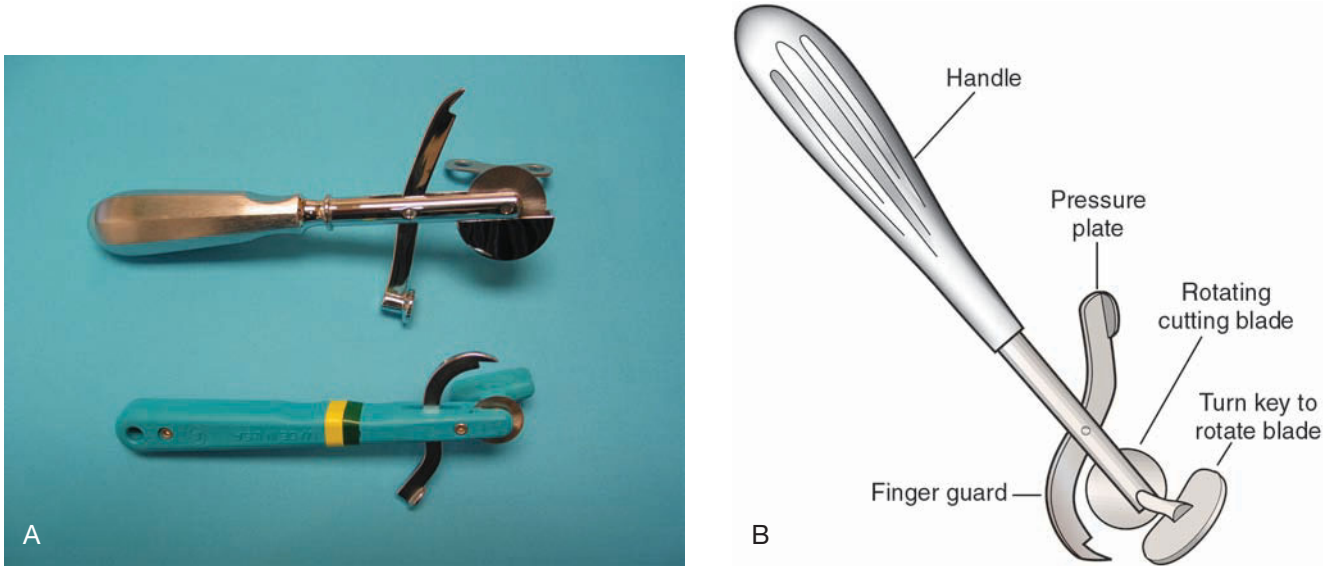

FIGURE 101-6. Manually operated ring cutters. **A.** Examples of manually operated ring cutters. **B.** The anatomy of a ring cutter.

tightening screw so that the closed jaws of the vice-grips fit over the ring (**Figure 101-10**). Close and clamp the vice grip so that the jaws close lightly on the ring. Release the jaws, turn the tightening screw one-quarter of a turn, and reclamp the jaws on the ring. Continue this process of releasing the jaws, turning the tightening screw one-quarter of a turn, and reclamping the jaws on different places of the ring each time until a crack is heard. Keep continuing this process of tightening the jaws and reclamping different areas of the ring until the ring breaks into pieces and falls off.

ALTERNATIVE TECHNIQUES

Patients may rarely present with other heavy circular objects on their digits such as steel rings, nuts, or washers that cannot be removed using a manually operated ring cutter. Powered cutting tools such as heavy-duty saws and bolt cutters may be needed to remove these objects. Battery-powered ring cutters may be ideal in these situations. Power saws and Dremel tools with carbon blades have been used to successfully remove hardened steel rings from a patient's fingers.[5] **If it becomes necessary to use a powered metal cutting device, additional care should be taken to protect the patient from secondary injury from the cutting element and the heat these powered devices may generate.**

ASSESSMENT

Thoroughly examine the finger for any injuries after the ring is removed. Reassess perfusion to the digit by noting the capillary refill time, the color, and the pulse oximeter reading on the affected digit compared to adjacent fingers.

FIGURE 101-7. The GEM Ring Cutting System (Mooney & Co., Ashland, OR). A battery-powered and motorized ring cutter.

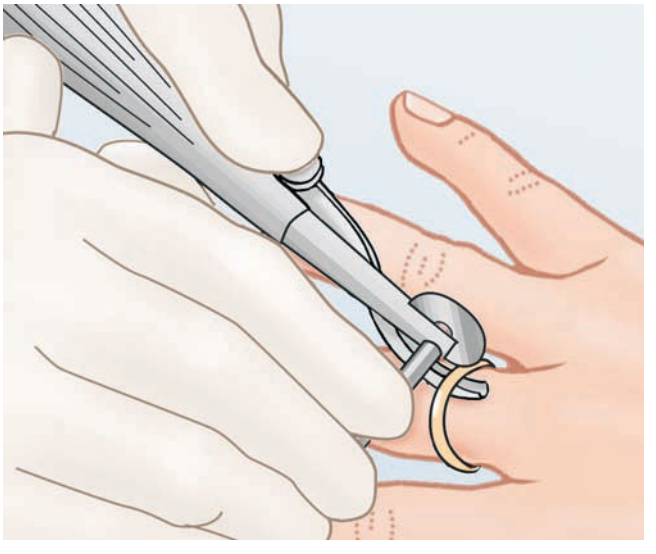

FIGURE 101-8. Ring removal using a manual ring cutter.

FIGURE 101-9. A pair of pliers is used to make the ring "oval" in shape. This may facilitate the use of a ring cutter.

AFTERCARE

No specific aftercare is required following the ring removal process. Elevation, nonsteroidal anti-inflammatory agents, and local wound care are all that is necessary. Consultation with a Hand Surgeon, Orthopedic Surgeon, Plastic Surgeon, or Podiatrist is recommended in severe cases that include embedded rings, infections, vascular compromise, and/or neurologic compromise. The aftercare is based on any lacerations and/or fractures of the digit. The patient's tetanus immune status should be ascertained and, if the skin is broken, the appropriate tetanus prophylaxis administered. Instruct the patient not to place any rings on the digit until the edema has completely resolved. Place the ring, and any pieces, in a specimen container and return it to the patient.

COMPLICATIONS

The direct complications of ring removal are minor compared to the complications that may occur from failure to remove a ring. Direct complications include secondary injury to soft tissues, vascular structures, and nerves and granuloma formation. This can be due to passing objects and instruments under an extremely tight ring or from improperly used instruments to remove the ring.

Ring cutters have their own specific issues. It may cut too slowly. Ensure that you are using the proper cutting technique. The cutting disk may be worn, dull, or the wrong cutting disk for the material.

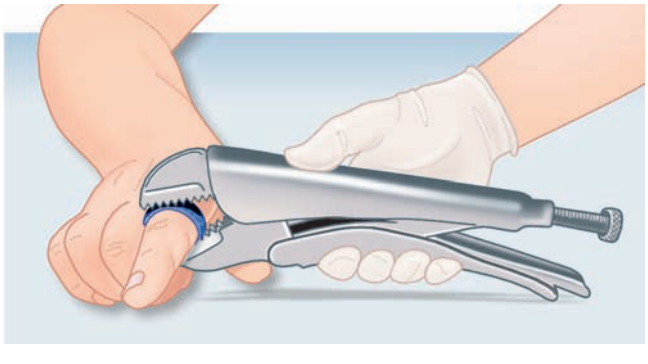

FIGURE 101-10. A vice-grip pliers can be used to remove hard or brittle rings.

Check that the proper cutting disk is on the ring cutter and that it is not dull or worn. Install fresh batteries or recharge them to maximize the power of the electric ring cutter. The ring, and the patient's finger, can become quite hot and burn the patient. Periodically check the progress and make sure that the ring has not been cut and you are now cutting the finger guard. Using a cutting disk that is dull, worn, or incorrect can generate significant heat. Correct these issues. Submerge the finger in ice water for a few minutes then resume cutting the ring.

SUMMARY

Ring removal is a relatively straightforward and simple procedure. In situations in which the ring is extremely difficult to remove, a variety of potential approaches may assure success. Use of the ring cutter is the most reliable and quickest technique. The decision to use a ring cutter should be based upon the urgency with which the ring must be removed and not upon the monetary or sentimental value of the ring.

102 Subungual Hematoma Evacuation

Steven H. Bowman

INTRODUCTION

The fingertips are sensitive, mobile, and prone to injury. Blunt trauma to the tip of the finger or toe may result in a variety of injuries including fractures, avulsions to the nail and nail apparatus, contusions, lacerations, and amputations. The most common injuries to the distal fingers and toes are crush injuries. The most common mechanisms of injury are closure of some type of door (car, house, etc.) on the finger, dropped objects on the fingers or toes, hand tools, and power tools.

Subungual hematomas often develop following blunt trauma to the distal finger or toe.[1–3] They result from the accumulation of blood between the nail and the nail bed. Treatment of a subungual hematoma is relatively straightforward, yet in some cases it is still controversial. It is important to understand the structure of the distal finger or toe, to determine whether simple drainage will be sufficient management, and to consider how initial management may affect outcome.

ANATOMY AND PATHOPHYSIOLOGY

The distal digits of the fingers and toes and the nail apparatus are complex structures (**Figure 102-1**). The perionychium is composed of the nail bed and the surrounding soft tissue. The hyponychium is the junction of the nail bed at the sterile matrix and the fingertip skin beneath the distal margin of the nail. The eponychium is the distal portion of the nail fold where it attaches to the proximal surface of the nail. The lunule is the white arc seen in the proximal portion of the nail. The nail bed consists of the germinal matrix on the proximal ventral floor of the nail fold and the sterile matrix, which extends from the lunule to the hyponychium. The germinal matrix is primarily responsible for the growth of the nail, with a significant contribution from the sterile matrix.[4,5] The nail bed must be smooth for normal nail growth. A nail matrix that has not been well approximated to minimize scar formation may develop a deformed nail.[1,3–8]

The nail bed receives its blood supply from the two terminal branches of the volar digital artery, which communicate to form

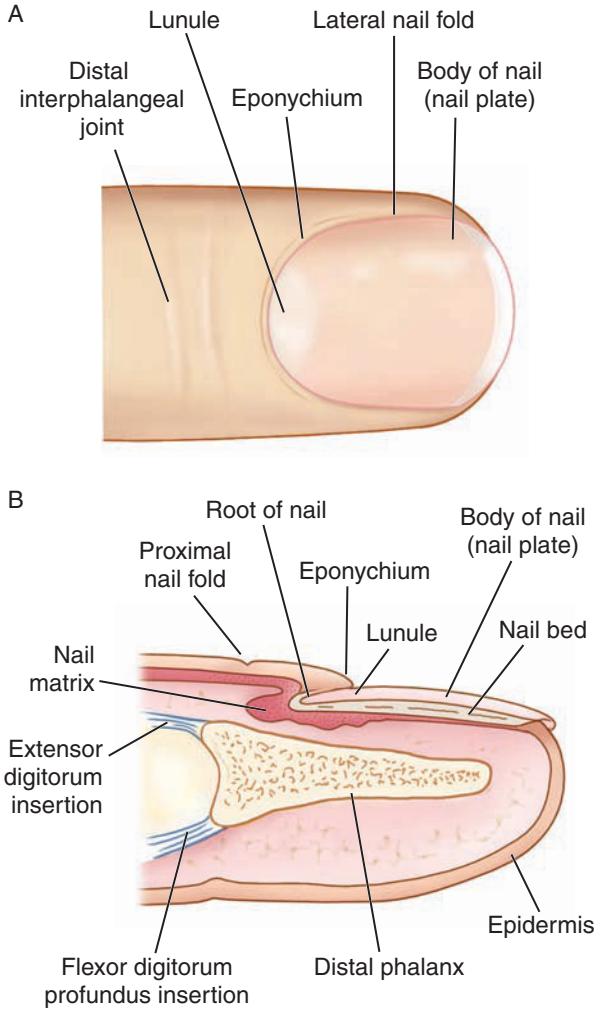

FIGURE 102-1. The anatomy of the distal fingertip and nail bed. **A.** Surface anatomy. **B.** Midsagittal view.

blood sinuses. Venous drainage begins at the proximal portion of the nail bed and the skin proximal to the nail fold.[4]

Force applied to the tip of the finger or toe disrupts the vascular structures in the nail bed. Trauma causes the capillaries of the nail bed to be compressed between the nail and the distal phalanx. Blood collects between the nail bed and the nail, forming a subungual hematoma (**Figure 102-2**). The patient's pain is directly related to the injury itself and the increased pressure from the hematoma. The hematoma appears as a black-and-blue or black-and-purple area under the nail that is extremely tender to palpation.

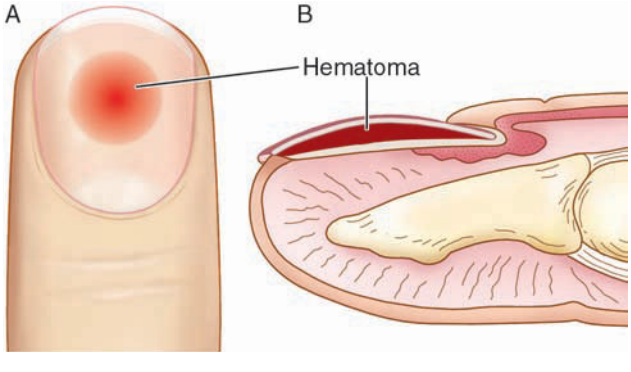

FIGURE 102-2. The subungual hematoma. **A.** Surface view. **B.** Sagittal view.

Nail bed injuries may be classified as simple lacerations, stellate lacerations, severe crush injuries, and avulsions.[1] It is important to understand that each of these types of nail bed injuries may result in a subungual hematoma.

The management of subungual hematomas is still somewhat controversial. The approach to management was initially very aggressive, since subungual hematomas are often seen with fractures of the distal phalanx, damage to the nail, and damage to the nail apparatus.[1,2,4–8] The surgical literature generally recommends removal of the nail, inspection of the nail bed, and repair of any nail bed injury if the subungual hematoma involves 25% or more of the nail surface.[1,2,4–9] This practice has been questioned recently by newer controlled studies that demonstrated excellent outcomes in patients with large (greater than 25%) subungual hematomas treated by trephination alone, regardless of the presence of fractures.[11,12] Larger hematomas involving over 50% of the nail surface may be treated successfully with trephination. Many authors, primarily Hand Surgeons, still advocate the removal of the nail plate to thoroughly inspect the nail bed and effect repair in all patients who present with a subungual hematoma. Although this approach is time-honored, more recent studies have demonstrated that it is not necessary if the patient's nail is still attached to the matrix, even in the presence of a distal phalanx fracture.[11,12]

INDICATIONS

Patients who present to the Emergency Department after sustaining an injury with a resultant subungual hematoma will generally complain of severe pain. Trephination, the process of making a small hole in the nail to allow the collected blood to escape, will provide significant relief for most patients.[2,9] **The trephination procedures described below should be utilized when patients present with a subungual hematoma and an intact (not fractured or avulsed) nail plate that is still attached to the matrix. If the nail plate is partially or completely avulsed from the matrix, simple evacuation of the hematoma may not constitute adequate therapy.**[9,10,11,13]

CONTRAINDICATIONS

Simple trephination is reserved for patients with intact nails. **Patients who present with nail plate fractures, avulsions of the nail plate, disruption of the nail margin, or partial amputations may require more extensive therapy with removal of the nail plate and repair of the nail bed.** A description of these techniques is provided in Chapters 96 and 104. Trephination using heat-based methods should be avoided in patients wearing artificial nails due to the potential for igniting the nail or nail adhesive.[13] **Subungual hematomas that extend proximal to the nail bed often represent proximal nail plate avulsions or injuries that require nail plate removal, nail plate repair or reinsertion, and nail bed repair.**

EQUIPMENT

Digital/Metacarpal Block

- Povidone iodine or chlorhexidine solution, or an isopropyl alcohol pad
- 3 mL syringe
- 25 or 27 gauge needle, 1 in. long
- Local anesthetic solution without epinephrine

Electrocautery

- Povidone iodine or chlorhexidine solution, or an isopropyl alcohol pad
- Battery-powered electrocautery device

Paper Clip Technique

- Povidone iodine or chlorhexidine solution, or an isopropyl alcohol pad
- Heat source (open flame)
- Paper clip
- Hemostat

Drill Technique

- Povidone iodine or chlorhexidine solution, or an isopropyl alcohol pad
- 18 gauge needle
- Cotton-tipped applicators

The PathFormer (Path Scientific, Carlisle, MA) is an FDA approved device for nail plate trephination. It allows for the precise control of the depth of penetration while making a 400 μm diameter hole in the nail plate. The device is a battery-powered drill that automatically retracts the drill bit after the nail plate is penetrated. Thus, the sensitive and vascular nail bed is not contacted or injured. Unfortunately, the PathFormer device is not often available in Emergency Departments.

PATIENT PREPARATION

Explain the procedure to the patient and emphasize that pain relief rapidly follows nail trephination. Obtain a consent to perform the procedure. Consider obtaining radiographs for significant traumatic injuries, suspected associated fractures, or any injury where the nail plate is damaged or avulsed. Place the patient in a sitting or semi-recumbent position on a gurney or multipositional procedure chair. Sit facing the patient. Place the hand with the injured digit palm side down on a flat surface such as a procedure table. Cleanse the injured digit of any dirt and debris. Apply povidone iodine or chlorhexidine solution over the nail plate and allow it to dry. An alcohol swab is an alternative to these solutions. **Always allow the alcohol to dry before touching the nail plate with a hot object so that the alcohol does not ignite.** A digital block is generally not needed if using heat-based methods to penetrate the nail plate.[2,5,9,13] The nail plate is not innervated and the hematoma prevents contact with the nail bed. A digital block may be required if the patient is excessively anxious, if additional injury is present, or if a drill technique is to be performed. Refer to Chapter 126 for the complete details regarding digital and metacarpal blocks. An alternative to the digital block is to soak the affected finger in ice water for a few minutes prior to the procedure. The techniques described below may be used on fingernails and toenails.

TECHNIQUES

ELECTROCAUTERY TECHNIQUE

Electrocautery is the preferred technique to drain a subungual hematoma. Battery-operated microcautery devices are generally available in the Emergency Department (**Figure 102-3**). Assure the patient that they will not be burned. Stabilize the injured digit proximally with the nondominant hand. Grasp the cautery unit like a pencil with the dominant hand. Press the button on the cautery unit to heat the tip. Release the button and allow the tip to cool for 1 to 2 seconds. This may prevent penetrating the nail plate too quickly and damaging the underlying nail bed. Place the hot tip on the nail plate, centered over the hematoma (**Figure 102-4**). **Tap the nail plate several times with the cautery pen tip. Do not constantly hold the hot tip against the nail plate.** The cautery tip will easily penetrate the nail plate. **Do not plunge as the nail bed can be injured in addition to causing additional pain to the patient.**

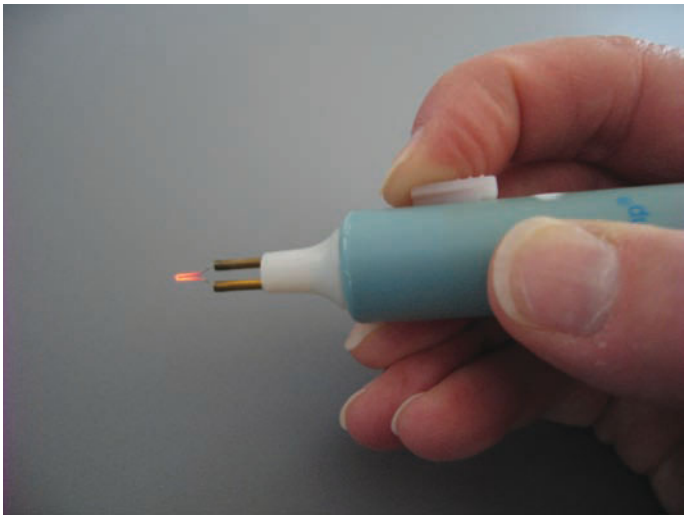

FIGURE 102-3. The battery-operated electrocautery device.

Darkened blood will flow out of the hole when the hematoma is entered. The nail will regain its normal color after the hematoma is drained. Apply slight digital pressure to the nail plate to ensure complete drainage of the hematoma. The patient will usually begin to feel pain relief at this point.

The tips of some microcautery devices are shaped in such a way that they will not make a hole that is wide enough to allow adequate drainage. Slightly rotate the cautery unit as it traverses the nail plate to ensure an adequate sized drainage hole of 3 to 4 mm. Some Emergency Physicians prefer to make an additional hole in the nail plate to ensure drainage if the first hole should become occluded.

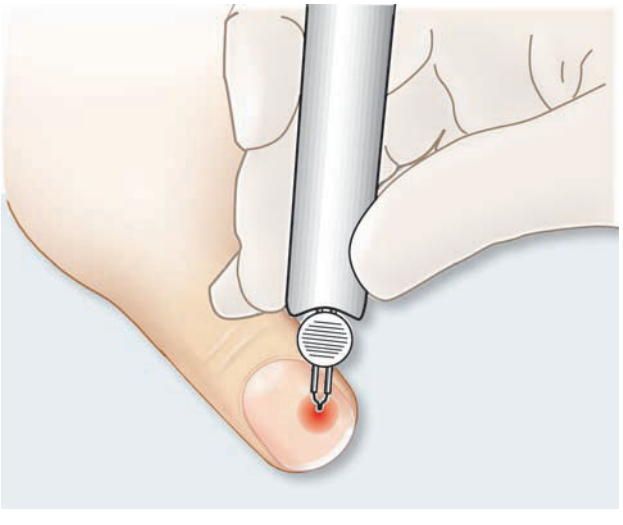

FIGURE 102-4. The electrocautery technique. The hot tip of the unit is centered over the subungual hematoma and allowed to penetrate the nail plate.

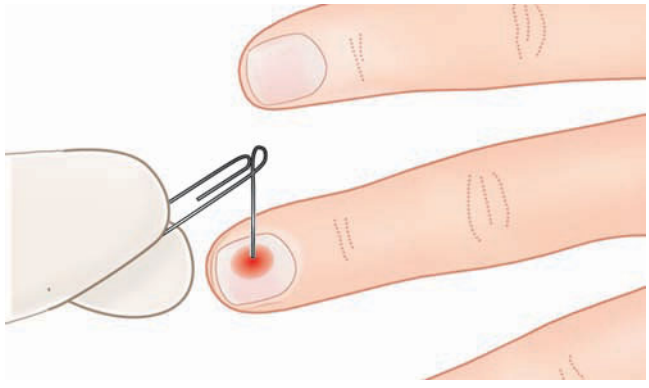

FIGURE 102-5. The paper clip technique. The hot tip of the paper clip is centered over the subungual hematoma and allowed to penetrate the nail plate.

As an alternative to the single large hole, place three to four smaller drainage holes in the nail plate.

PAPER CLIP TECHNIQUE

This technique is similar to that using the electrocautery unit. Unfold and heat the tip of a paper clip with a flame from a lighter or alcohol lamp. Place the heated tip of the paper clip against the nail plate, centered over the subungual hematoma (**Figure 102-5**). Apply slight downward pressure to allow the paper clip to perforate the nail plate. **Do not plunge as the nail bed can be injured in addition to causing additional pain to the patient.** A drop of blood will be seen as the paper clip enters the hematoma. Place at least one additional hole in the nail plate to ensure drainage if the first hole should become occluded.

The paper clip will not get as hot as a cautery device. More than one attempt may be necessary to penetrate a thick nail. Another disadvantage of this technique is the possibility of introducing carbonaceous material into the hole. The use of an open flame may be potentially dangerous or prohibited in the Emergency Department.

DRILL TECHNIQUE

This technique uses a needle as a small drill to penetrate the nail plate (**Figure 102-6**). Small electric nail drills are available that greatly simplify this procedure, though they may not be readily available in the Emergency Department. Drilling through the nail plate may require a digital block. This is particularly true if there is a fracture, another associated injury, or the nail plate is very thick. Grasp an 18-gauge needle by its hub with the dominant thumb and forefinger (**Figure 102-6A**). Place the tip of the needle over the nail plate, centered over the subungual hematoma. Spin the needle back and forth while applying gentle downward pressure. Small shavings will appear as the needle begins to drill through the nail plate. A loss of resistance will be felt as the hematoma is entered and darkened blood will flow from the hole. **Do not plunge as the nail bed can be injured in addition to causing additional pain to the patient.** Place at least one additional hole in the nail plate to ensure drainage if the first hole should become occluded.

The editor uses a modified version of this technique (Reichman, personal communication). A cotton-tipped applicator may be wedged into the needle hub to facilitate the drilling (**Figure 102-6B**). This method makes the drilling more efficient, as the cotton-tipped applicator is easier to hold and offers a mechanical advantage when it is twisted. The drill technique is very useful in the absence of a heat-generating device.

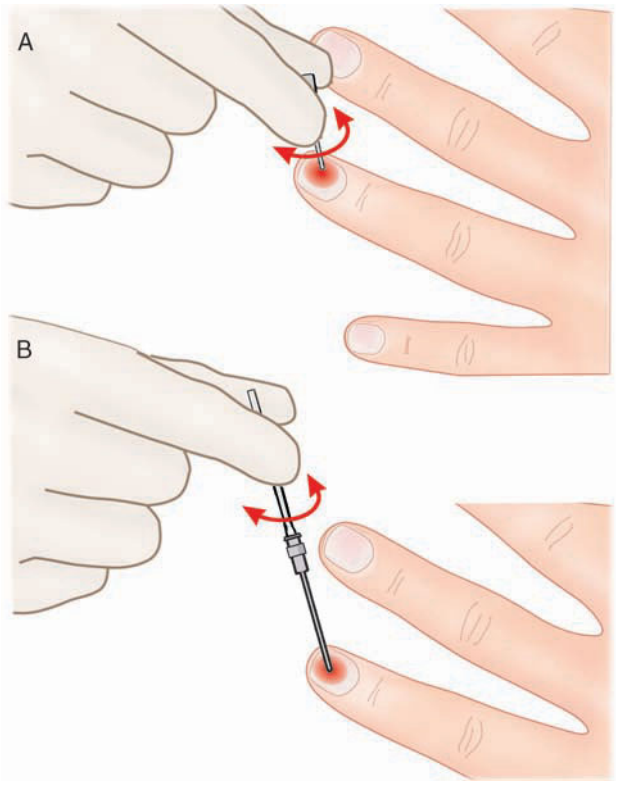

FIGURE 102-6. Drill techniques. **A.** A twisting motion of the 18 gauge needle is used to penetrate the nail plate. **B.** A cotton-tipped applicator has been inserted into the hub of the needle. A twisting motion is used to penetrate the nail plate.

ASSESSMENT

Gently compress the nail plate to evacuate the hematoma. Any underlying injury should be evaluated and managed.

AFTERCARE

The patient should keep the wound clean and monitor drainage. The nail plate may be covered with a nonadherent dressing. The hematoma may continue to drain for several hours or up to 1 to 2 days. If there is a reaccumulation, denoted by the reappearance of darkened blood beneath the nail, the nail can be soaked in warm water and pressure applied to express the hematoma. Inform the patient that the discoloration under the nail plate can persist for several weeks. Also inform them that the nail plate may fall off and it can take up to 3 months for another nail plate to completely form. A splint should be applied if a distal phalanx fracture is present. No studies have demonstrated that prophylactic antibiotics are beneficial in the management of a subungual hematoma.[9,14] The patient should immediately return to the Emergency Department or their primary physician for fever, increased pain, purulent drainage from the nail, or any redness or swelling of the digit.

COMPLICATIONS

Direct complications from nail trephination are rare.[11–13] Complications will more likely result from the original injury and include nail loss, nail deformity, cosmetic changes, and infection. Patients should be warned that as the nail grows out, loss of the nail is a possibility. The hematoma may reaccumulate if the hole in the nail is too small and becomes occluded. Reaccumulation can be

prevented by making a large hole or multiple holes in the nail plate. Plunging through the nail plate with a cautery unit or needle will cause the patient pain and injury to the nail bed that may be permanent and result in a deformed nail plate.

SUMMARY

Fingertip injuries are common. Patients will often present to the Emergency Department with a subungual hematoma and a complaint of pain. Rapid relief of pain and good outcomes can be obtained in the majority of cases by simply performing a nail trephination. It is important to distinguish when trephination alone will not be adequate therapy. Patients presenting with nail plate fractures, avulsions of the nail plate, or partial finger amputations will require removal of the nail plate and repair of the nail bed.

103 Subungual Foreign Body Removal

Steven H. Bowman

INTRODUCTION

Subungual foreign bodies are often difficult to treat. Foreign bodies such as wood or metal splinters, pencil lead, thorns, spines, or hair may become lodged beneath the fingernail.[1–3] Tradesmen such as carpenters, landscapers, auto mechanics, and individuals who work without hand protection with materials that produce small splinters are at risk for this type of injury. Subungual foreign bodies may also present less commonly under the toenails.

Patients generally present for medical intervention with pain after unsuccessfully attempting to remove the foreign body. Prior removal attempts often result in breakage of the foreign body or pushing it further beneath the nail; both of which complicate the next extraction attempt. Left untreated, retained subungual foreign bodies often become infected or cause tissue reactions and granuloma formation. These injuries may be treated rapidly with complete removal of the foreign body and without causing additional patient discomfort.

ANATOMY AND PATHOPHYSIOLOGY

The distal fingertip and nail apparatus are complex structures (**Figure 103-1**). The perionychium is composed of the nail bed and the surrounding soft tissue. The hyponychium is the junction of the nail bed at the sterile matrix and the fingertip skin beneath the distal margin of the nail plate. The eponychium is the distal portion of the nail fold where it attaches to the proximal surface of the nail plate. The lunule is the white arc seen on the proximal portion of the nail plate. The nail bed consists of the germinal matrix on the proximal ventral floor of the nail fold and the sterile matrix that extends from the lunule to the hyponychium. The germinal matrix is primarily responsible for the growth of the nail. The subungual space is the area immediately beneath the nail plate.

Foreign bodies may enter the subungual space at the distal fingertip beneath the nail, or may penetrate the nail plate directly (**Figure 103-2**). In either event, separation of the nail from the nail bed results in severe pain. Patients frequently attempt to remove the foreign body immediately because of this intense pain. An infection or foreign body reaction will often ensue if the foreign body is not removed in its entirety.

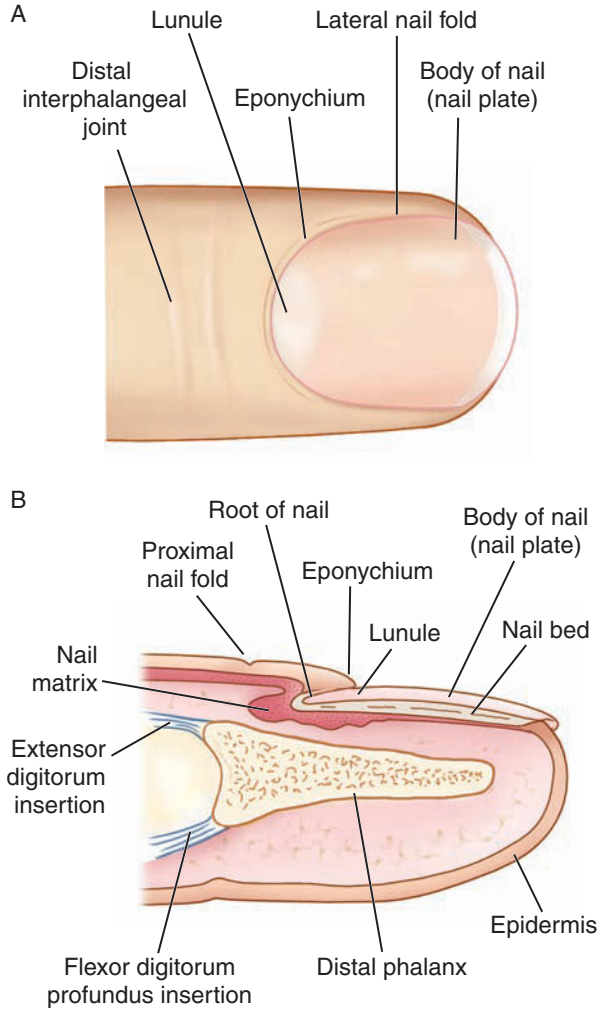

FIGURE 103-1. The anatomy of the distal fingertip and nail bed. **A.** Surface anatomy. **B.** Midsagittal view.

INDICATIONS

Subungual foreign bodies should be removed to prevent the complications of infection, foreign body reaction, and possible nail deformity. Deeply embedded foreign bodies, splintered foreign bodies, those that traverse the nail plate, or contaminated foreign bodies may require the removal of the nail plate to extract the foreign body. Refer to Chapter 104 regarding the details of removing the nail plate. Consult a Hand Surgeon if the foreign body cannot be removed, if the site is infected, if the foreign body is "chronic"

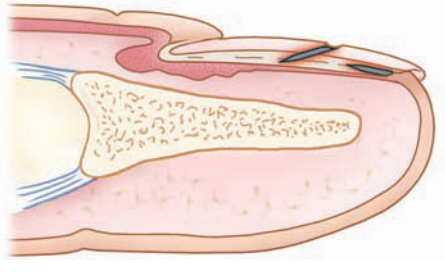

FIGURE 103-2. Subungual foreign bodies can enter from under the distal nail plate or through the nail plate.

and an osteomyelitis is present on radiographs, or if significant injury to the digit is present.

CONTRAINDICATIONS

There are no absolute contraindications to the removal of a subungual foreign body.

EQUIPMENT

General Supplies

- Povidone iodine or chlorhexidine solution
- Alcohol swabs
- Sterile saline solution
- Topical antibiotic ointment
- Nonadherent dressing (e.g., petrolatum gauze)
- 4 × 4 gauze squares
- Adhesive tape

Digital/Metacarpal Block

- 3 mL syringe
- 25 or 27 gauge needle, 1 in. long
- 3 to 5 mL local anesthetic solution without epinephrine

Scrape Technique

- Splinter forceps
- #11 or #15 scalpel blade on a handle

Wedge Technique

- Splinter forceps
- Tissue scissors or nail clippers

Needle Technique

- Needles, 19 and 25 or 27 gauges
- Splinter forceps
- Hemostat

PATIENT PREPARATION

Explain the risks and benefits of the procedure to the patient and/or their representative. Obtain an informed consent for the procedure. Ascertain the patient's tetanus immune status and administer the appropriate tetanus prophylaxis. The Emergency Physician should attempt to gain the patient's cooperation. Place the patient sitting or in a semi-recumbent position with their hand on a bedside procedure table. Clean any dirt and debris from the affected finger. Apply povidone iodine or chlorhexidine solution and allow it to dry. Any manipulation of the nail bed will result in additional patient discomfort. Determine the need for a digital or metacarpal block depending on the type and extent of the foreign body and the removal technique. Please refer to Chapter 126 for the complete details regarding anesthesia of the finger or toe. Radiographs are not required unless a metallic foreign body cannot be visually located or the clinical suspicion exists for an osteomyelitis or a gas forming finger infection.

TECHNIQUES

Foreign bodies protruding through or from underneath the nail plate may be grasped with a forceps and removed. A scalpel blade or 18 gauge needle may be used to entrap a small protruding tip of the foreign body against the nail plate and draw it out. **Do not attempt to remove the foreign body through a puncture wound or small incision.** Enlarging the access site allows for easier removal, not breaking or fragmenting the foreign body, and complete removal. Superficially located subungual foreign bodies may be removed by one of the following techniques.

SCRAPE TECHNIQUE

This technique has been described anecdotally.[4,5] It appears promising as it does not require the administration of a digital block and causes less trauma to the nail and the nail bed compared to other techniques. This technique works well for subungual foreign bodies that either traverse the nail plate or are lodged beneath the distal or middle portion of the nail.

Support the patient's hand on a procedure table. Sit on a chair facing the patient. Place a #11 or #15 scalpel blade on the nail plate and directly over the foreign body (**Figure 103-3A**). Hold the blade perpendicular to the surface of the nail plate. Draw the scalpel blade from proximal to distal using short strokes and gentle pressure over the foreign body (**Figure 103-3A**). A small shaving of the nail plate is removed with each stroke of the scalpel blade. The finger may be soaked in lukewarm water for 15 to 20 minutes to soften the nail plate if it is thick and difficult to shave. Continue to remove successive slivers of the nail plate to eventually create a U-shaped defect and expose the foreign body (**Figure 103-3B**). Grasp the foreign body with a splinter forceps and remove it once a significant portion protrudes. The defect created in the nail plate will move distally and eventually be replaced as the nail plate continues to grow.

WEDGE TECHNIQUE

The wedge technique works well for subungual foreign bodies lodged beneath the distal portion of the nail plate.[1,6] Patients will require a digital or metacarpal block prior to attempting this technique since it involves manipulation of the nail bed.

Sit on a chair facing the patient. Cut a triangular wedge from the distal portion of the nail plate overlying the foreign body with a small pair of tissue scissors or nail clippers (**Figure 103-4A**).

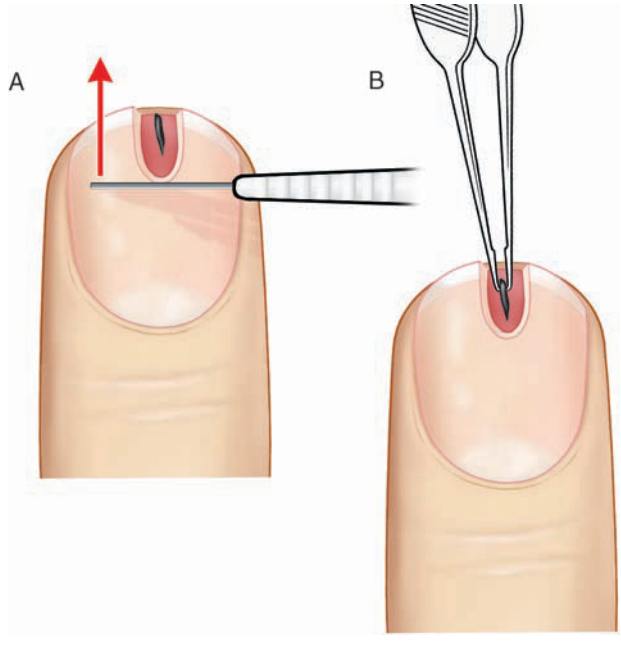

FIGURE 103-3. The scrape technique. **A.** With the scalpel blade held 90° to the nail bed, strokes are made in a proximal to distal direction. A U-shaped defect will be created to expose the foreign body. **B.** The foreign body is grasped and removed with a forceps.

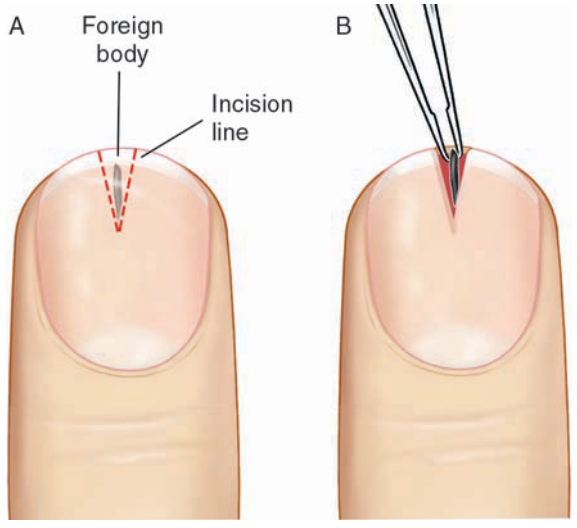

FIGURE 103-4. The wedge technique. **A.** A triangular incision is made in the nail plate overlying the foreign body. **B.** The cut section of the nail plate has been removed. The foreign body is grasped with a forceps and removed.

Prevent iatrogenic injury to the nail bed by ensuring that the tip of the scissors under the nail plate is aimed upward and against the nail plate. Remove the wedge of nail. This will provide enough exposure to grasp and remove the foreign body with splinter forceps (**Figure 103-4B**).

NEEDLE TECHNIQUES

The needle technique works well for subungual foreign bodies located beneath the distal portion of the nail plate.[1] Patients will require a digital or metacarpal block prior to attempting this technique. Insertion of a needle into the nail bed is extremely painful. The major drawback of this technique is the potential for leaving fragments of the foreign body beneath the nail plate.

Sit in a chair facing the patient. Introduce a 19-gauge needle beneath the nail plate and along the track of the foreign body (**Figure 103-5A**).[7] Use the tip of the needle to touch the foreign body. Lower the hub of the needle to raise its tip and trap the foreign body between it and the nail plate. Withdraw the needle while dragging the foreign body out along the nail plate. Alternatively, tease out and move the foreign body distally until it can be grasped with a splinter forceps.

Two alternate techniques have also been described for the needle extraction of a subungual foreign body.[7,8] The first is a modification of the needle technique.[7] Place a hook in the distal end of a 25 or 27 gauge needle with a hemostat or needle driver (**Figure 103-5B**). Pass the bent needle along the foreign body tract. Grasp the foreign body with the tip of the bent needle. Withdraw the needle to move the foreign body distally so that it may be grasped with a splinter forceps. A third technique involves the excision of a small portion of the nail plate overlying the foreign body with an 18 gauge needle.[8] This is similar to the shave technique with the exception of an 18 gauge needle being used instead of a scalpel blade.

ASSESSMENT

The subungual area should be inspected for any remaining fragments of the foreign body that may have broken off in the nail bed. **Any remaining fragments of the foreign body must be removed.** Refer the patient to a Hand Surgeon if the foreign body fragments cannot be removed.

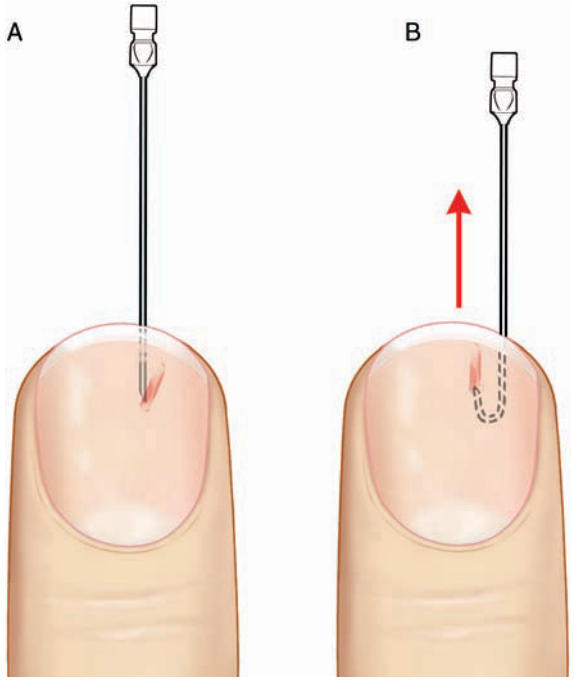

FIGURE 103-5. Needle techniques. **A.** A 19 gauge needle is inserted along the tract of the foreign body. The tip is used to tease the foreign body out of the tissues. **B.** The tip of a 25 or 27 gauge needle has been formed into a hook with the aid of a hemostat. The needle is inserted along the tract of the foreign body. The tip is used to grasp the foreign body and pull it out of the tissues.

AFTERCARE

In most cases, local wound care and the application of a topical antibiotic are all that is required. Irrigate the foreign body tract and excision site with sterile saline. Apply topical antibiotic ointment to the area. Apply a nonadherent dressing over the nail. Follow-up with a Hand Surgeon and systemic antibiotics may be necessary in severe cases, such as the presence of a nail deformity or chronic foreign bodies with an infection. Postprocedural pain can be managed with acetaminophen or nonsteroidal anti-inflammatory drugs. The use of prophylactic antibiotics is not recommended unless the foreign body was contaminated or had deeply penetrated into the soft tissue of the digit. Instruct the patient to return immediately to the Emergency Department if they develop any signs of an infection (i.e., purulent drainage, increased tenderness, redness or swelling of the digit, or fever).

COMPLICATIONS

There are a few potential complications from subungual foreign body removal. Damage to the nail bed can result in a residual nail deformity. Failure to completely remove a subungual foreign body may result in a nail deformity, an infection, or a foreign body reaction with granuloma formation. An infection can result from a contaminated foreign body, flora on the nail plate or skin driven into the soft tissues by the foreign body, or if aseptic technique is not followed.

SUMMARY

Patients with subungual foreign bodies often present in severe pain after prior unsuccessful attempts at removal or after complications develop. Though sometimes challenging, it is important that the

Emergency Physician completely remove the foreign material in the subungual space to prevent further complications. Providing adequate anesthesia and using the appropriate instruments and techniques allows the successful removal of most subungual foreign bodies in the Emergency Department.

104 Nail Bed Repair

Raemma Paredes Luck and Eric F. Reichman

INTRODUCTION

The fingertip, the most sensitive area of the hand, is often our first contact with the environment. It has important functional roles in grasping and pinching, in addition to its sensory and cosmetic functions.[1,2] The fingernail protects the fingertip and provides increased sensation to the volar pulp.[3] However, it also conceals the true extent of fingertip injuries. Hand injuries, with the fingertips most frequently involved, are second only to back injuries as the most common occupational injuries resulting in loss of work days.[4] Hence, it is important for the Emergency Physician to evaluate the full extent of the injury, to assess potential disabilities, and to recognize the need for prompt referral to a Hand Surgeon.

The fingernails are frequently injured due to their anatomic location and their functional role. Immediate primary repair is the ideal management when these injuries involve the nail bed and surrounding skin fold structures.[3,5] Careful repair is necessary to avoid functional impairment and cosmetic derangement of the nail plate.[6] The following discussion will refer primarily to the fingernail. The toenail has less importance, both cosmetically and functionally, as grasp and pinch are not needed. However, all the principles and recommendations made also apply to the toenail.[7]

ANATOMY AND PATHOPHYSIOLOGY

Knowledge of the anatomy of the nail unit enables the Emergency Physician to recognize the types of injuries and provide anticipatory guidance of the consequences of these injuries to the patients. The "perionychium" or the nail unit consists of the nail fold, the nail plate, nail bed, and the hyponychium (**Figure 104-1**).[1,2]

The nail plate enhances the sensibility of the fingertip by applying a counterforce to the pulp space nerve endings.[3] The digital tip and the nail plate also function in unison to smoothly coordinate normal pinch and grasp, which are important for picking up fine objects such as coins and pins.[3,8]

The nail plate is comprised of compacted, flattened, and elongated anucleated cells that originate from cornified epithelial cells.[9] There are three atomic sites where these cells exist.[5,8] The nail bed contains two of the sites: the sterile matrix and the germinal matrix.[8] The other location is the dorsal roof matrix (**Figure 104-1A**). Of these, the germinal matrix is the most important for normal nail growth.[5] The germinal matrix is responsible for approximately 90% of the nail plate by volume.[8] The sterile matrix is responsible for a small percent of the nail plate by volume and varies from individual to individual. This cell production accounts for the nail plate being thicker at its distal tip compared to its proximal origin.[8] The nail cells from the dorsal roof matrix are small in number and form a very thin layer on the surface of the nail plate. These cells are responsible for the shine of the nail. If the dorsal roof is destroyed, the nail will lose its shine and become dull.

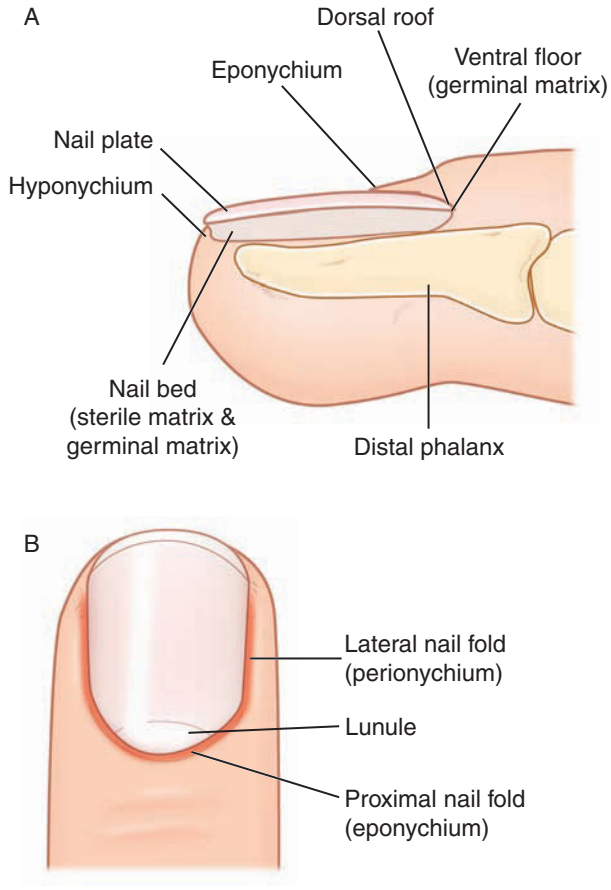

FIGURE 104-1. Anatomy of the fingernail. **A.** Lateral view. **B.** Top view. The colored area represents the perionychium.

Skin overlies the nail plate proximally and laterally (**Figure 104-1B**).[9] The proximal skin fold is referred to as the eponychium. The eponychium protects the germinal matrix located in the proximal nail bed and is the home of the dorsal roof matrix. The skin immediately over the dorsal roof is called the nail wall.[8] The lateral skin folds, the adjacent cutaneous areas, and the adjacent nail bed (germinal matrix and sterile matrix) are collectively referred to as the perionychium (**Figure 104-1B**).[6,8,9] The lunule is the pale arc just distal to the eponychium and roughly corresponds to the location of the germinal matrix.[1,2,8,9]

The nail bed is comprised of the germinal matrix proximally and the sterile matrix distally. The borders of the nail bed are the proximal nail fold, the lateral nail folds, and the hyponychium distally. The hyponychium is the thick layer of cells at the junction of the distal nail bed (sterile matrix) and the fingertip skin.[8] It is located just under the distal free margin of the nail plate (**Figure 104-1A**). The hyponychium serves as a barrier preventing the delicate nail bed from exposure to bacteria and fungi.[8]

The rate of nail growth varies from finger to finger, from individual to individual, and varies with age.[3,8] Nail growth is fastest between 4 and 30 years of age and after 80 years of age. Fingernails grow four times faster than the toenails.[1] A new nail takes a minimum of 4 months to grow, and even longer following an injury. Progression of the distal nail occurs at a rate of 0.1 mm/day or 0.5 to 1 mm/week.[3,9] This rate varies and is usually faster in fingers than in toes, and faster in the summer months.[3] The pressure of new cells being formed leads to the flattening and elongation of the older cells as well as their progression distally.[8]

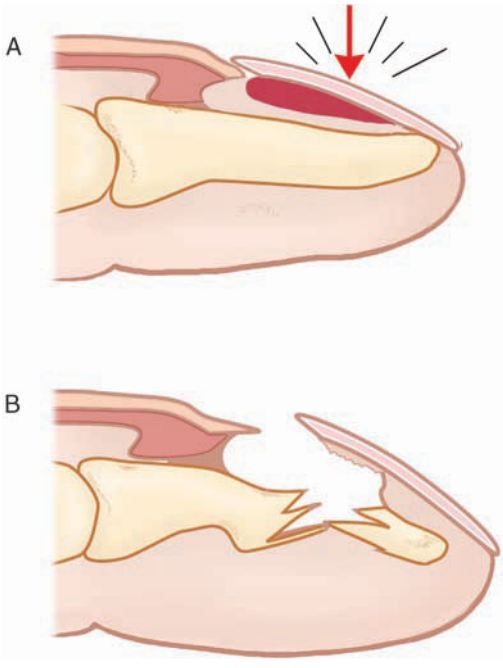

FIGURE 104-2. A crush injury to the distal fingertip. **A.** Proximal nail bed avulsion. **B.** A more severe crush injury can result in a proximal nail bed avulsion and fracture of the distal phalanx. Note that the distal nail plate remains attached to the sterile matrix in both of these injuries.

The sterile matrix is more adherent to the nail plate than to the adjacent germinal matrix. Therefore, avulsions involving nail bed tissue are more likely to occur at the sterile matrix.[8,10,11] Conversely, the nail plate is loosely held to the germinal matrix. This accounts for the peculiar injury of avulsions of the proximal nail plate from the proximal nail fold while the distal nail plate remains attached (**Figure 104-2**).

The digital artery supplies the volar radial and ulnar sides of the finger and consistently sends even smaller branches to the proximal nail fold and to the nail bed producing a rich capillary network.[1] The small veins of the nail bed, pulp, and lateral nail folds coalesce proximally to form a larger commissural vein that runs lateral to the distal phalanx and a terminal vein that runs dorsal to the distal phalanx. The digital nerve accompanies the digital artery and sends branches beyond the distal interphalangeal joint and into the nail fold, nail bed, and the finger pulp. The extensor tendon attaches itself to the distal phalanx just proximal to the germinal matrix.[8,11] The periosteum of the distal phalanx, in turn, closely adheres to the sterile matrix.[8]

With these anatomic considerations in mind, certain patterns emerge as a result of injury. Avulsions of the nail bed tend to occur in the sterile matrix rather than the less adherent germinal matrix. Another pattern of injury seen is the avulsion of the proximal nail plate from the proximal nail fold while the distal part remains attached to the nail bed (**Figure 104-2**). Because the sterile matrix closely adheres to the periosteum of the distal phalanx, fractures of the distal phalanx might injure the nail bed producing a subungual hematoma.[6] Due to the close proximity of the germinal matrix and the attachment of the extensor tendon, injuries to or repair of these structures might involve the other. A subungual hematoma is a collection of blood between the nail bed and the nail plate. Although a large subungual hematoma may require repair of the underlying nail bed, this is controversial.

Emergency Physicians must consider in each case whether there exists enough damage to require surgical nail bed repair. It is important to note that significant force is required to break, penetrate, or avulse the nail plate.[6] Therefore, the fragile nail bed is most likely disrupted if the nail plate is disrupted.

INDICATIONS

Injuries to the fingertip and nail, if not initially managed correctly, have long lasting functional as well as cosmetic consequences. The most important consideration is functional.[9] Normal nail growth after injury requires a smooth nail bed. Therefore, nail bed injuries must be meticulously repaired to prevent cosmetic deformities and functional impairment.[9–11] Scar tissue may form between the wound edges if the nail bed is not accurately approximated. This scar tissue will not form the intermediate nail cells responsible for nail adherence.[8] Furthermore, loss of the germinal matrix alone will result in permanent loss of the nail plate.[5,12] The skin folds surrounding the nail margins must also be preserved.[5,11] Failure to do so will result in the painful complication of adhesion formation between the skin fold and the nail bed.[5,11] Secondary repair of these spaces, or of the nail bed, requires more complex procedures and are usually associated with a poor outcome.[4,10] **Therefore, every effort should be made to primarily repair all significant nail bed injuries.**

CONTRAINDICATION

No absolute contraindications exist for primary nail bed repair. Any life-threatening injuries, limb-threatening injuries, and/or uncontrolled hemorrhage must be addressed prior to nail bed repair.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Restraining device(s), as necessary
- 10 mL syringe armed with a 27 gauge needle
- Local anesthetic solution without epinephrine, 1% lidocaine or 0.25% bupivacaine
- Digital tourniquet
- #15 scalpel blade on a handle
- Magnification device
- Sterile prefabricated nail, if available
- Nonadherent petrolatum gauze
- 5-0, 6-0, and 7-0 chromic gut (or polyglactin 910 or irradiated polyglactin 910) on a p-3 cutting needle
- 6-0 monofilament nylon sutures
- Needle driver
- Curved hemostat
- Fine scissors or periosteal elevator
- Forceps
- Sterile towels or drapes
- Sterile gloves
- Dry gauze/tube gauze
- Splinting material
- Battery-powered electrocautery device

The use of a digital tourniquet is essential to properly repair a nail bed. Its use provides a bloodless field, which allows for a more meticulous and precise wound approximation. Numerous options are available to use as a tourniquet in the Emergency Department. Home-grown options include the use of a sterile Penrose drain,

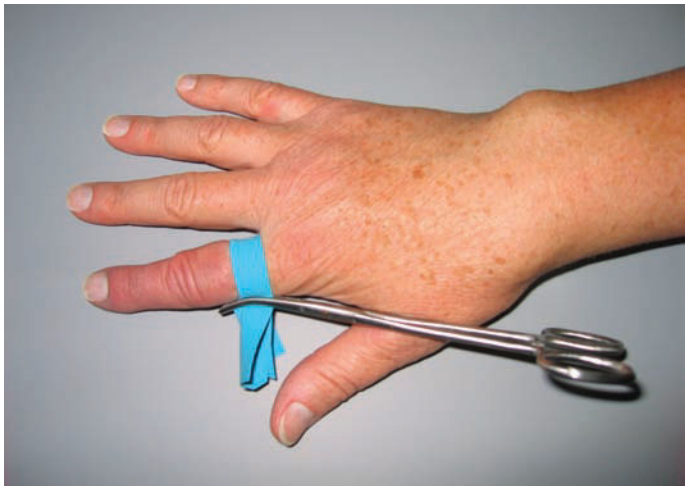

FIGURE 104-3. A sterile Penrose drain or IV tourniquet used as a digital tourniquet.

FIGURE 104-5. The Tourni-cot digital tourniquet.

rubber IV tourniquet, or sterile glove. A sterile Penrose drain or IV tourniquet secured with a hemostat is often used as these items are readily available (**Figure 104-3**). A sterile glove may be used as a tourniquet (**Figure 104-4**). Apply a sterile glove onto the patient's hand that is snug or a size one-half smaller than their actual glove size. Cut just the tip off of the glove over the affected finger(s). Roll the cut finger back and onto the proximal phalanx to form the tourniquet (**Figure 104-4**).

Several commercially produced digital tourniquets are often available in the Emergency Department. The Tourni-cot (Mar Med Co., Grand Rapids, MI) is a sterile, single use, disposable, rubber ring that slides over the fingertip and rolled backward until it rests over the proximal phalanx (**Figure 104-5**). These come in several sizes to fit the appropriate finger size. The advantage of the Tourni-cot is that it exsanguinates the digit as it is applied. The T-Ring (Precision Medical Devices LLC, San Clemente, CA) is a "one size fits all" digital tourniquet (**Figure 104-6**). It is a sterile, single use, disposable, rubber diaphragm with a central hole. It slides over the fingertip and is pushed backward until it rests over the proximal phalanx. The T-Ring also exsanguinates the digit as it is applied.

PATIENT PREPARATION

The first step in the evaluation of fingertip injuries is obtaining a thorough history. The mechanism of injury can provide some clues to the type and extent of injuries as well as amount of contamination to be expected. Other pertinent information includes age, hand dominance, occupation or hobbies, comorbidities, and tetanus vaccination status. All significant injuries to the fingertip should be evaluated radiographically for fractures. The management of fingertip injuries may differ in the presence of a fracture. Thoroughly evaluate and document a complete neurovascular examination, tendon function and intactness, and ligamentous stability of the joints. Ascertain the patient's tetanus immune status and administer prophylaxis if required.

It is important to explain both the risks of doing the procedure and of not doing the procedure. Document this conversation and obtain an informed consent. Place the patient on a gurney with the hand on a bedside procedure table in a well-lit area. Be prepared to use age-appropriate sedation or to apply appropriate restraints for children.[11] Procedural sedation may be necessary in patients who are agitated, uncooperative, or require extensive repair. Apply a type

FIGURE 104-4. A sterile glove used as a digital tourniquet.

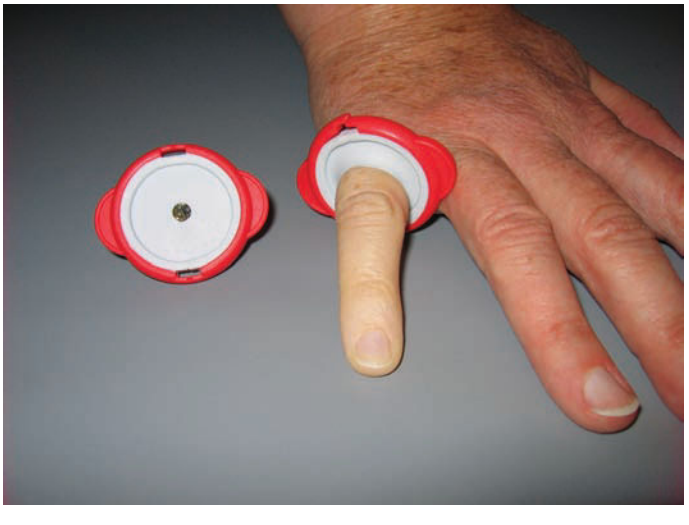

FIGURE 104-6. The T-Ring digital tourniquet.

of magnification device if available. This may consist of a head-strap device, a swing arm device, magnification glasses, or loupe magnification glasses.

Anesthetize the injured digit(s). Anesthesia may be achieved with a digital block or a metacarpal block when only a single digit is involved.[6] Lidocaine (1% or 2%) can provide pain relief of up to 3 hours. For longer analgesia, use 0.5% bupivacaine. Although recent studies have shown that the practice of using lidocaine with epinephrine for digital blocks is safe, this is still controversial and many do not advocate its use.[13–15] Multiple metacarpal blocks or an axillary nerve block may be performed if multiple digits are involved.[6] Please refer to Chapter 126 for the details regarding regional nerve blocks.

Thoroughly clean the hand of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry.[16] Irrigate the wound with sterile saline. If the nail plate has been avulsed, irrigate it with a dilute povidone iodine or chlorhexidine solution followed by a gentle rinse with sterile saline. **It is important not to scrub the undersurface of the avulsed nail plate because adherent squamous tissue may be destroyed.**[6]

A bloodless field is desired and, in many cases, necessary. Apply a digital tourniquet as described in the "Equipment" section above.[6] If available, a pneumatic tourniquet may be placed on the arm instead of using the digital tourniquet. The pneumatic tourniquet is especially helpful when the patient has fractures or lacerations of the proximal digit that preclude the use of a digital tourniquet. Avoid using a blood pressure cuff, as these tend to deflate during use. **As with all tourniquets, limit the amount of time in which the tourniquet is in place.** Create a sterile field by applying sterile towels.

TECHNIQUES

Adhering to certain principles will improve the outcome when repairing nail beds. A smooth and flat nail bed is necessary to the normal growth of the nail and should be the primary goal in any repair. Avoid or severely limit the amount of debridement.[5] The germinal matrix must be meticulously repaired and the proximal nail fold, the eponychium, preserved or that space is obliterated within a few days and result in adhesions or abnormal nail growth.[5] Thoroughly clean and replace the nail plate whenever possible. This will preserve the nail folds surrounding the nail bed, allow the nail plate to serve as a splint for fractures, and act as a protective cover for the healing nail bed.[6] Treatment goals also include preservation of length and sensation of the fingertip, early mobilization, prevention of joint contractures, and attention to cosmesis.[4,17]

The technique of nail bed repair depends upon the type of injury as well as which structures are involved. Various classification schemes, such as the nature of injury or anatomic location, have been developed to categorize fingertip injuries and guide treatment. Nail bed injuries are classified as simple lacerations, crushing lacerations, avulsion-lacerations, lacerations with associated fractures, lacerations with loss of skin and pulp, and fingertip amputations.[2,12]

NAIL PLATE REMOVAL

A significant force is required to break the nail plate. **The nail plate should be removed to visualize the underlying nail bed if the nail plate is damaged or avulsed, or the lateral skin folds lacerated as an associated nail bed injury is highly likely.** Removal of the nail plate is unnecessary in minor injuries where the nail plate is not damaged and still attached to the nail folds.

Remove the nail plate to repair nail bed injuries or to inspect the nail bed for potential injuries (**Figure 104-7**). Insert the closed tips of a fine scissors between the nail bed and the nail plate. A periosteal elevator, if available, can be substituted for the scissors. Hold the scissors parallel to the long axis of the finger. Slightly angle the tips of the scissors toward the nail plate to prevent any damage to the nail bed.[11] Advance the tips of the scissors 1 to 2 mm. Open the blades of the scissors to separate the nail bed from the nail plate. Close the blades of the scissors. Continue to advance the tips of the scissors in 1 to 2 mm increments and separate the nail bed from the nail plate. Stop advancing the scissors when the tips of the blades are at the level of the eponychium. Firmly grasp the nail plate with a hemostat. Pull the nail plate parallel to the long axis of the finger to completely remove it from the finger.

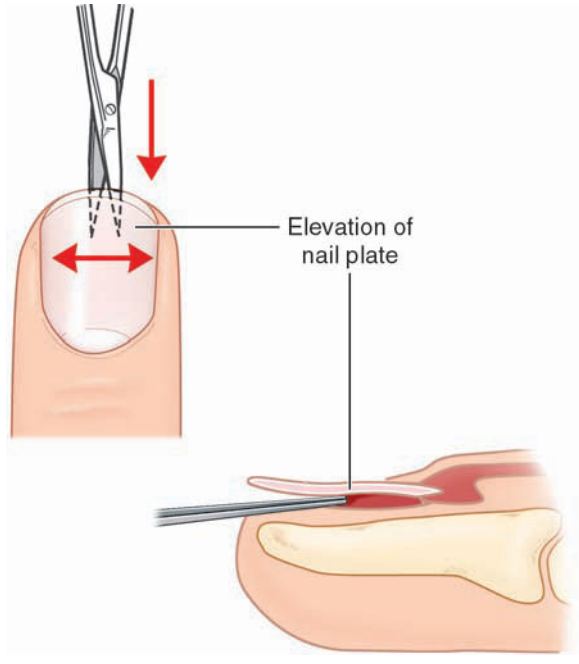

FIGURE 104-7. Removal of the nail plate. Dissect along the plane between the nail plate and the nail bed using a pair of fine scissors or periosteal elevator.

Making two linear incisions with a scalpel at 90° from the eponychial edge will allow greater exposure to the germinal matrix for repair (**Figure 104-8**).[7] This allows the eponychium to be folded or sutured back and therefore increase exposure of the germinal matrix.[2,17]

SIMPLE LACERATIONS

Simple lacerations are caused by localized blows to the nail plate. After removing the nail plate and exposing the nail bed, repair the laceration meticulously using 6-0 or 7-0 chromic gut or irradiated polyglactin 910 sutures.[2,6,17] **Minimize debridement as much as possible to avoid scarring that will result in nonadherence or**

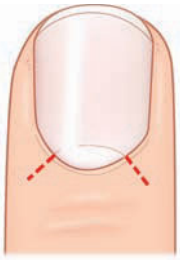

FIGURE 104-8. Incisions can be made at 90° to the corners of the eponychium for better exposure of the germinal matrix.

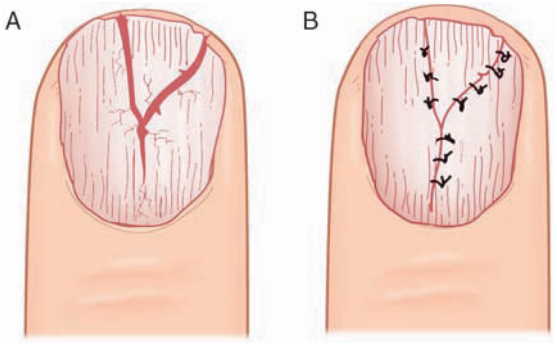

FIGURE 104-9. Crushing lacerations to the nail bed. **A.** Stellate or complex lacerations of the nail bed can occur after a crush injury. **B.** Approximation of the nail bed with fine absorbable sutures.

splitting of the nail plate. Repair any skin lacerations adjacent to the nail bed using 6-0 or 5-0 monofilament nylon sutures.[5] Nail fold lacerations may require repair in layers in order to preserve these spaces.[9]

CRUSHING LACERATIONS

The second type of injury is a crush injury with resultant lacerations. Crushing injuries may produce stellate lacerations and fragmentation of the nail bed (**Figure 104-9A**). Attempt to meticulously repair the fragmented nail bed using 6-0 or 7-0 chromic gut or irradiated polyglactin 910 sutures to achieve precise approximation and the smoothest result possible (**Figure 104-9B**).[6]

AVULSION-LACERATIONS

The third type of nail bed injury is the avulsion-laceration (**Figure 104-10A**). These injuries are more complex than the previously described injuries. Distal nail bed avulsions simply require petrolatum gauze to be placed over the injury followed by sterile gauze. Suture the petrolatum gauze and sterile gauze in place using 5-0 or 6-0 nylon suture for 10 days to allow the wound to heal by second intention (**Figure 104-10B**).[5,17] Avulsion-laceration injuries may require consultation with a Hand Surgeon depending on the amount of tissue involved and whether the germinal matrix is involved.[6,11,12] More severely damaged nail beds with a large amount of avulsed tissue usually require dermal grafts or split-thickness matrix grafts.[6]

Small fragments of avulsed nail bed may remain attached to the nail plate. These may be simply treated by carefully replacing the nail plate in its anatomic position.[18] Larger segments of avulsed nail bed that remain attached to the nail plate should be repaired (**Figures 104-11A & B**). Gently shave away the nail bed from the nail plate with a #15 scalpel blade (**Figure 104-11C**). Replace the avulsed nail bed and suture it in place with 5-0 or 6-0 chromic gut or irradiated polyglactin 910 sutures (**Figure 104-11D**).[10,18] Apply a petrolatum gauze dressing and replace the nail plate.

A special type of avulsion injury occurs when there is a crush injury to the distal fingernail. This results in an avulsion of the proximal nail plate with or without involvement of the germinal matrix (**Figure 104-2**). The proximal nail plate is less adherent to the nail bed and can be pulled out from under the eponychium (**Figure 104-2**). Remove the nail plate if the proximal nail plate is avulsed without involvement of the germinal matrix. Clean the nail plate and nail bed with sterile saline. Replace and secure the nail plate.

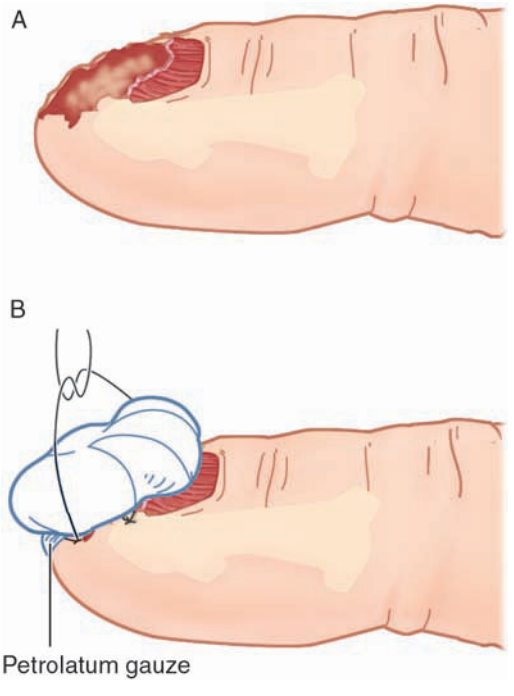

FIGURE 104-10. Avulsion-laceration of the nail bed. **A.** The dorsal aspect of the fingertip is avulsed with the nail plate. **B.** Petrolatum gauze is placed over the injury. This is subsequently covered with sterile gauze and sutured into place for 10 days.

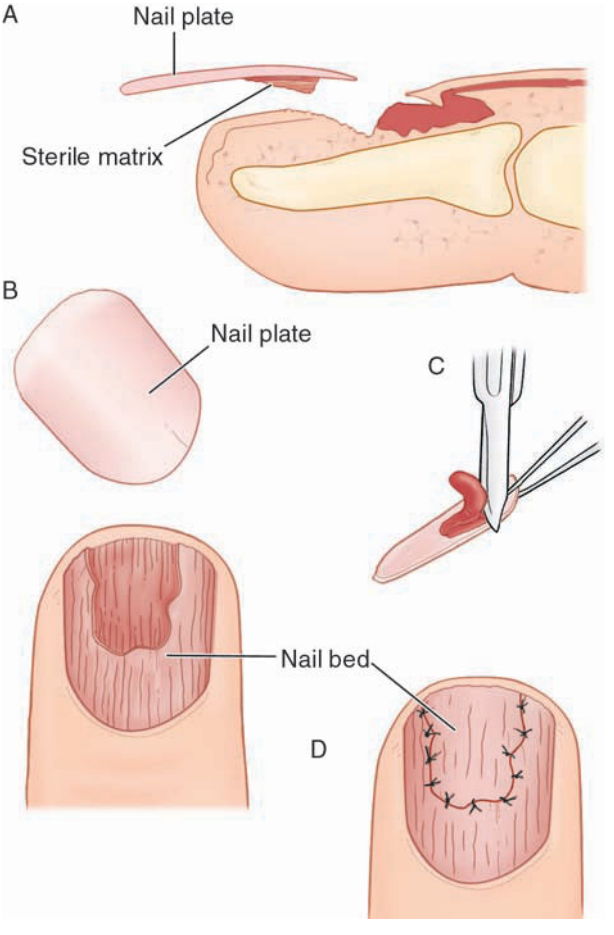

FIGURE 104-11. Large avulsion of the nail bed that is adherent to the nail plate. **A.** Lateral view of injury. **B.** Top view of injury. **C.** Gently shave away the avulsed segment. **D.** Repair the nail bed using the avulsed segment.

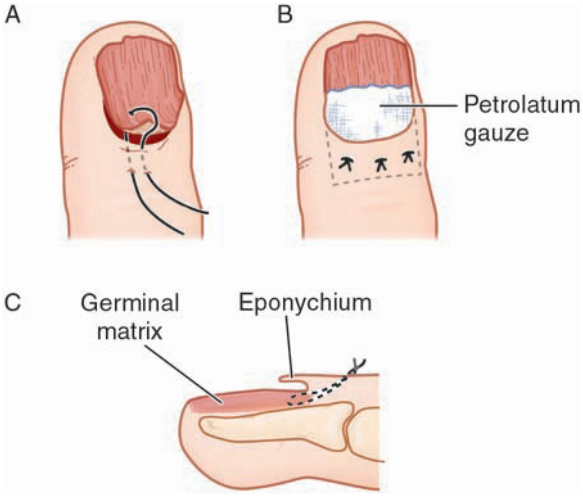

FIGURE 104-12. Repair of the germinal matrix after an avulsion. **A.** A series of horizontal mattress sutures are placed. **B.** The nail bed is returned to its proper location and the sutures tied. **C.** Lateral view of the repair.

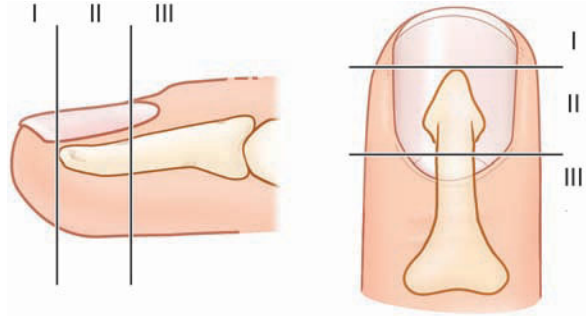

FIGURE 104-13. Classification of fingertip injuries. Zone I is distal to the bony phalanx. Zone II is distal to the lunule and over the bony phalanx. Zone III is proximal to the distal end of the lunule.

More often with these crush injuries the germinal matrix is avulsed as well. In these cases, the germinal matrix should be replaced with a series, usually three, of 6-0 nylon simple interrupted or horizontal mattress sutures (**Figure 104-12**).[5,6,10] Place all three sutures before returning the nail bed to its proper location. Making two linear incisions with a scalpel at 90° from the eponychial edge will allow exposure to the germinal matrix for repair (**Figure 104-8**).[7] This allows the eponychium to be folded or sutured back and therefore increase exposure of the germinal matrix. Place a piece of petrolatum gauze between the eponychium and the germinal matrix after the repair (**Figure 104-12B**). Larger germinal matrix avulsions require consultation with a Hand Surgeon for grafting.[2,6,11,17]

LACERATIONS WITH ASSOCIATED FRACTURES

The fourth type of nail bed injury is lacerations associated with fracture(s). Approximately 50% of nail bed injuries have an associated phalangeal tuft fracture.[19] The nail bed laceration should be repaired as previously described and the fracture addressed as a separate entity.[5] It is important to remember that the sterile matrix is closely adherent to the dorsal periosteum of the distal phalanx. Therefore, fractures require precise anatomic reduction in order for normal nail bed healing and nail plate growth to take place.[6,10,12] Replacing the nail plate and splinting the finger after repairing the nail bed laceration is often enough to reduce these fractures. Occasionally, fixation may be employed by a Hand Surgeon using Kirschner wires to prevent rotation of the bony fragments.[2,6]

LACERATIONS WITH SKIN LOSS AND FINGERTIP AMPUTATIONS

The final two types of injury are lacerations with loss of skin and pulp, and fingertip amputations. They can be further classified according to zones based upon the anatomic level of amputation (**Figure 104-13**).[3] Zone I injuries occur distal to the bony phalanx. These do not result in the loss of function and rarely result in a cosmetic deformity. Management consists of cleansing, placing topical antibiotic ointment over the injured area, and then applying a layer of petrolatum gauze. This should be followed by a sterile dressing and a splint. Zone II injuries occur distal to the lunule and over the bony phalanx. These injuries often have exposed bone. Zone III injuries occur proximal to the distal end of the lunule. Zone II and Zone III injuries should be managed in consultation with a Hand Surgeon. Either type of injury may require reconstruction with a pedicle flap and/or skin grafting.[3]

TREPHINATION FOR A SUBUNGUAL HEMATOMA

A subungual hematoma is a collection of blood under the nail plate caused by blunt trauma to the fingertip. The nail bed is usually crushed or lacerated with resultant extravasation of blood into the plane between the nail plate and the nail bed.[11] As pressure builds up, compression of nail bed nerves occurs and often causes significant pain. Usually this pain is what causes the patient to seek medical attention. The management of subungual hematomas is discussed separately because these injuries are typically minor and treated by simple trephination. A complete discussion of the management of subungual hematomas can be found in Chapter 102.

It is generally accepted that subungual hematomas <50% of the nail plate may be managed conservatively by simple trephination (puncture) of the nail plate.[2,5,6,11,17,20,21] This allows for drainage of blood and immediate pain relief. No anesthesia is usually necessary for this procedure. Ideally, this is accomplished with the use of an electrocautery device creating a 3 to 4 mm hole in the nail plate overlying the hematoma. The nail plate should be clean and dry for this procedure. If an electrocautery device is not available, a heated paperclip may be used.[5] Refer to Chapter 102 for more complete details of the procedure.

Some controversy exists over the management of subungual hematomas >50% of the nail plate. The concern is that a larger hematoma may hide an occult laceration that requires repair in order to avoid the complication of step-off with subsequent ridging as the new nail grows back. Some authors feel that it is impossible to accurately assess the amount of damage beneath a subungual hematoma unless the nail plate is removed to directly inspect the nail bed.[6,21] These authors noted that subungual hematomas that have separated greater than 50% usually have lacerations that require repair. Another study found that a subungual hematoma with more than 50% separation had a 60% incidence of having a nail bed laceration that required repair and up to a 95% incidence when there was an associated phalanx fracture.[21] In contrast to these studies, a prospective study found no complications at 6 months follow-up for subungual hematomas treated by electrocautery trephination alone.[2,20] This was regardless of the size of the subungual hematoma or the presence of a fracture. These authors feel that removing the nail plate and attempting repair may actually cause further trauma to the nail bed.[20]

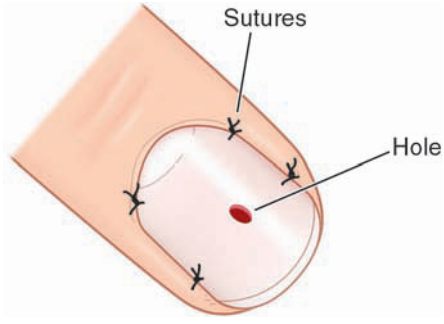

FIGURE 104-14. A hole is placed in the nail plate before it is sutured in place.

It was previously recommended that radiographs be obtained to rule out a fracture for all hematomas larger than 50% of the nail plate. A newer study found no correlation between the size of the hematoma and the presence of fractures.[20] If a fracture is suspected, have a low threshold to obtain plain radiographs prior to evacuating the hematoma.

In summary, most subungual hematomas may be treated by simple nail trephination using an electrocautery device. This procedure will lead to beneficial drainage only if done before 36 to 48 hours from the time of the injury.[11] The clinical benefit of nail bed repair with larger subungual hematomas is controversial. **It may be prudent to maintain a lower threshold for nail bed repair with a larger subungual hematoma, particularly if an ideal cosmetic outcome is desired.**

AFTERCARE

Whenever possible, the nail plate should be replaced after repairing any of the above-mentioned injuries. The nail plate covers the sensitive nail bed and protects it from injury, maintains the proximal nail fold (eponychium) to allow for growth of a new nail, and splints the nail bed. In order to accomplish the best outcome, place a hole in the center of the nail plate to allow for fluid drainage.[11] Make one or two holes in the lateral aspects of the nail plate. Suture the nail plate in place using 5-0 nylon sutures through the lateral skin folds (**Figure 104-14**).[6,10,11] These sutures should remain in place for 7 days. An alternative to suturing the nail plate in position is to use tissue adhesive. After replacing the nail plate, apply tissue adhesive along the eponychium and lateral nail folds at the area where they overlap the nail plate. An artificial nail may be used if the original nail plate is not available. The potential problem with sterile prefabricated nails is that there exists an increased risk for infection and a risk of erosion into the nail bed or nail folds.[6] The editor recommends petrolatum gauze be used to maintain the nail fold structures when the original nail plate is not available or significantly damaged (**Figure 104-15**).

After repair of the nail bed, the digit(s) involved will need to be bandaged in order to protect it from infection, moisture, and trauma. The application of becaplermin, recombinant human platelet-derived growth factor, has shown to improve outcomes.[22] This substance is not routinely used in the Emergency Department and should be applied after consultation with a Hand Surgeon. Place petrolatum gauze over the nail bed to avoid adherence from secretions. Apply a tube gauze dressing followed by a digital aluminum splint.[3] Movement of the distal interphalangeal joint should be restricted for 7 to 10 days with a splint.[6] For infants and young children, the entire hand should be dressed. If petrolatum gauze was used to keep the proximal nail fold (eponychium) open, it should be removed in 5 to 10 days.[6] Petrolatum gauze used to keep open the lateral nail folds (perionychium) should remain in place for 10 days.[5] Any sutures placed in the skin structures or nail folds should be removed in 7 to 10 days.[5]

Prophylactic antibiotics are not routinely required. They are recommended for large avulsions, amputations, and associated fractures when there is contamination with organic material.[6] Topical antibiotics may be applied to Zone I fingertip amputations. All injuries require a wound check in 24 to 72 hours.[3,5,6] The patient's tetanus immune status should be determined and prophylaxis administered if required. The hand should be elevated whenever possible. Narcotic analgesics may be prescribed as needed for pain control.

It is important to explain to the patient that regeneration of a new nail may take up to 6 to 12 months.[6] Warn the patient that as the new nail forms, it may look irregular and snag on cloth or string objects.[6] The patient should trim and file the leading edge of the new nail once it extends past the hyponychium in order to avoid snagging.

COMPLICATIONS

The complications associated with failure to repair or improper repair of a nail bed can be either functional, cosmetic, or both. The more serious complications are those which impair function or cause pain. There are basically seven complications that may arise. These exclude the infectious complications (abscess formation, cellulitis, and lymphangitis) that are inherent to all wounds. The occurrence of osteomyelitis from these injuries is rare, even with open fractures. The seven complications are loss of the nail, a split nail, a nonadherent nail, an ingrown nail, a malaligned nail, wide nails, and narrow nails.[12]

The complete loss of a nail could result in significant functional impairment to the fingertip as well as an abnormal looking fingertip. Complete nail loss occurs when there is complete disruption of the germinal matrix, either by significant avulsion of the matrix or amputation. Remember that if the germinal or roof matrices are not

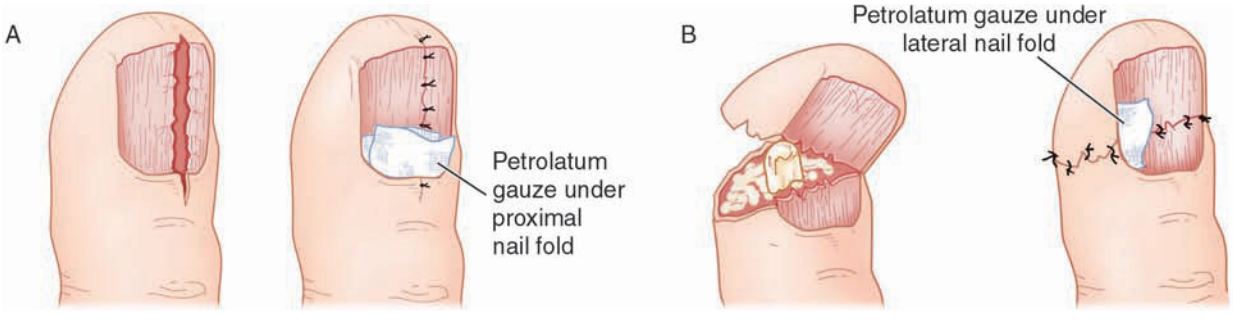

FIGURE 104-15. Petrolatum gauze may be placed between the dorsal roof and germinal matrix (**A**) or between the lateral skin fold and nail bed (**B**) to preserve the skin fold spaces.

repaired, the pouch deep to the proximal skin fold (eponychium) is obliterated within a few days.[20]

A split nail occurs when the germinal matrix is improperly approximated.[5,6,12] A wide scar will result that will not form a new nail. Subsequently, a split nail develops. This can be avoided by the careful approximation of the nail bed with sutures.

A nonadherent nail occurs when the nail bed is not repaired and granulation tissue forms secondarily. The nail plate will not adhere at the site of the granulation tissue as well as distal to the granulation tissue.[12] The nail can snag and be exposed to repeated tears once the nail plate loses adhesion to the nail bed.

The nail plate may ingrow if the lateral skin folds or sulci are not maintained and kept open.[12] Adhesions that form between the skin and nail bed can be very painful when the new nail tries to grow through that space.[5] Ingrown nails also have the long-term problem of a higher rate of infections (paronychia). This can be avoided by the replacement of the nail plate or the placement of petrolatum gauze to elevate the lateral nail fold from the nail bed.

The nail plate will grow in a malaligned direction if the matrix is displaced or repaired in such a manner that it is improperly aligned.[12] Functional impairment and cosmetic deformity may ensue depending upon the degree of this misdirected growth.

Wide nails often result from a crush injury with a tuft fracture.[12] Separated bony fragments leave the nail bed flatter and wider. Narrow nails occur when a central avulsion-laceration is not repaired. Scar tissue forms in the center and allows the intact lateral portions to contract toward each other.[12] The new nail subsequently becomes narrow and thick.

Tubular gauze dressings are commonly applied after the repair of a nail bed. When improperly placed, tubular gauze dressings can result in significant injury.[23,24] This includes digital ischemia that may be permanent and require an amputation. Tubular gauze dressings should not be placed by healthcare personnel not trained in their proper application.

SUMMARY

Nail bed injuries are common and may result in a cosmetically deformed or functionally impaired fingertip. Complications may occur even with precise repair. The treatment of choice is immediate primary repair of the nail bed and surrounding structures. Remember to minimize any debridement and to replace the nail plate whenever possible. Injuries with associated fractures and simple subungual hematomas are managed separately from the nail bed injury. Always be thorough and meticulous when repairing nail bed injuries to provide the best possible outcome. Finally, know when to consult with a Hand Surgeon.

105 Ganglion Cyst Aspiration and Injection

Thomas P. Graham

INTRODUCTION

Ganglion cysts, also known as synovial cysts or ganglia, are the most common soft tissue tumors of the wrist and hand.[1] They are a common reason for patients to present to the Emergency Department. The chief complaint is usually a mild pain or ache, exacerbated by movement, and localized to a 1 to 2 cm mass on the wrist or hand. Patients may also present with concerns about a painless "lump." Acute trauma prior to presentation is uncommon, though patients often give a history of repetitive motion at the site. The mass usually increases in size progressively over time or, occasionally, may grow rapidly over a short period. Patients presenting to the Emergency Department with ganglia may have already attempted one of several popular home remedies, including homeopathic medications or striking the cyst firmly with a large book or hammer.

Ganglion cyst aspiration is a relatively simple procedure that may be performed by the Emergency Physician. The practice of cyst aspiration has been challenged because of the high recurrence rate after the procedure.[2,3] Recurrence rates of up to and even greater than 50% have been described.[4,5] However, the procedure usually alleviates presenting symptoms, is occasionally curative, and is more cost-effective than referring all patients for surgical treatment.[6]

ANATOMY AND PATHOPHYSIOLOGY

Ganglia are synovial cysts that originate from a joint capsule or tendon sheath. They have no malignant potential. It is unclear whether ganglia are formed by herniation of the tendon sheath, myxomatous degeneration of connective tissue, or some other mechanism. Contained within the cyst is a viscous, jelly-like fluid. Ganglia often connect with the underlying synovial cavity or tendon sheath by a stalk. Hyaluronic acid makes up all or part of the mucoid fluid.[7]

Ganglia are usually encountered on the dorsum of the wrist, in particular over the scapholunate ligament (**Figure 105-1**). They may also be found on the palmar surface of the wrist, the lateral surface of the wrist, or on the hand itself. Ganglia of the foot and ankle are less commonly seen.[8] Ganglia are less commonly encountered in other areas such as the shoulder, hip, elbow, knee (including the anterior cruciate ligament), the lumbar spine, temporomandibular joint, and even the odontoid process of the cervical spine.[9–11]

Ganglia present as fixed or slightly movable masses that are usually solitary. Frequently characterized as smooth and "rubbery," cysts may become more noticeable with wrist flexion. They vary in size from barely palpable to 3 cm in diameter (smaller than 1.5 cm being the norm). Tenderness is sometimes but not invariably present. Ganglion cysts will transilluminate, as they are fluid-filled. They may "disappear" over time by spontaneously rupturing or resorption.

Diagnosing a ganglion cyst is usually not difficult. However, ganglia of the foot and those occurring in other uncommon locations may be difficult to palpate despite causing significant discomfort. The differential diagnosis of ganglia includes joint capsulitis, neuromas, and other soft tissue neoplasms such as sarcomas and chondrosarcomas. Ultrasonography can be employed to aid in the diagnosis, particularly of occult ganglia or ganglia presenting atypically.[12] MRI is frequently used to confirm the diagnosis and plan its

FIGURE 105-1. Oblique view of the wrist demonstrating a ganglion cyst overlying the scapholunate joint.

operative removal. Plain radiographs and laboratory tests are not helpful in the work-up.

INDICATIONS

The most common indication for ganglion aspiration is worsening pain and swelling, in particular when normal range of motion is restricted or occupational disability is present. Failure of conservative measures such as rest, splinting, and the use of nonsteroidal anti-inflammatory medications to resolve symptoms may also prompt ganglion aspiration in the Emergency Department.

CONTRAINDICATIONS

There are few contraindications to ganglion cyst aspiration. Introducing a needle through an area of cellulitis should be avoided. However, cellulitis overlying a ganglion is uncommon and should raise suspicion for an alternate diagnosis such as a skin abscess. The procedure can be safely deferred, with the patient being given a referral to a Hand Surgeon, if the diagnosis of a ganglion is uncertain.

The location of a ganglion is generally not a contraindication to aspiration. However, the procedure should be deferred if there is a concern that the aspirating needle could damage an adjacent structure and cause neurologic or vascular injury. Aspiration of lower extremity ganglia may be performed in a similar fashion to hand and wrist lesions, with similar results.[8,13] Some literature suggests that volar wrist ganglion cysts recur at an even higher rate than those of the dorsal wrist and lower extremity; leading some authors to recommend surgical excision, and not aspiration, as the primary therapy for this subset of ganglia.[14]

EQUIPMENT

- Sterile gloves
- Povidone iodine solution or chlorhexidine solution
- Local anesthetic solution without epinephrine
- 25 or 27 gauge needle on a 3 mL syringe for local anesthesia
- 16 or 18 gauge needle on a 5 or 10 mL syringe for aspiration
- 10 to 15 mg methylprednisolone acetate (20 mg/mL) or prednisolone tebutate (20 mg/mL)

PATIENT PREPARATION

Explain the risks and benefits of the procedure to the patient and/or their representative. Obtain an informed consent, either signed or verbal, with adequate documentation to support the latter method. If available, ultrasonography can be used to confirm the diagnosis and to facilitate needle entry into the cyst. When ganglia are located near neurovascular structures, ultrasound can help to avoid these structures.[15] Place the patient on a gurney with the hand on a bedside procedure table. Clean the skin of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry. It is recommended to provide local anesthesia for patient comfort, although the cyst can be aspirated and/or injected without anesthesia. Place a subcutaneous wheal of local anesthetic solution immediately over or adjacent to the periphery of the ganglion.

TECHNIQUE

GANGLION ASPIRATION

Manipulate the wrist (or other affected extremity) to expose more of the cyst and facilitate needle entry into the cavity. Insert a 16 or 18 gauge needle on a 5 or 10 mL syringe through the anesthetized tissue and into the ganglion cyst cavity (**Figure 105-2**). Apply negative pressure to the syringe to aspirate the cyst contents once the tip of the needle is within the cyst cavity. The contents may be difficult to aspirate, as the mucinous contents of the cyst are quite viscous. The cyst can be manipulated and compressed to express more of the contents into the syringe once the very viscous, clear or yellow material begins to flow into the syringe. Generally, 1 to 2 mL of fluid can be aspirated from a typical ganglion. Withdraw the needle when fluid can no longer be aspirated. Apply a simple dressing. A pressure dressing may also be temporarily applied, taking care not to compromise neurologic or vascular function.

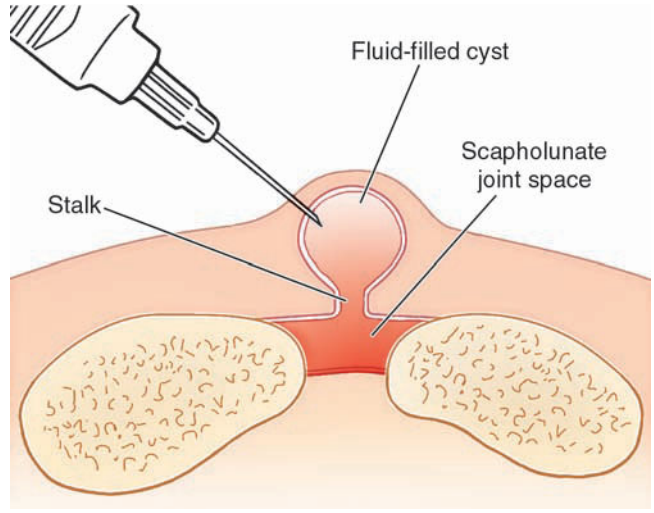

FIGURE 105-2. Cross section through the scapholunate joint demonstrating a ganglion cyst. The needle is inserted into the cyst cavity to aspirate its contents.

GLUCOCORTICOID INJECTION

The injection of glucocorticoids into a ganglion cyst immediately after aspiration is commonly recommended. One small study showed glucocorticoid injections decreased recurrence rates compared to aspiration alone.[16] The literature has not yet shown a clear benefit.[17] If a steroid injection is desired, securely hold the aspirating needle in place after the cyst contents have been aspirated into the syringe. Remove the syringe. Without moving the needle, attach a second syringe containing 10 to 15 mg of the glucocorticoid solution onto the needle. Aspirate to confirm the tip of the needle is not within a vascular structure. Inject the glucocorticoid solution into the cyst cavity. Withdraw the needle and apply a simple dressing.

ALTERNATIVE TECHNIQUES

Other variations of ganglion cyst aspiration and injection have been described in the literature. The injection of hyaluronidase into the cyst, with or without corticosteroids, has shown favorable results.[18,19] Puncturing the ganglion wall at multiple separate locations has not been proven to decrease the recurrence rate when compared to aspiration at a single point alone.[20] Injection of hypertonic saline and other sclerosants (e.g., 1 mL of 3% sodium tetradecyl sulfate) has been suggested. Further study is necessary before these techniques can be recommended for widespread use in the Emergency Department.

ASSESSMENT

Patients usually report total or near-total relief of their symptoms immediately after aspiration. Obtaining highly viscous, clear or yellow fluid from the cyst virtually confirms the diagnosis.

Obtaining purulent fluid suggests a skin abscess and not a ganglion cyst. Failure to obtain fluid does not rule out the diagnosis of a ganglion, but should prompt an evaluation for alternative diagnoses.

AFTERCARE

Patients should be reassured that ganglia are not malignant tumors. Immobilization of the affected limb may be performed temporarily for patient comfort. However, splinting limits the ability of patients to function normally and does not appear to affect recurrence rates.[21] Aftercare instructions should direct patients to return to the Emergency Department for any significant increase in pain, erythema at the site or up the extremity, swelling beyond the ganglion's original size, purulent discharge, continued bleeding, or the development of a fever. Patients should also be directed to elevate the extremity, avoid strenuous activity of the affected limb, and rewrap the pressure dressing (if one is applied) to make it snug but not uncomfortable. Acetaminophen or nonsteroidal anti-inflammatory medications may be recommended for relief of mild postprocedure pain. Narcotic analgesics are not required nor recommended. Oral corticosteroids have not been demonstrated to play a role in ganglion therapy.

All patients with ganglion cysts aspirated in the Emergency Department should be informed of the potential for recurrence and the possibility of definitive ganglion treatment by surgical excision. Referral to a Hand Surgeon should be provided, if desired by the patient. Although reports of postsurgical recurrence rates vary widely, currently the most effective therapy for ganglion cysts is believed to be open excision. During this procedure, a Hand Surgeon removes the cyst and, if possible, the stalk or pedicle that connects it to the normal synovium. Arthroscopic removal of wrist ganglia has also been described and performed successfully.[22]

COMPLICATIONS

Complications of ganglion cyst aspiration are uncommon. They include bleeding and infection. Bleeding is self-limited and easily controlled with manual pressure. The use of sterile technique will minimize any infectious complications (abscess, cellulitis, or septic arthritis). Rare complications of corticosteroid injection include localized depigmentation that is due to injection outside of the cyst capsule or leakage out of the cyst capsule through the needle tract.[23] Subcutaneous infiltration of glucocorticoids can also result in fat atrophy, skin atrophy, and skin dimpling from fat atrophy.

SUMMARY

Ganglion cysts are common growths of the wrist and hand. They frequently enlarge to cause pain, sometimes to the point of disability. Contraindications to the aspiration of a ganglion cyst in the Emergency Department are few. The procedure is often warranted due to debilitating pain, deformity, or inability on the patient's part to promptly seek the care of a surgical specialist. The procedure is simple, quick, and only slightly uncomfortable if performed correctly. Although the injection of steroids into the cyst is commonly advocated to prevent recurrence, the efficacy of this procedure has not been conclusively demonstrated. Ganglia recurrence is very common after aspiration and may occur even after surgical excision. This fact must be clearly relayed to the patient. All patients should be offered referral to a Hand Surgeon on a nonemergent basis to discuss further intervention.

106 Subcutaneous Abscess Incision and Drainage

Samuel J. Gutman and Michael B. Secter

INTRODUCTION

Subcutaneous abscesses are commonly seen in the Emergency Department. Approximately 1% to 2.5% of patients present with this chief complaint.[1–3] Abscesses occur in numerous anatomical areas with varied etiology and bacteriology. An abscess is a tender and fluctuant mass located in the dermal or subdermal tissue. It usually demonstrates the classic inflammatory responses of rubor, tumor, dolor, and calor. Although the abscess is usually tender, the surrounding and underlying tissue should not be tender.[4,5] There is usually minimal surrounding erythema in a mature abscess.

Incision and drainage is the definitive treatment of a soft tissue abscess.[6] This procedure results in significant improvement in symptoms and a rapid resolution of the infection in uncomplicated cases.[7] However, premature incision before localization of pus will not be curative and may be deleterious. In cases of immature abscesses or cellulitis, oral antibiotics and warm compresses may be of value in helping the infection to coalesce. These methods are not a substitute for incision and drainage and should not be continued for more than 24 to 36 hours without a reassessment of the patient. With the emergence of methicillin-resistant *Staphylococcus aureus* (MRSA), the role for ancillary antibiotic use has come into question.

ANATOMY AND PATHOPHYSIOLOGY

PATHOGENESIS

An abscess is a localized collection of pus caused by suppuration buried in a tissue, organ, or confined space.[8] Intact skin is very resistant to bacterial invasion. Localized pyogenic infections are usually initiated by a breakdown in the normal epithelial defense mechanisms in the normal host. Plugging of the ducts of a superficial exocrine gland, such as apocrine and sebaceous glands or a congenital cyst or sinus, may initiate the process. Occlusion prevents desquamation and provides a moist environment for organisms to proliferate. The combination of a high concentration of organisms, the presence of nutrients, and sufficient damage to the corneal skin layer to allow organisms to penetrate the skin defenses results in abscess formation.[1,9]

Subcutaneous abscesses typically begin as a cellulitis with organisms that cause necrosis, liquefaction, and accumulation of leukocytes and debris. Early stages appear as an area of hyperemia and tender inflammation that later becomes fluctuant as an exudate of leukocytes, necrotic material, and cellular debris accumulates. This is followed by loculation and walling off of the pus. This progresses and the area of liquefaction increases until it "points" and eventually ruptures through the area of least resistance.[5]

The body area involved depends upon host factors such as drug use, employment-related exposures, or minor trauma.[9,10] Areas with a compromised blood supply are more prone to infection as normal host cell-mediated immunity is not as available.[9] The frequency of abscess occurrence in different body areas includes the buttocks and perirectal area in 25% of cases, the head and neck in 20%, the extremities in 18%, the axilla in 16%, and the inguinal area in 15%.[1]

BACTERIOLOGY

The majority of abscesses are polymicrobial with the isolated organisms usually representing the normal resident flora associated with

the body area on which the abscess is found.[1,11] Nonresident bacteria are found in abscesses that occur as a result of direct inoculation of extraneous organisms such as those following human bite wounds, intravenous drug use, or bacterial seeding of embedded foreign bodies.[12] In normal hosts, aerobic *Staphylococcus* and group A *Streptococcus* are the most common organisms isolated from abscesses of the head, neck, extremities, and trunk.[11,13] Anaerobes are found in all areas of the body but predominate in abscesses of the buttocks and perirectal regions.[11,13]

Staphylococcus aureus occurs in 24% to 60% of abscesses and in pure cultures is the only organism in 21% to 72% of cases.[1,13–16] Community-acquired MRSA (CA-MRSA) is presently considered to be the most common identifiable pathogen causing abscess at major centers.[17] CA-MRSA is defined as infection with MRSA acquired in the community lacking the traditional risk factors of hospital-acquired MRSA including a recent stay in a long-term care facility or in a day care setting, recent healthcare contacts or surgery, an indwelling device, dialysis, immunosuppression, chronic illness, or recent antibiotic use.[18,19] Many cohorts of patients who are at a higher risk of acquiring MRSA infections include those with recent household or daycare contacts, children, men who have sex with men, those in the military, incarcerated patients, athletes (especially those in contact sports or who share equipment), Native Americans, Pacific Islanders, patients with previous MRSA infections, and intravenous drug users.[18–21] While it is important to consider MRSA in patients with aforementioned risk factors it is essential not to exclude MRSA in the absence of them.[17] Patients presenting with a complaint of a "spider bite" should be investigated for MRSA.[18,19,22] In a recent observational study of urban patients, MRSA was isolated from abscesses in 51% of patients.[23] An American study of 11 academic centers found MRSA incidence rates as high as 74% in patients presenting with abscesses.[17] As much as 77% of MRSA-related illness, especially presenting in the Emergency Department, are skin and soft tissue infections (SSTI).[24]

CA-MRSA carries the *mec*A gene, which is thought to impart the antimicrobial resistance. This is carried on the Staphylococcal Cassette Chromosome Type-IV, which is distinct from other forms of MRSA.[18,19] CA-MRSA also produces an exotoxin called Panton-Valentine Leukocidin (PVL) that predisposes patients to cutaneous infections.[18,19] PVL has been identified in up to 98% of CA-MRSA cases.[17]

Up to 17% of abscesses are sterile.[1,7,13] Nearly 40% of these are secondary to intravenous drug use and most likely result from injection of necrotizing chemical irritants.[3] Viruses (e.g., herpes), autoimmune mechanisms, or systemic illnesses including metastatic tumors, benign tumors, and granulomatous disease may also cause sterile abscesses.[4,25] These atypical etiologies may present with the absence of local inflammatory signs and symptoms and only with an exacerbation of the underlying disease process.

SPECIFIC CLINICAL ENTITIES

Furuncles, or boils, are acute circumscribed abscesses of the skin and subcutaneous tissue that most commonly occur on the face, neck, buttocks, thigh, perineum, breast, or axilla. Carbuncles are aggregates of interconnected furuncles that frequently occur on the back of the neck where the thick skin causes lateral extension of the infection rather than pointing toward the skin surface. These occur with a higher frequency in diabetics. They can be large and cause systemic signs, symptoms, and complications. Carbuncles often require surgical consultation and treatment in the Operating Room.

Hidradenitis suppurativa is a chronic relapsing inflammatory disease process affecting the apocrine glands primarily in the axilla, the inguinal region, or both.[26] Initially, this process will appear like a typical abscess and is only identifiable in its chronic scarring phase when there are multiple lesions with tender areas of induration and inflammation in various stages of healing. The chronic process leads to draining fistulous tracts that require ongoing surgical management. Emergency Department management involves the usual incision and drainage procedure of any area of fluctuance. Patients should be informed that the intervention is not curative and that the problem is chronic. Arrange a referral to a General Surgeon, Dermatologist, or Plastic Surgeon for long-term follow-up.

Up to 80% of breast abscesses occur in nonlactating women.[4] Peripheral and superficial lesions are similar to abscesses elsewhere on the body and respond to conservative incision and drainage with an incision that radiates out (centripetally) from the nipple.[27] Deeper and periareolar abscesses are often complex and require surgical referral and general anesthesia to properly treat. Postpartum mastitis is common and precipitated by milk stasis and bacterial invasion through a cracked nipple. The offending organism is commonly *Staphylococcus aureus* or *Streptococcus* species. Treatment includes the application of heat, oral antibiotics, and continued breast emptying with a breast pump or feeding of the baby. The mastitis may evolve into an abscess and is often associated with systemic symptoms. Appropriate antibiotic therapy and follow-up in 24 to 48 hours is required.

Sebaceous cysts are a common cause of a subcutaneous abscess. They can persist for long periods as nontender subcutaneous swellings before becoming infected. They appear like most other abscesses. Sebaceous cysts can be identified by a small punctate sinus tract near the center of the fluctuant area. The initial treatment is incision and drainage. The contents are usually thick cheesy material that needs to be manually expressed. A sebaceous cyst has a definite shiny white capsule that must be excised, preferably at the time of incision and drainage or at the first follow-up visit, to prevent recurrence. The area is then treated as any other healing abscess cavity.

The recurrence of an abscess that has been previously drained should suggest the possibility of underlying osteomyelitis, a retained foreign body, or the presence of unusual organisms such as mycobacteria or fungi. Recurrent abscesses should prompt further investigation including an assessment of the patient's immune status.

SPECIAL CONSIDERATIONS

The precise risk for endocarditis associated with subcutaneous abscesses is unknown. Up to 5% of patients with abscesses have bacteremia at the time of presentation.[4,16] Incision and drainage of cutaneous abscesses can result in transient bacteremia with the organism causing the abscess.[7,14,28] More recently, the clinical relevance of this bacteremia has become controversial.[16] **At this time, only patients considered to be at high risk for endocarditis are recommended to receive antimicrobial prophylaxis before incision and drainage (Table 106-1).**[29] Bacterial endocarditis prophylaxis should be directed at the most likely pathogen causing the infection. An antistaphylococcal penicillin or a first-generation cephalosporin is an appropriate choice for most soft tissue infections (**Table 106-2**). Clindamycin is an acceptable alternative for patients allergic to penicillin. Patients with immunodeficiency and localized soft tissue abscesses may be at higher risk for developing septicemia secondary to bacteremia induced by incision and drainage, but it is unclear if they are at higher risk of complications and death.[30,31] These patients may benefit from prophylactic antibiotics prior to incision and drainage, but only indirect evidence and no controlled studies are available.[32] **High-risk patients with known**

TABLE 106-1 Cardiac Conditions at Risk for Endocarditis that Require Antibiotic Prophylaxis for Incision and Drainage[29]

Prosthetic cardiac valves—including bioprosthetic and homograft valves
Previous bacterial endocarditis
Unrepaired cyanotic congenital heart disease (CHD)—including palliative shunts and conduits
Repaired CHD with prosthetic material or device—within 6 months after the procedure (regardless of method of placement)
Repaired CHD with residual defects at or adjacent to site of prosthetic patch or device
Cardiac transplant with cardiac valvulopathy
Except for the conditions listed above antibiotic prophylaxis is no longer recommended for any other form of CHD

or suspected MRSA infection should receive IV Vancomycin or Clindamycin when undergoing incision and drainage.[29]

PATIENT ASSESSMENT

Prior to the treatment of an abscess, a focused history should be taken assessing for trauma, intravenous drug use, history of fever, and past medical history. Specifically inquire about diabetes, renal failure, steroid use or other immune suppression, peripheral vascular disease, and valvular heart disease. It is important to note any of the aforementioned risk factors for CA-MRSA as this may alter management of certain patient populations. Past anesthetic history and the potential for aspiration should be assessed if procedural sedation is to be considered.[33] Medications and allergies should be queried. The patient's tetanus status must be confirmed and booster doses provided as required.

A brief physical examination documenting function and intact distal neurovascular status of extremities involved is required. Evidence of pain on passive or active movement of fingers may suggest a deep space infection.[4] A high index of suspicion is required, especially in injection drug users (IDU), to identify those seemingly simple cutaneous infections that unpredictably evolve into extensive necrotizing soft tissue infections.[34] General assessment of the airway and cardiopulmonary system, vital signs, and mental status is indicated if procedural sedation is to be employed.[33]

Routine laboratory studies are not indicated in otherwise healthy individuals. In immunocompromised patients, a CBC looking for leukopenia or toxic granulations should be considered. Diabetics should have electrolytes, BUN, creatinine, and glucose assessed. Elevated potassium in diabetics may indicate myonecrosis.[35] Consider a urinalysis for myoglobinuria.

Culturing the purulent material from a drained abscess was previously considered to be of little value. Controversy exists today as to the value of culture in abscess management. While many experts suggest that it is of little value because it has no bearing on acute management (curative I & D), others suggest that it is vital to help determine antimicrobial susceptibility and outbreak patterns.[22] **Cultures should be obtained as they may alter later management in cases with recurrent or refractory infections, those patients who are seriously ill or immunocompromised, patients on an antimicrobial with variable activity, those who have failed surgical treatment, and any patient being admitted to the hospital.[22,36]** Gram stain and cultures for both aerobic and anaerobic bacteria may be helpful in those patients who are febrile, systemically unwell, immunocompromised, or who present atypically. Consider obtaining radiographs of the affected areas if there is a history of trauma, drug use, or concern regarding deep infection. Foreign bodies and fractures may not be easily identifiable because of the edema and tenderness caused by the infection. Gas or osteolytic lesions on plain radiographs may indicate severe deeper infection, the need for urgent surgical consultation, and prompt antibiotic therapy.[37]

ULTRASONOGRAPHIC EVALUATION

Bedside ultrasound use in the Emergency Department is of great value to the Emergency Physician in evaluating skin and soft tissue infections. This modality can be used to differentiate a cellulitis from an abscess in difficult cases. Ultrasound is portable, inexpensive, comfortable for patients, and provides no radiation

TABLE 106-2 Prophylactic Antibiotic Regimens for Procedures[29]

Clinical situation	Agent	Dose*	Timing
Standard general prophylaxis	Amoxicillin	Adults: 2.0 g Child: 50 mg/kg	PO, 30–60 min prior to the procedure
Unable to take oral medications	Ampicillin	Adults: 2.0 g Child: 50 mg/kg	IV or IM, 30 min prior to the procedure
Unable to take oral medications	Cefazolin or Ceftriaxone**	Adults: 1.0 g Child 50 mg/kg	IV or IM, 30–60 min before procedure
Allergic to penicillin or ampicillin	Cephalexin**	Adults: 2.0 g Child: 50 mg/kg	PO, 30–60 min prior to procedure
Allergic to penicillin or ampicillin	Clindamycin	Adults: 600 mg Child: 20 mg/kg	PO, 30–60 min prior to procedure
Allergic to penicillin or ampicillin	Azithromycin or Clarithromycin	Adults: 500 mg Child: 15 mg/kg	PO, 30–60 min prior to procedure
Allergic to penicillin and unable to take oral medications	Cefazolin or Ceftriaxone**	Adults: 1.0 g Child: 25 mg/kg	IV or IM, 30–60 min prior to procedure
Allergic to penicillin and unable to take oral medications	Clindamycin	Adults: 600 mg Child: 20 mg/kg	IV or IM, 30-60 min prior to procedure
Known or suspected MRSA	Vancomycin	Adults: 1 g Child 20 mg/kg	IV, 30 min prior to procedure

*Total child dose should not exceed adult dose.

**Cephalosporins should not be used in patients with immediate-type hypersensitivity reactions (urticaria, angioedema, or anaphylaxis) to penicillin.

exposure. It is fast and easy to gain proficiency for specific applications.[38] Ultrasound is indicated for ambiguous physical findings such as widespread cellulitis, localizing an incision site, and for ruling out dangerous masses such as a pseudoaneurysm that masquerade as an abscess.[39] Ultrasonography is helpful in identifying small or early abscesses, deep abscesses, abscesses under previous scars, and for localizing adjacent major vessels or nerves.[39] Recent studies have found that ultrasound has a sensitivity of 98% and specificity of 88% in detecting an abscess.[38] One study of presumed cellulitis in the Emergency Department found that ultrasound changed the case management in 71 of 126 patients (56%), as swelling thought to be due to cellulitis can hide an abscess.[40] In the pediatric population, ultrasound is useful in evaluating a cellulitis and determining if an incision and drainage is necessary.[41] Finally, ultrasound can be used to guide an aspiration to confirm the presence of an abscess and to obtain material for culture and gram stain.[42]

Before ultrasonographic examination, it is important that the Emergency Physician has an appreciation of the anatomical structures of the area. The location and sonographic appearance of arteries, veins, nerves, and tendons should be known before the incision and drainage procedure. Generally, a 5 to 7.5 MHz linear array transducer is used. Some find a standoff pad or gel-filled glove to be useful for superficial structures.[39] Once the probe has been electronically focused to an ideal depth, scan the area of infection in two orthogonal planes.[39,40] Lower frequency transducers are useful for deeper abscesses, while higher frequency probes are more effective for superficial abscesses. **It is important to use probe covers as well as proper cleaning and disinfecting supplies in order to avoid cross contamination.**

Differentiation between a cellulitis and an abscess on ultrasound is based on several findings. Cellulitis shows diffuse hyperechogenicity and thickening of the skin and subcutaneous fat. The presence of echo-poor strands between hyperechoic fatty lobules in the subcutaneous tissue is known as cobblestoning and is indicative of cellulitis.[38,39,42] (**Figure 106-1**). An abscess has a wider array of presentations on ultrasound. Most frequently, an abscess is a spherical or elliptical shaped anechoic or echo-poor region with sharper echogenic borders.[39,43] (**Figure 106-2**). Within the echo-poor area there may be gas, lobulations, septations, and echogenic debris. There are some cases where the abscess can appear to be isoechoic and even hyperechoic. In these cases, there may be a role for ultrasound-guided aspiration.[43] If unsure if an abscess is present on ultrasound, gentle digital palpation or pressure may induce motion of the purulent material within the abscess.[43] Posterior acoustic enhancement can be seen in the presence of an abscess.[39] This technique can help rule out similarly presenting hematomas, necrotic tumors, vascular lesions, or schwannomas.[42] There is an emerging role for Doppler ultrasound in abscess evaluation. The findings of increased vasculature, peripheral blushing and hyperemia, and increased large vessel flow around the abscess are common (**Figure 106-3**).[44]

FIGURE 106-1. Ultrasound image of a breast showing cobblestoning of the subcutaneous tissue indicative of edema secondary to cellulitis with echogenic material surrounded by echo-poor areas consistent with early abscess formation.

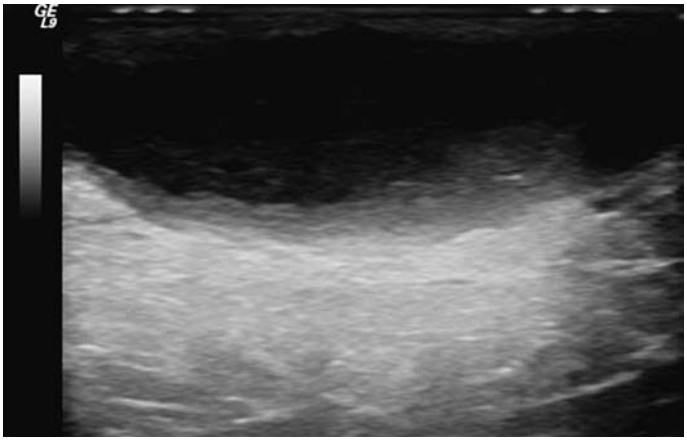

FIGURE 106-2. Ultrasound image showing a large hypoechoic area representing a large superficial abscess.

INDICATIONS

The presence of a fluctuant mass in an area of induration, erythema, and tenderness is clinical evidence that an abscess requires incision and drainage. Antimicrobial treatment without incision and

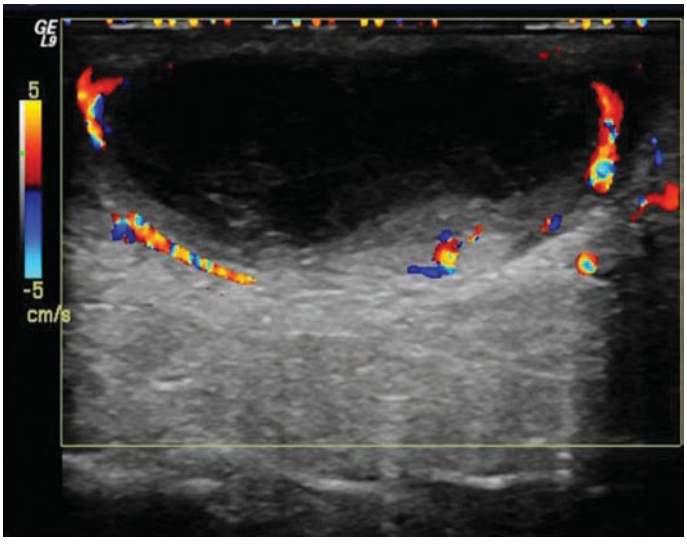

FIGURE 106-3. Color Doppler ultrasound image showing peripheral hyperemia around a large abscess cavity.

drainage can lead to treatment failures in patients with abscesses.[45] Examination alone may not definitively indicate an abscess, especially if it is deep. This can be further confirmed by bedside ultrasound, with or without needle aspiration.[4] Obtaining purulent material on aspiration identifies an abscess and is an indication for incision and drainage.[4] If no pus is aspirated, oral antibiotics, warm compresses, and follow-up in 24 hours must be arranged for a reassessment.

CONTRAINDICATIONS

The only absolute contraindication to the incision and drainage of an abscess in the Emergency Department is the possible association with a mycotic aneurysm.[10,35] Commonly, abscesses overlie large vessels including those in the anterior triangle of the neck, the supraclavicular fossa, the deep space of the axilla, the antecubital fossa, the groin, and the popliteal space.[46] In these locations, or if the abscess is pulsatile, fine needle aspiration for blood, diagnostic imaging, and/or angiography is indicated prior to incision and drainage.

Relative contraindications to incision and drainage include an inability to achieve adequate anesthesia. An abscess associated with a deep foreign body that requires additional real-time imaging such as a fluoroscopy or ultrasound may require surgical referral.[47] Proximity of an abscess to important neurologic, tendinous, or vascular structures may require specialty consultation and magnification in the operating room. Deep space infections or involvement of any joint requires admission for parenteral antibiotic therapy and possible operative debridement. Patients presenting with soft tissue infections exhibiting pain out of proportion to physical examination findings or deep anesthesia of the involved or distal area should raise the possibility of deeper infections such as necrotizing fasciitis or myonecrosis.[37] Perirectal and periurethral abscesses are often larger and deeper than they appear and may be complicated by sinus tracts that require exploration under general anesthesia. Manipulation of abscesses in the "danger triangle" of the face (corners of the mouth to glabella) can lead to septic thrombosis of the cavernous sinus. Periorbital or orbital abscesses require ophthalmologic assessment and treatment.

EQUIPMENT

Anesthesia

- 18 and 27 gauge needles, 1½ in. long
- 10 mL syringes
- Povidone iodine or chlorhexidine solution
- Local anesthetic solution with epinephrine
- Local anesthetic solution without epinephrine if abscess is near an end arteriolar system
- Ethyl chloride spray
- Ice pack

Procedure

- #11 and #15 scalpel blades on a handle
- Two hemostats, in two sizes for breaking up loculations and probing the cavity
- Scissors
- Normal saline
- 10 or 20 mL syringe with a 20 or 22 gauge angiocatheter
- Suction source, tubing, and catheter for larger abscesses
- 4 × 4 gauze squares
- Iodoform gauze packing
- Adhesive tape
- Culture swabs and vials
- Ultrasound machine with a 5 to 7.5 MHz probe
- Ultrasound probe covers
- Ultrasound gel
- Standoff pad
- Ultrasound probe cleaning and disinfecting solutions

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Patients should be warned of potential cosmetic complications prior to proceeding. Obtain an informed consent to perform the procedure. If endocarditis prophylaxis is indicated, oral regimens should be given 1 hour prior to the procedure and parenteral regimens within 30 minutes of the procedure (**Table 106-1**). Clean the skin of any dirt and debris. Apply povidone iodine or chlorhexidine solution to the skin and allow it to dry. Apply drapes to delineate a sterile field. Many Emergency Physicians regard this last step optional. The procedure of cutting into a contaminated abscess is considered to be clean and not sterile.

ANESTHESIA

It is usually possible to achieve adequate anesthesia for the skin incision but any additional manipulation may be painful. Local anesthetic infiltration is often less effective than in other procedures. The pH of infected tissue is often low and retards the diffusion of the local anesthetic solution into nerve axons.[48] A regional field block can be instituted by injecting a ring of 1% lidocaine or 0.5% bupivacaine subcutaneously approximately 1 cm away from the perimeter of the erythematous border of the abscess. The onset of anesthesia occurs after about 5 minutes. A small amount of local anesthetic solution can be injected intradermally into the roof of the abscess in a linear fashion along the line of the planned incision (**Figure 106-4A**).[4] Be careful during this portion of the procedure as the abscess may be under pressure. The inadvertent injection of local anesthetic solution into the abscess cavity may cause fluid to be forcibly ejected toward the Emergency Physician. **Appropriate universal precautions should be employed including a face mask and eye protection.**

In superficial abscesses or furuncles, which are unlikely to require significant exploration, topical ethyl chloride spray can be used to provide anesthesia. Invert the bottle and compress the spray nozzle to begin the flow of fluid. Direct the spray toward the planned site of incision. The pain relief from ethyl chloride is variable and fleeting. It is also highly flammable.[5] The application of an ice pack over the planned incision site secured with an elastic bandage for 15 minutes can also be effective. This may be especially useful for children, those with severe needle phobias, or in cases of a true anesthetic allergy.

Nitrous oxide is safe and was previously thought to be effective as an adjunct to the incision and drainage of abscesses.[49] More recently, it has been shown to cause no significant reduction in pain and to only be marginally effective as an anxiolytic.[50] Procedural sedation with agents such as ketofol (ketamine and propofol in a 50:50 mixture in a dose of approximately 1 mL/kg IV in adults) can be useful in deep abscesses that require extensive probing.[51] It is difficult to obtain adequate pain control in these cases, even with a well-performed field block.

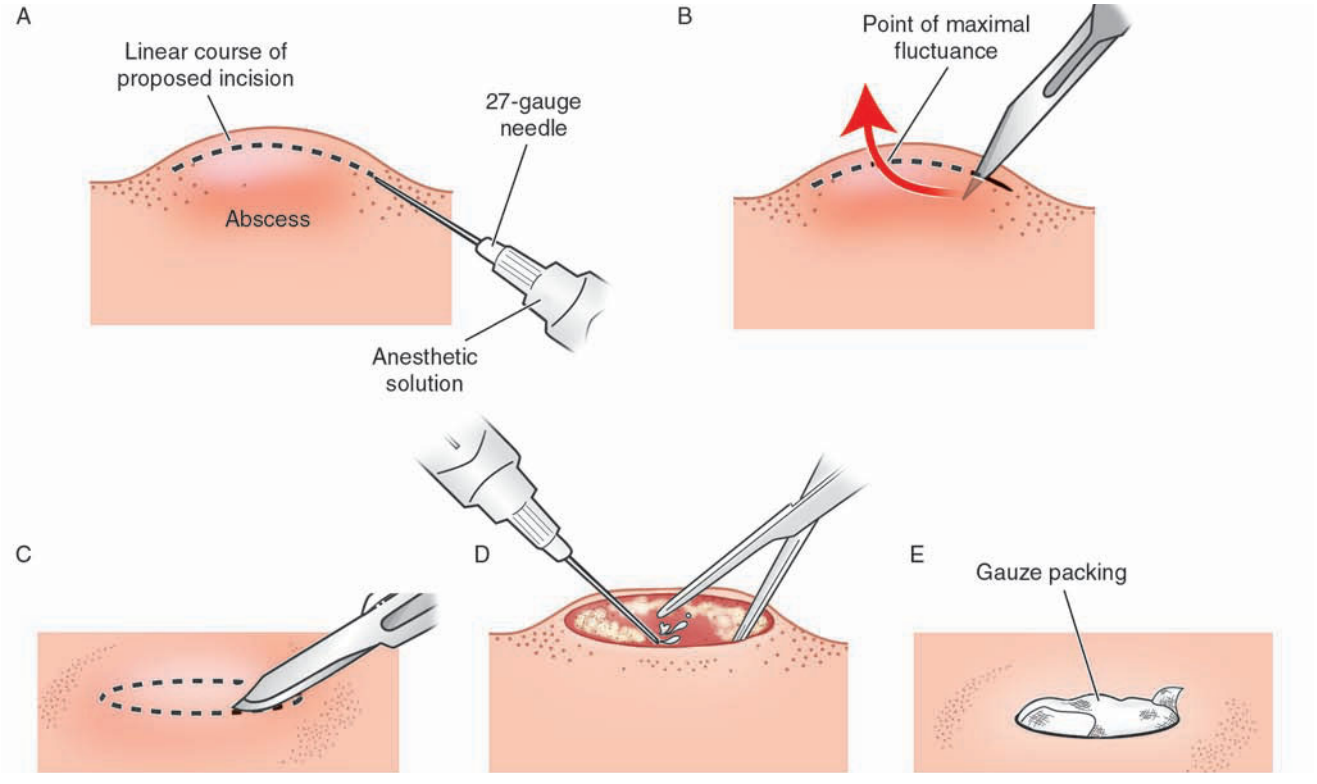

FIGURE 106-4. Incision and drainage of a subcutaneous abscess. **A.** Infiltration of local anesthetic solution over the abscess. **B.** A straight incision to drain the abscess. **C.** An elliptical incision to drain the abscess. **D.** The wound is irrigated with sterile saline. Any pockets of pus are opened by blunt dissection with the hemostat. **E.** The wound is packed open.

TECHNIQUES

ASPIRATION

Aspiration is performed as a diagnostic procedure in cases of soft tissue infections where the presence of an abscess is unclear, a mycotic aneurysm must be ruled out, or samples for Gram stain and culture are required. **Aspiration is not a therapeutic procedure in and of itself.** Anesthetize the skin. If ultrasound is available, locate the abscess cavity and try to determine the shortest needle path. Insert an 18 gauge needle attached to a 10 mL syringe into the skin. On ultrasound, the needle should appear as a bright, hyperechoic line with posterior reverberation artifact.[42] As the needle penetrates deeper, it should become increasingly oblique. Apply negative pressure to the syringe. Advance the needle into the area where pus or blood is presumed to be loculated. The procedure should be terminated and incision and drainage should be performed immediately if pus is obtained on aspiration. Anaerobic and aerobic culture bottles should be inoculated directly from the syringe if cultures are indicated. Simple swabbing of the purulent material after incision and drainage is inadequate for growth of anaerobic organisms. If blood is aspirated, terminate the procedure and apply firm pressure to the area to prevent a hematoma from forming. Angiography with surgical consultation should immediately follow. If no pus or blood is aspirated, redirect the needle in several directions to confirm the absence of an abscess. Discharge the patient with oral antibiotics, warm compresses, and follow-up in 24 hours for a reassessment.

INCISION AND DRAINAGE

Make an incision spanning the entire area of fluctuance and parallel to the relaxed skin tension lines to reduce scarring.[35] A straight incision with a #11 scalpel blade is usually performed (**Figure 106-4B**). An elliptical incision with a #15 scalpel blade is an alternative and often results in a similar appearing final scar (**Figure 106-4C**). The purpose of the elliptical incision is to remove a full thickness wedge of tissue so that the wound will remain open. This type of incision should not be made in cosmetically sensitive areas (e.g., face, neck, or breasts) or in areas with minimal subcutaneous tissue (e.g., hands and feet). **It is important to ensure a large enough incision to promote adequate drainage with the exception of cosmetically sensitive areas where a stab incision may be initially attempted to limit scar formation.**[5]

Debride any necrotic or devitalized tissue. Probe the cavity by inserting a hemostat. Gently spread the jaws open to break up any loculations and to release any further pockets of purulent material (**Figure 106-4D**).[6] Rotate the hemostat around the entire abscess to break any loculations. A scalpel should not be used for the blunt dissection of an abscess cavity as it may cause additional tissue damage and bacteremia.[14] Remove the tough shiny capsule by grasping the edges with a hemostat and applying firm traction if the abscess is due to an infected sebaceous cyst. The capsule can often be removed intact.

Irrigate the abscess cavity with an 18 gauge angiocatheter attached to a 10 mL syringe containing sterile saline (**Figure 106-4D**). This will flush away all loosened purulent and necrotic material. Loosely pack iodoform gauze into the abscess cavity (**Figure 106-4E**). Leave 1 to 2 cm of gauze exiting from the cavity to prevent the incision from sealing over and ensure an adequate drainage tract for the cavity. The value of antiseptic impregnated gauze over plain gauze is uncertain. Do not over pack the abscess cavity as this may interfere with the inflammatory hyperemia necessary for healing or retard drainage and reproduce "abscess-like" conditions.[6] Apply an absorbent dressing of 4 × 4 gauze over the

wound. Splinting and elevation of the affected area may be beneficial in select patients (e.g., young patients and confused patients).

AFTERCARE

The majority of available evidence suggests that incision and drainage of subcutaneous abscesses alone is adequate treatment and additional antimicrobial therapy is unnecessary in healthy patients with no major comorbidities. Many recent studies involving abscesses, including those caused by MRSA, have demonstrated that patients have similar outcomes regardless of whether or not appropriate antibiotics were used after an abscess incision and drainage.[17,24,52–54] A pediatric study demonstrated 94% resolution with incision and drainage alone in patients with abscesses smaller than 5 cm in diameter.[52] Some conflicting evidence from a retrospective cohort found ancillary antimicrobial treatment active against MRSA had a resolution of 95% while those patients not receiving antimicrobial treatment had a resolution of only 87%.[55]

Consider empiric antimicrobial therapy active against MRSA in cases involving multiple lesions, cutaneous gangrene, immunocompromised patients, extensive surrounding cellulitis, systemic toxicity, unusual pathogens, and in patients requiring hospitalization.[36,56] Further, recommendations from the Center for Disease Control suggest antibiotics after incision and drainage in those with rapid progression, comorbidities such as diabetes mellitus, HIV, neoplastic disease, those patients at extremes of age, abscesses in locations that are difficult to drain or have a risk of septic phlebitis associated with it, and lack of response to incision and drainage alone.[19] Pediatric patients with abscesses greater than 5 cm should also receive empiric antimicrobial therapy.[52]

An oral antibiotic such as cephalexin can be a good first choice for healthy individuals in areas where the prevalence of MRSA is extremely low.[19] **Knowledge of local MRSA prevalence and antimicrobial susceptibility patterns are paramount when selecting the appropriate antibiotic.**[19,36] If more than 10% to 15% of community *Staphylococcus aureus* isolates are MRSA, empiric treatment with agents that show activity against MRSA is warranted.[57] Current guidelines for outpatient therapy suggest using trimethoprim-sulfamethoxazole, Clindamycin, Doxycycline, Minocycline, or Linezolid. Rifampin can be added to many of these antimicrobials, but should not be used alone. IV therapy for patients with significant comorbidities and signs of systemic infection should include either Vancomycin, Daptomycin, Linezolid, or Tigecycline.[22,56] Trimethoprim-sulfamethoxazole, Clindamycin, and Doxycycline (if over the age of 7 years) are recommended in healthy children.[58] More serious infections should be approached with IV Vancomycin or Clindamycin, with the addition of nafcillin or gentamicin, and admission to the hospital.[58] The addition of an agent active against Group A Streptococcus is also recommended in cases with a severe surrounding cellulitis.[19] Current literature and consideration of the local antibiotic resistance patterns should guide antimicrobial selection.[19,56,59]

Follow-up in 24 to 48 hours to remove the packing and assess the response to therapy should be arranged. Pain can be adequately controlled with the use of acetaminophen or nonsteroidal anti-inflammatory drugs. Narcotic analgesics are rarely required. Instruct the patient to immediately return to the Emergency Department if they develop fever, chills, increased pain, increased swelling, or increased redness to the surrounding skin. Repack the cavity approximately every 48 hours until granulation tissue is developing throughout the wound and the drainage tract is well established if a large amount of drainage continues.[15,60] At that time, the remaining packing is removed and the patient is instructed to soak the area in warm water three to four times per day.[3] Healing occurs in 5 to 9 days in most cases.[4,6,15] The patient may be discharged from medical care when all signs of infection (i.e., erythema, drainage, pain, and induration) have resolved.

FUTURE ADVANCES IN ABSCESS MANAGEMENT

It is currently standard practice to pack an abscess cavity after an incision and drainage. Packing is used for hemostasis, to keep the abscess cavity from closing prematurely, and to debride the abscess cavity. Packing an abscess cavity can be painful and requires multiple follow-up visits. These visits are at an additional cost to the patient. A small, prospective study of noncomplicated abscesses found not packing an abscess cavity resulted in less pain, less analgesic use, and no increased morbidity.[62] Further studies are required before any definitive recommendation can be made regarding to pack or not to pack an abscess cavity.

Abscesses are currently allowed to heal by granulation. This process can take weeks and results in large scars. Primary suture closure after incision and drainage has been used around the world except in the United States.[63,64] This treatment can reduce scarring, reduce pain, and promote faster healing. Most of the studies involve a small number of patients, administered preprocedural antibiotics, and were performed in the Operating Room. Further studies are required before this change in practice can be recommended for the Emergency Department management of abscesses.

DECOLONIZATION AND PREVENTION

The role of decolonization regimes after incision and drainage does not have established effectiveness.[19] However, a decolonization regimen may play a role in those patients with recurrent infections, those not responding to therapy, or in patients with a closely associated cohort at risk (e.g., infirmed family, sports teams, or the institutionalized).[36] A recent randomized controlled trial of 2% chlorhexidine gluconate wash, 2% mupirocin intranasal ointment and oral rifampin, and doxycycline for 7 days found that after 3 months, 74% of patients were free of MRSA colonization.[61] This number dropped to 54% at 8 months post-treatment.[61] Colonization rates vary by geography and colonization is considered a risk factor for MRSA infection. However, decolonization is not routinely recommended due to limited supporting evidence, poor patient compliance, and the risk of increasing antibiotic resistance.[22]

Patient education is the most effective way to reduce the spread of infection and recurrent infections from MRSA.[19,22] Maintaining a clean and dry wound, frequent handwashing and bathing, avoiding sharing any personal items at all (athletic or otherwise), laundering clothing that has come into contact with the wound, avoiding skin to skin contact and disinfecting equipment and other surfaces are essential recommendations that should be made to outpatients with MRSA skin and soft tissue infections.[19]

COMPLICATIONS

Complications resulting from the incision and drainage of an abscess are uncommon. In most cases, some scarring will result from deliberate open packing and secondary intention granulation of the wound. Infectious complications, including inciting bacterial endocarditis as discussed earlier, are possible. **Endocarditis can be avoided with appropriate screening of patients and the administration of prophylactic antibiotic therapy in patients at risk.** Precipitation of septicemia because of transient bacteremia in an immunodeficient patient must be considered prior to the procedure. Incision and drainage of a mycotic aneurysm should not occur if an appropriate assessment is completed prior to making the incision.

SUMMARY

Simple incision and drainage under local or regional anesthesia in the Emergency Department can effectively treat most subcutaneous abscesses. Adjunctive procedural sedation may be required to adequately probe a deep cavity. A directed history and physical examination will identify those who may require additional lab work, imaging, specialty consultation, and follow-up. The majority of patients will not require antibiotics, although there may be a role for ancillary treatment in selected patients with MRSA infections. Attention must be paid to requirements for endocarditis prophylaxis and consideration given to the possibility of inducing bacteremia in any given patient.

107 Paronychia or Eponychia Incision and Drainage

Lisa R. Palivos

INTRODUCTION

A paronychia is an infection or abscess of the tissues around the base and along the sides of the nail plate. It is the most common infection in the hand.[1] A paronychia can be located on the fingers or the toes. It occurs in all age groups. It can cause significant pain and discomfort leading to a visit to the Emergency Department.

A paronychia initially presents with redness, swelling, and tenderness along the edges of the nail plate. This can progress to an abscess that requires drainage. An infection that extends to the overlying proximal cuticle is termed an eponychia. This chapter discusses the treatments, which vary with the extent and the location of the infection.

ANATOMY AND PATHOPHYSIOLOGY

The dorsal aspect of the distal digit consists of the nail plate, the nail bed (matrix), and the perionychium (**Figure 107-1**). The nail bed is situated beneath the nail plate and is responsible for growth of the nail. The perionychium consists of the soft tissue surrounding the nail plate (eponychium and lateral nail folds).

A paronychia is usually the result of frequent trauma, tight fitting apparel (e.g., gloves, pantyhose, and shoes), aggressive manicures, the use of artificial nails, hangnails or ingrown nails, or nail biting.[2] A disruption of the seal between the nail plate and nail fold allows bacteria to enter, leading to pus formation in the eponychial space (**Figure 107-1**). It begins as a swelling and erythema in the dorsolateral corner of the nail fold that can progress to an abscess. A paronychia can grow and spread to adjacent structures and result in a felon, an osteomyelitis, or a tenosynovitis. Many paronychias are polymicrobial, containing both aerobic and anaerobic organisms.[14] The most common organism to cause a paronychia is *Staphylococcus aureus*.[3] In children and nail biters, paronychias are often caused by anaerobes secondary to finger sucking or nail biting.[4] Gram-negative organisms should be considered in immunocompromised hosts. Chronic paronychias are the result of separation of the nail from the nail plate, which leaves a space for bacteria and fungi to collect.[12] These infections are usually caused by *Candida albicans*.[5]

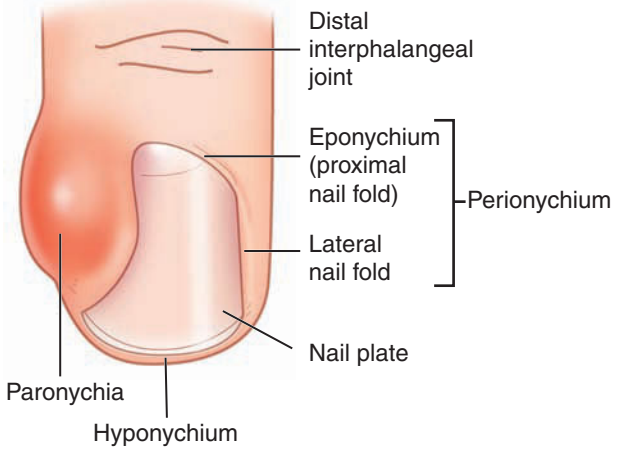

FIGURE 107-1. The distal finger illustrating a paronychia and the surface anatomy.

INDICATIONS

An early paronychia with signs of cellulitis may be treated nonsurgically. This requires frequent warm soaks (e.g., water, vinegar, or Burow's solution), immobilization, elevation, topical antibiotics (e.g., bacitracin or Mupirocin) with or without topical corticosteroids, and follow-up in 24 hours.[2,6,11,12] Paronychia resistant to these measures should be treated with oral antibiotics to cover *Staphylococcus*, plus anaerobic coverage if nail biting or finger sucking were causative agents.[12] Amoxicillin/clavulanate, clindamycin, and trimethoprim-sulfamethoxazole are commonly used antibiotics. Take into account the prevalence of methicillin-resistant *Staphylococcus aureus* in your community when deciding upon the choice of antibiotic.

A progression of the infection results in fluctuance and the formation of an abscess. The digital pressure test may be used to diagnose the presence of an abscess when the exam is otherwise equivocal. Instruct the patient to oppose the thumb and affected finger and apply light pressure to the distal volar aspect of the affected digit. If an abscess is present, the skin under the nail plate will blanch.[10] The presence of an abscess, fluctuance, or pus beneath the nail plate requires an incision and drainage procedure. This procedure will relieve the patient's pain, promote healing, and prevent complications from local extension into surrounding bone and soft tissues.

CONTRAINDICATIONS

A herpetic whitlow is a herpes simplex virus infection of the distal phalanx that can be confused with an early paronychia or felon. The presence of multiple clear vesicles that coalesce suggests a herpetic whitlow. The herpetic whitlow is a nonsurgical and self-limited infection. Treatment consists of a dry dressing to the affected finger in order to prevent autoinoculation and transmission of the infection, oral antiviral agents, and analgesics. Incision and drainage is not recommended, will prolong the recovery, and lead to secondary bacterial infection.[7] A chronic paronychia should be referred to a Hand Surgeon or Dermatologist for treatment.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Sterile gloves
- #11 scalpel blade or an 18 gauge needle
- Local anesthetic solution without epinephrine
- 18 and 27gauge needles
- 5 to 10 mL syringe
- Ethyl chloride spray
- Forceps

- Mosquito hemostat
- Ribbon-gauze packing, ½ in. wide
- Petrolatum gauze, ½ in. wide
- Scissors
- 4 × 4 gauze squares
- 18 gauge angiocatheter
- 20 mL syringe
- Sterile saline
- Adhesive tape

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain an informed consent for the procedure. Assess and update the patient's tetanus immune status if indicated. Place the patient on a gurney with the extremity on a bedside procedure table in a well-lit room. Soak the digit in warm water for 5 minutes to soften the skin. Perform a digital nerve block if the patient is apprehensive, has significant tenderness, or if it is not a simple paronychia or eponychia. Refer to Chapter 126 for the complete details regarding digital anesthesia techniques. Alternatively, apply ethyl chloride spray to the area until the skin turns frosty and pale. Apply povidone iodine or chlorhexidine solution circumferentially to the distal digit and allow it to dry. The digit can be secured to a sterile tongue depressor for better control, especially in uncooperative children.

TECHNIQUES

SIMPLE PARONYCHIA OR EPONYCHIA

There is no need for a skin incision in an uncomplicated paronychia or eponychia. Simply lifting the eponychium off the nail plate at the point of maximal tenderness and/or fluctuance is usually curative. Slide the tip of a #11 scalpel blade (or an 18 gauge needle) under the paronychia, or eponychia, at the site of maximal fluctuance (**Figure 107-2**). Advance the scalpel blade to lift the soft tissue from the nail plate until there is an efflux of purulent fluid. Apply digital pressure to the area to express the pus. Gently place a hemostat under the soft tissue to break any loculations. Irrigate the pocket with an angiocatheter on a syringe containing sterile saline.

Packing a paronychia is controversial and physician-dependent. Place a small piece of ribbon gauze or petrolatum gauze under the elevated soft tissue followed by a simple dressing. If packing is not performed, apply an antibiotic ointment followed by a simple dressing or bandage. Oral antibiotics are not recommended for an uncomplicated paronychia or eponychia.

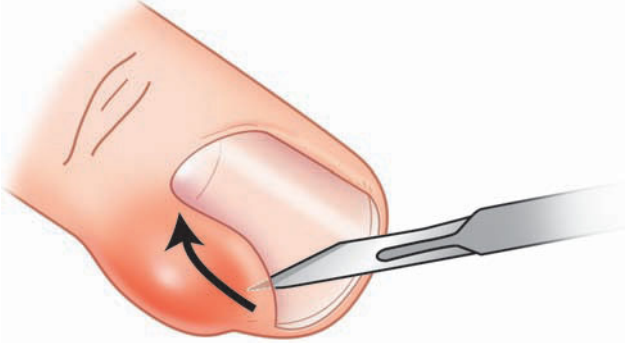

FIGURE 107-2. Drainage of a simple paronychia or eponychia. The eponychial fold is elevated from the nail plate with a #11 scalpel blade. Note that the blade is parallel to the nail plate, thereby avoiding injury to the nail matrix and not incising the skin.

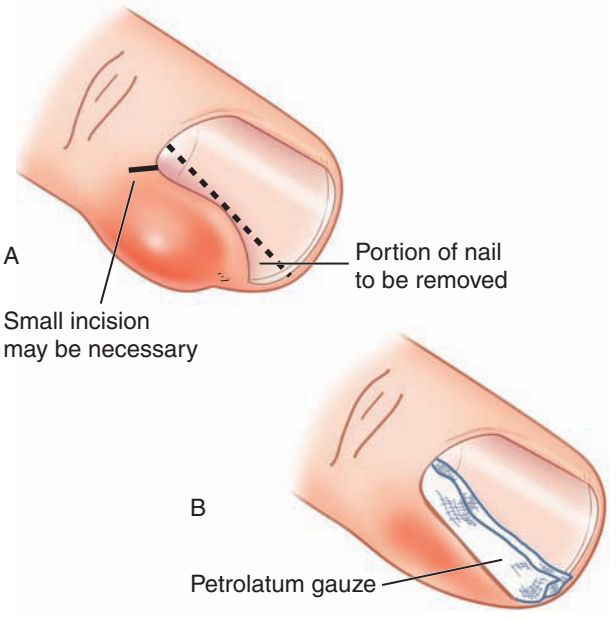

FIGURE 107-3. Removal of the lateral nail plate is required when pus extends laterally below the nail plate. **A.** The dotted line over the nail represents the incision required to remove the nail plate. An additional incision may be required on the eponychium. **B.** The lateral portion of the nail plate has been removed and petrolatum-gauze packing has been inserted to keep the nail fold elevated from the nail bed.

PARONYCHIA WITH EXTENSION UNDER THE LATERAL NAIL PLATE

A more extensive incision and drainage is required when pus accumulates laterally and beneath the nail plate. Remove the lateral nail plate to allow adequate drainage (**Figure 107-3A**). Use scissors to cut the nail plate longitudinally. Aim the point of the scissors upward and against the undersurface of the nail plate to prevent injuring the nail bed. Remove the lateral nail plate with a hemostat. A small (2 to 3 mm) incision may be required in the corner of the nail fold to remove the nail plate (**Figure 107-3A**). This will result in the egress of pus. Irrigate the area with saline. Insert a small piece of petrolatum gauze under the nail fold (**Figure 107-3B**). This will prevent the nail fold from fusing to the nail bed.

PARONYCHIA WITH EXTENSION UNDER THE PROXIMAL NAIL PLATE

A paronychia with extension under the proximal nail plate also requires the removal of a portion of the nail plate (**Figure 107-4**). Make two 3 to 4 mm long incisions at the corners of the nail folds (**Figure 107-4A**). Cut the proximal one-third of the nail plate with scissors (**Figure 107-4B**). Aim the point of the scissors upward and against the undersurface of the nail plate to prevent injuring the nail bed. Grasp and remove the proximal segment of the nail plate with a hemostat. This will result in the egress of pus. Irrigate the area with saline. Insert a piece of petrolatum gauze under the nail fold to prevent it from fusing to the nail bed (**Figure 107-4C**).

Removal of the entire nail is rarely necessary except in the case of an extensive subungual abscess. An alternative to nail removal

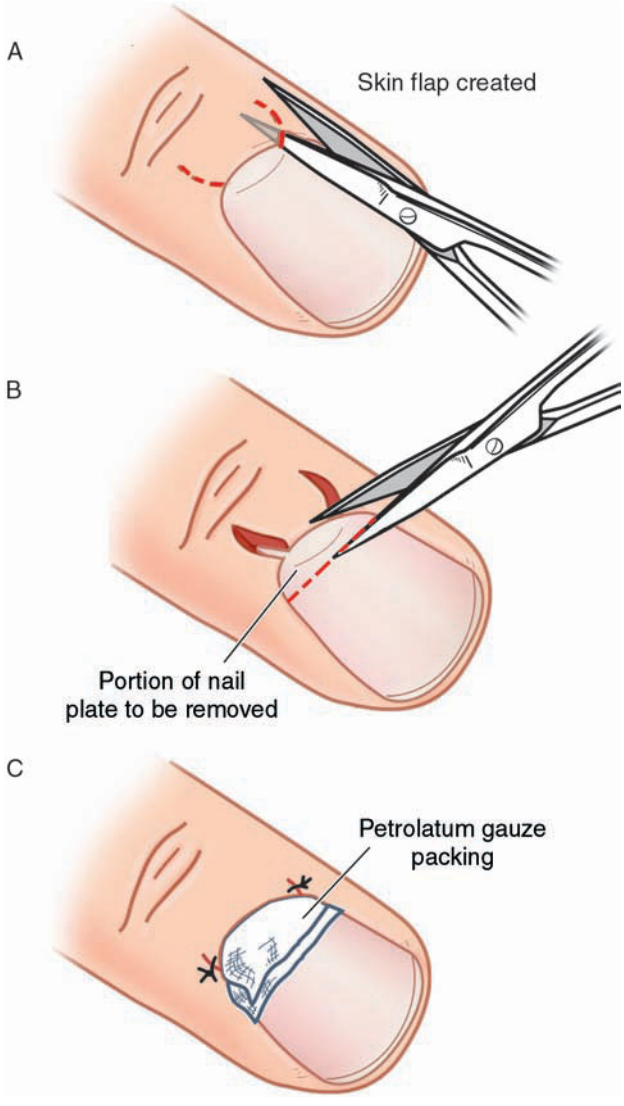

FIGURE 107-4. Removal of the proximal nail plate is required when pus extends proximally below the nail plate. **A.** Two incisions are required through the eponychium, represented by dotted lines. **B.** The dotted line over the nail plate represents the incision required to remove the nail plate. **C.** The proximal portion of the nail plate has been removed and petrolatum-gauze packing has been inserted to keep the nail fold elevated from the nail bed.

is trephination with a heated paper clip or a microcautery unit.[8] A large opening or multiple holes are required with this technique in order to eliminate the pus. Refer to Chapter 102 for the complete details regarding trephination.

CHRONIC PARONYCHIA

A chronic paronychia occurs from recurrent episodes of inflammation or from neglected infections. It is much more difficult to treat and eradicate than an acute infection. A chronic paronychia is seen frequently in immunosuppressed patients, such as those with diabetes or cancer. These effects are due to the disease process, such as in diabetes, or due to effects of treatment, as seen with certain HIV drugs and chemotherapeutic agents.[12] A chronic paronychia is also common in people who wash their hands often, such as dishwashers and healthcare providers. It can also be due to frequent contact with chemicals, finger biting or sucking, and cuticle trimming. The most frequently isolated organism is *C. albicans*, which commonly coexists with *S. aureus*.[5,6] Initial treatment typically includes avoiding the noxious exposure, topical emollients, and antifungals.[13] Definitive treatment for a chronic paronychia is eponychial marsupialization. This involves removal of a crescent-shaped piece of skin proximal to the nail fold and parallel to the eponychium, extending from the radial to ulnar borders. In addition to marsupialization, complete or partial nail removal may be necessary if nail ridging is present.[9] A chronic paronychia may be confused with another condition that looks similar and mimics a chronic paronychia such as cysts, foreign body reactions, malignancies, psoriasis, and verrucae. Refer all chronic paronychia to a Hand Surgeon due to the higher rate of recurrence, the complexity in management, and where follow-up care can be more consistent.

AFTERCARE

Immobilize and elevate the digit. Instruct the patient to avoid nail biting or sucking. Any discomfort can be treated with acetaminophen or nonsteroidal anti-inflammatory medications. Follow-up care in 24 hours is important as complications can occur despite proper Emergency Department management. Packing of a simple paronychia should be removed in 24 hours. Warm soaks can begin immediately if packing is not placed. Otherwise, warm soaks should be delayed until the packing is removed in 24 hours. There is no evidence that oral antibiotics improve outcome after the incision and drainage of a simple and uncomplicated paronychia. Oral antibiotics are not necessary unless the nail bed is involved, there is apparent cellulitis of the surrounding tissue, or if there are systemic signs of infections such as lymphangitis and fever.[6] Patients should return to the Emergency Department if they develop a fever, reaccumulation of pus, redness extending up the finger and hand, or increased tenderness to the digit.

Most simple paronychias resolve within a few days. If they persist longer or recur, consult a Hand Surgeon for more aggressive management, such as eponychial marsupialization and nail plate removal.

Paronychia or eponychia that extend under the nail plate require follow-up in 24 hours. The packing must be maintained between the nail fold and the nail bed for at least 5 to 7 days. The nail fold will fuse to the nail bed if the packing is removed too soon and a new nail plate will not form. These infections require a 5 to 7 day course of oral antistaphylococcal antibiotics. Nonsteroidal anti-inflammatory medications supplemented with occasional narcotic analgesics will provide adequate pain control for these patients.

COMPLICATIONS

Complications, even in a properly drained paronychia, include a felon, osteomyelitis of the distal phalanx, and a tenosynovitis. Superinfection with *C. albicans* or other fungi can also occur. These complications can be due to the paronychia itself or from an inadequate incision and drainage procedure.

Complications from the incision and drainage procedure are rare if it is properly performed. Care must be taken if the lateral or proximal nail plate is removed to avoid damaging the underlying matrix so that a nail deformity does not result. Fusion of the nail fold to the nail bed will result in a new nail not being formed. Inadequate drainage can result in the infection spreading to adjacent bone and soft tissues. Incision of the skin instead of elevating it off the nail plate can result in prolonged healing.

SUMMARY

A paronychia is one of the most common hand infections. The treatment depends on the extent and location of the infection. The incision and drainage procedure is quick, simple, and easy to perform.

Simple paronychias require elevation of the nail fold with no incision. A more extensive incision and drainage is required along with nail excision when pus accumulates below the nail plate. Follow-up is critical as complications may occur, even when the Emergency Department treatment is optimal.

108 Felon Incision and Drainage

Lisa R. Palivos

INTRODUCTION

A felon is a subcutaneous infection or abscess in the pulp space on the volar surface of the distal phalanx. It is usually caused by penetrating trauma, an abrasion, spread from adjacent tissues (e.g., eponychium, osteomyelitis, or paronychia), or a minor cut with invasion of bacteria. A felon can also develop in the presence of a foreign body, such as a wood splinter or a thorn.[1] It can be iatrogenic from multiple fingersticks for glucose determination.[2] The offending organism is usually *Staphylococcus aureus*. Mixed infections and gram-negative infections may occur in the immunocompromised patient. A felon can less commonly occur on the toes. The information in this chapter can be applied to a felon of the finger or the toe.

ANATOMY AND PATHOPHYSIOLOGY

Felons initially present with a gradual onset of pain and erythema of the distal volar finger. Intense throbbing pain, warmth, and swelling develop with the formation of an abscess as the infection progresses. **The proper treatment for a felon is incision and drainage.** There are multiple techniques to incise and drain a felon. The patient requires digital elevation, immobilization, oral antistaphylococcal antibiotics, oral analgesics, and close follow-up to prevent complications following the incision and drainage.[3–7]

The distal finger consists of a closed compartment that is bound by the nail plate dorsally, by the skin ventrally and distally, and by the flexion crease proximally (**Figure 108-1**). This pulp region is divided by multiple (up to 15 or 20) vertical fibrous septa.[8] These septa extend from the volar surface of the fat pad to the periosteum of the distal phalanx. They divide and compartmentalize the pulp area. When an abscess occurs, it is confined by the septa. They also limit the proximal spread of an infection. Unfortunately, they also inhibit the abscess from reaching the surface and inhibit drainage after the incision and drainage procedure. Blood is supplied by branches of the digital arteries that run parallel and lateral to the phalanx and terminate in the pulp region. The terminal branches of the digital nerves lie palmer and superficial to the arteries. The flexor digitorum profundus tendon inserts on the volar surface of the proximal distal phalanx.

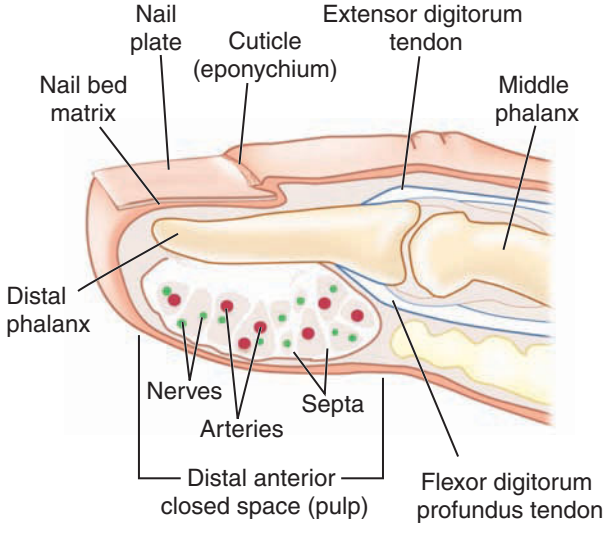

FIGURE 108-1. Midsagittal section demonstrating the anatomy of the distal finger.

INDICATIONS

All felons that are fluctuant should be incised and drained. Volar digital pads that are tense, tender, painful, and suspected of containing a felon should be incised and drained regardless if fluctuance is palpated or not.

CONTRAINDICATIONS

Felons that are not yet fluctuant, as in an early infection, may be treated with warm soaks, elevation, oral antibiotics, and follow-up in 24 hours.[6,7] A herpetic whitlow can sometimes be confused with a felon.[5,9] A herpetic whitlow can be clinically distinguished by the presence of multiple vesicles and a history of recurrence or simultaneous genital or oral lesions. Treatment of a herpetic whitlow is nonsurgical and consists of a protective dry dressing, oral antiviral agents, and analgesics. Incision and drainage of a herpetic whitlow may spread the virus and predispose the patient to secondary bacterial infection.[9]

Consult a Hand Surgeon for complicated felons. This includes a felon that is associated with lymphangitis, osteomyelitis, a tenosynovitis, an infection that has spread proximal to the distal interphalangeal joint, or if the patient is immunocompromised. These patients require hospital admission, intravenous antibiotics, and possible incision and drainage in the Operating Room.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Sterile gloves
- #11 scalpel blade on a handle
- Local anesthetic solution without epinephrine
- 18 and 27 gauge needles
- 5 or 10 mL syringe
- 20 mL syringe
- Ethyl chloride spray
- Sterile saline
- 18 gauge angiocatheter
- Mosquito hemostat
- Ribbon gauze, ½ in. wide
- Bandage material
- Digital splint (plaster, preformed, or tongue depressor)
- Sling
- Digital tourniquet, optional
- Aerobic and anaerobic culture bottles, optional

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain an informed consent for the procedure. Assess and update the patient's tetanus immune status if indicated.

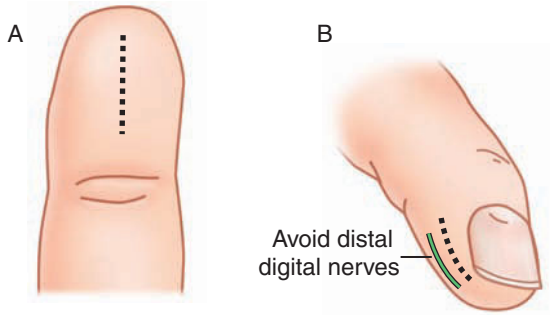

FIGURE 108-2. Recommended incisions for the incision and drainage of a felon. A felon should be incised and drained in the area of maximal fluctuance. **A.** The longitudinal fat pad incision over the area of maximum fluctuance. **B.** The unilateral longitudinal incision is high, lateral, and just below the level of the nail.

Some physicians prefer to obtain anteroposterior and lateral radiographs of the digit to rule out an osteomyelitis or foreign body prior to performing the procedure. A positive radiograph for osteomyelitis will alter the time course for antibiotic therapy and require follow-up with a Hand Surgeon.

Place the patient on a gurney with the extremity on a bedside procedure table in a well-lit room. Soak the digit in warm water for 5 minutes to soften the skin. Perform a digital nerve block if the patient is apprehensive, has significant tenderness, or if it is not a simple felon. Refer to Chapter 126 for the complete details regarding digital anesthesia techniques. Alternatively, apply ethyl chloride spray to the area until the skin turns frosty and pale. Apply povidone iodine or chlorhexidine solution circumferentially to the distal digit and allow it to dry. Apply sterile drapes to delineate a sterile field. The digit can be secured to a sterile tongue depressor for better control, especially in uncooperative children. The application of a digital tourniquet to create a bloodless field is optional.

TECHNIQUES

Multiple incisions can be employed. Make an incision in the area of greatest fluctuance or tenderness with a #11 scalpel blade.[3–6] Make a longitudinal incision if the maximal tenderness is in the center of the pulp of the distal fingertip (**Figure 108-2A**). **The incision should not come within 4 mm of or cross the crease of the distal interphalangeal joint as this can lead to injury of the flexor digitorum longus tendon or the joint, flexor tenosynovitis, and flexion contractures.**[7] Make the incision along the lateral surface of the finger if the felon has maximal tenderness on the radial or ulnar aspect of the finger (**Figure 108-2B**). Purulent and/or bloody pink fluid will exit from the incision. While not required, consider obtaining aerobic and anaerobic cultures of the purulent material. Gently probe the loculations with a mosquito hemostat. Irrigate the wound with an 18 gauge angiocatheter on a 5 or 10 mL syringe containing sterile saline. Place a piece of ribbon gauze into the wound. Apply a dry bulky dressing.

ALTERNATIVE TECHNIQUES

Alternative incisions have been advocated but are not recommended because they have higher complication rates (Figure 108-3). These incisions can result in neurovascular injury, painful scars, and altered fingertip sensation. The hockey stick incision can result in digital nerve injury and produce numbness to the fingertip (**Figure 108-3A**).[5] The through-and-through or bilateral longitudinal incision can result in bilateral digital nerve injury and complete anesthesia of the fingertip (**Figure 108-3B**).[6] The transverse palmar incision may transect the digital neurovascular bundles (**Figure 108-3C**). The fishmouth or horseshoe incision is very extensive, can take a long time to heal, produces a large scar, and an unstable pulp (**Figure 108-3D**).[5]

AFTERCARE

Splint the involved digit. Provide the patient a sling to keep the hand elevated. Since the incidence of community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) skin and soft tissue infections presenting to the Emergency Department are increasing, an oral antibiotic effective against CA-MRSA is recommended.[10,11] Depending on local resistance patterns, sulfamethoxazole-trimethoprim, doxycycline, or clindamycin are appropriate choices for a 7 to 10 day course. Nonsteroidal anti-inflammatory medications supplemented with narcotic analgesics will control any postprocedural pain. Instruct the patient to soak the digit in warm water several times a day to speed healing. Patients should immediately return to the Emergency Department if they experience fever, increased pain, difficulty using the finger, redness of the finger or hand or arm, or a discharge from the wound.

The patient should be reevaluated in 24 to 48 hours for removal of the gauze and inspection of the digit. Remove the gauze during the follow-up visit. Perform a digital or metacarpal block for patient comfort. Irrigate the wound with sterile saline and break up any further loculations, if needed. Replace the gauze for another 24 to 48 hours if there is continued drainage.

COMPLICATIONS

Untreated or mistreated felons may cause skin necrosis, osteitis or osteomyelitis of the distal phalanx, septic arthritis of the distal interphalangeal joint, extension of the infection into the palm and adjacent fingers, suppurative tenosynovitis, and lymphangitis.[12] Flexor tenosynovitis can occur if the incision is extended too far proximally and too deep. Improperly placed incisions can result in injury

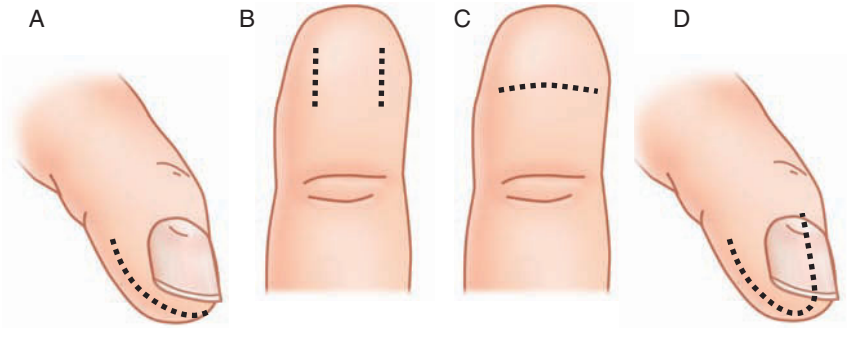

FIGURE 108-3. Incisions not recommended for the drainage of a felon. **A.** The hockey stick incision. **B.** The through-and-through or bilateral longitudinal incision. **C.** The transverse palmar incision. **D.** The fishmouth incision.

to the flexor digitorum profundus tendon or the distal interphalangeal joint, mobility of the pad of the finger, neurologic compromise, and/or vascular compromise. The lack of improvement within 24 to 48 hours requires consultation with a Hand Surgeon.

SUMMARY

Felons require incision and drainage. The procedure is quick, simple, and easy to perform. The incision should be made at the point of maximal fluctuance while avoiding injury to the digital arteries, digital nerves, the flexor digitorum profundus tendon, and the distal interphalangeal joint. Close follow-up is mandatory to prevent any complications. Consult a Hand Surgeon for any complications associated with the felon.

109 Pilonidal Abscess or Cyst Incision and Drainage

Lauren M. Smith

INTRODUCTION

Controversy surrounds pilonidal disease, from who first described it, to the etiology, and how to manage it surgically. Some believe that pilonidal disease was first described in 1880 by Hodges.[1] However, others say it was first described in 1833 by Mayo.[2] Hodges used the term "pilonidal sinus" to describe a chronic infection that contained hair and was usually found between the buttocks. The word "pilonidal" comes from "pilus" or hair and "nidus" or nest. It literally means "nest of hair." The condition did not receive much attention until it became a significant problem in the armed services around the time of World War II. In 1940, in the United States Navy, the number of sick days caused by pilonidal disease and its complications exceeded those of either syphilis or hernias.[3] This condition was coined as "jeep disease" by Buie in 1944 because of the high occurrence rate in those that drove or were frequent passengers in military vehicles.[4]

Pilonidal sinus disease primarily affects Caucasian males. Blacks are infrequently affected and the condition is rare in Asians and Indians. Males are affected three to four times more frequently than females. The affected females tend to be younger than males.[19] The condition is prevalent from the onset of puberty to young adulthood and is rare after the age of 40. The peak age of incidence is 21 years. The increased incidence in adolescents and young adults is attributed to hormonal effects of increased hair on the torso, increased activity of sebaceous and sweat glands, fat deposition on the buttocks, and deepening of the gluteal cleft. Other risk factors may include hirsutism, obesity, and poor personal hygiene. Repeated trauma to the area may also contribute to the formation of pilonidal disease. There is an increased prevalence in drivers and others with occupations requiring long periods of sitting.[6,7]

Patients with pilonidal sinus disease may present with three different clinical pictures: asymptomatic disease, an acute abscess, or chronic disease. Asymptomatic disease patients have a painless sinus pit at the top of the natal cleft. Patients with chronic disease may have mild discomfort and a chronically draining sinus in the upper gluteal region. Approximately 50% of patients with symptomatic pilonidal disease will present acutely with severe pain and frequently swelling that is indicative of a pilonidal abscess that necessitates incision and drainage.[8,9] Inspection will reveal one or more midline sinus tract openings, often with protruding tufts of hair. The area will be tender, erythematous, and indurated when an abscess is present. Fluctuance and swelling may not be readily appreciated. The sinuses may be quite extensive depending upon the chronicity of the disease process prior to presentation.

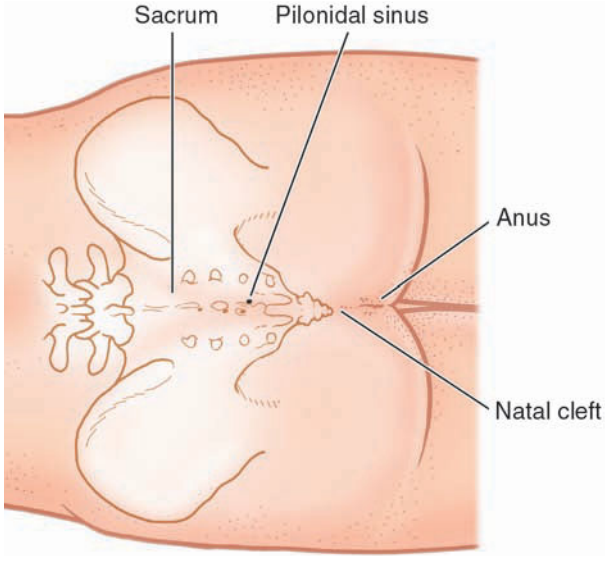

FIGURE 109-1. Pilonidal sinuses occur in the midline, approximately 4 to 5 cm above the anus and in the natal cleft.

ANATOMY AND PATHOPHYSIOLOGY

A pilonidal sinus consists of a characteristic midline opening, or series of openings, in the upper aspect of the gluteal cleft and approximately 4 to 5 cm from the anus (**Figure 109-1**). The skin enters the sinus giving the opening a smooth edge. This primary tract leads into a subcutaneous cavity that contains granulation tissue and often a nest of hairs (**Figure 109-2**). The hairs may be seen projecting through the skin opening. Many sinuses have lateral or secondary openings (fistulas) extending from the pilonidal abscess (**Figure 109-2**).

There have been various opinions as to the etiology of the condition since the first description of the disease. In the first half of the twentieth century, it was generally attributed to a congenital lesion. Some authors believed that the pilonidal sinus originated from a remnant of the medullary canal that subsequently became infected. However, pilonidal disease can form in other areas of the body that lack hair, as some barbers have experienced in interdigital spaces.[10,11] Currently, it is widely accepted that pilonidal disease is acquired.[5] Some of the contributing factors to this belief are the

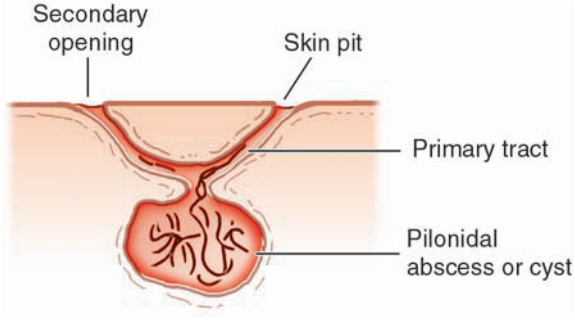

FIGURE 109-2. Cross section through a pilonidal abscess and sinus. A primary tract and skin pit leads to the subcutaneous abscess. There may be secondary or lateral openings (fistulas).

rate of recurrence after excision, occurrence at other sites than the gluteal cleft, and the frequency seen among certain populations (i.e., barbers, armed forces, etc.).[10,11]

Loose hairs from the adjacent gluteal region are thought to form a bristly tuft and penetrate into the skin, perhaps in an area of skin irregularity. This process may be aided by pressure on the region in persons with occupations that require long hours of driving or sitting. The hairs may also be pulled in by a suction effect between the moving buttocks. The hair penetrates the skin and causes a foreign body reaction and secondary inflammation with the potential for infection and abscess formation. The sinuses spread cranially and laterally. They rarely approach the anus and generally remain superficial to the presacral fascia.[9,10,12]

INDICATIONS

Incision and drainage is indicated whenever a patient presents with a pilonidal abscess. Antibiotics alone are ineffective in treating a pilonidal abscess. Rarely, systemic signs and symptoms may ensue. There are reported cases of necrotizing fasciitis from neglected pilonidal sinus disease. Thus, it is preferable to treat pilonidal abscesses expeditiously with an incision and drainage procedure.

CONTRAINDICATIONS

The great majority of pilonidal abscesses may be drained in the Emergency Department. Patients occasionally present with fever, systemic signs and symptoms, and/or toxicity. They should be admitted to the hospital for parenteral antibiotics, incision and drainage, and observation. This is particularly true if the patient has diabetes or is immunocompromised. Consult a Surgeon to manage these patients. Extensive abscesses should be incised and drained in the Operating Room under general anesthesia. Patients who are asymptomatic do not require an incision and drainage and can be referred to a Surgeon for removal. The procedure should be conducted under general anesthesia in the Operating Room if adequate anesthesia cannot be obtained and pain limits the procedure.

EQUIPMENT

- Gown, face mask, and gloves
- Benzoin solution
- Povidone iodine or chlorhexidine solution
- Skin razor
- 10 mL syringe
- 25 or 27 gauge needle, 2 in. long
- Local anesthetic solution with epinephrine, lidocaine, or bupivacaine
- #11 scalpel blade on a handle
- #15 scalpel blade on a handle
- Curved hemostat
- 4 × 4 gauze squares
- Ribbon gauze, plain or iodoform
- Adhesive tape

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. The postprocedure care should be explained as well. Document the discussion of the risks and benefits of the procedure. Obtain a signed informed consent for the procedure.

The best visualization of the sacral region, particularly in obese patients, occurs with the use of a proctoscopic examination table, if available (**Figure 109-3A**). Place the patient prone on a gurney or on the proctoscopy table. Alternatively, place the patient in the lateral knee-chest position to expose the affected area (**Figure 109-3B**). Apply benzoin solution to the buttocks and allow it to dry. Apply adhesive tape to the buttocks and tape them open (**Figure 109-4**). Clean any dirt and debris from the skin overlying the abscess or cyst. Apply povidone iodine or chlorhexidine solution and allow it to dry. Shave the surrounding area, if the patient is hirsute, to aid in the application of the dressing after the procedure. Some authors advocate shaving the sacral region to prevent recurrence as well, although this has not been proven to be effective. A gown, face mask, and gloves (nonsterile) are recommended to be worn for this procedure.

ANESTHESIA

Local anesthesia should be administered, recognizing that it is often difficult to obtain complete anesthesia by direct infiltration of an abscess. Local anesthetics are weak acids and are less effective in the acidic environment of an abscess. The skin over the abscess

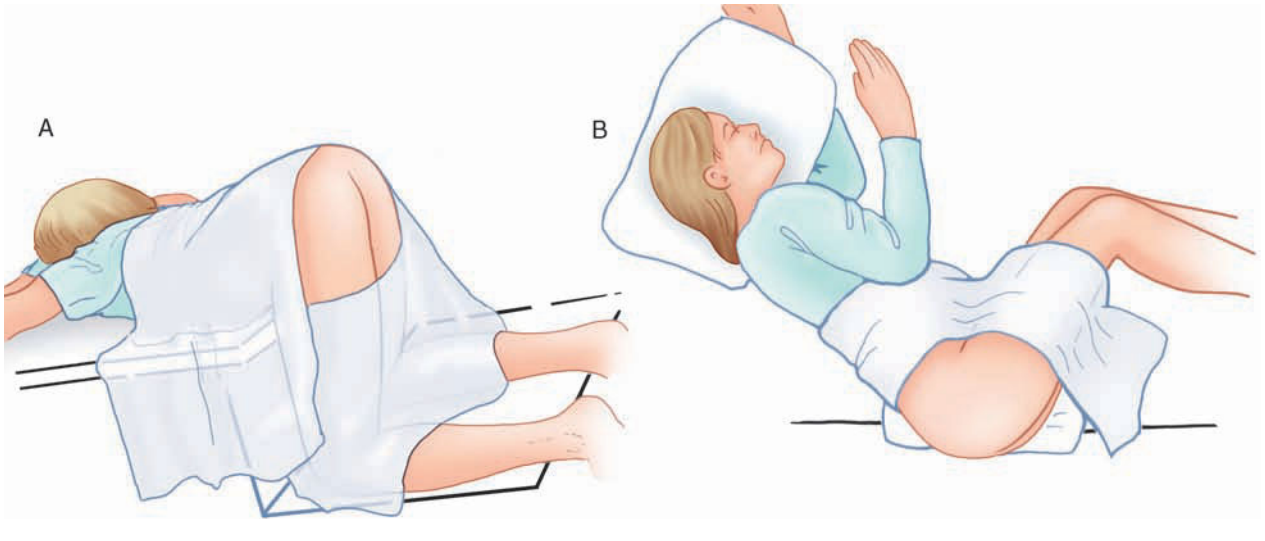

FIGURE 109-3. Patient placement. **A.** Prone on a proctoscopy table. The patient may also be placed prone on a gurney. **B.** The lateral knee-chest position.

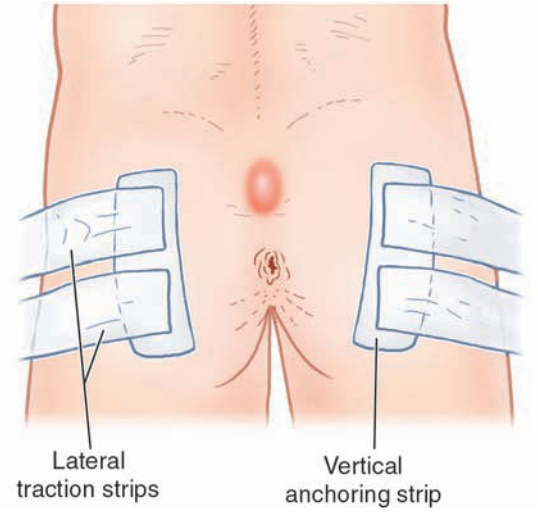

FIGURE 109-4. Exposure of the abscess.

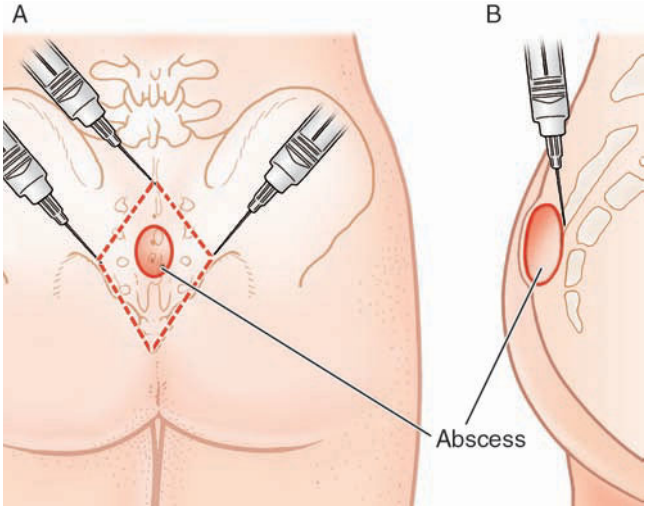

FIGURE 109-6. Field block anesthesia for a pilonidal abscess. **A.** Local anesthetic solution is infiltrated subcutaneously on all four sides of the abscess. **B.** The local anesthetic solution is infiltrated deep to the abscess cavity in a fan-like pattern.

cavity usually becomes insensate, but anesthesia of the abscess cavity itself is not possible. The pain caused by injection of the local anesthetic solution is related to the rate that it is injected and the force necessary to inject it. **Inject the local anesthetic solution slowly through a small-bore needle (25 or 27 gauge) as the needle is withdrawn through the dermis.** The needle bore will create a passage through the subcutaneous tissue as it is inserted that enables the local anesthetic solution to be infiltrated slowly and with less discomfort.

Hold the syringe horizontal in reference to the skin surface. Inject 3 to 4 mL of local anesthetic solution intradermally over the dome of the abscess (**Figure 109-5**). The skin will blanch if the injection is given properly. **Do not inject the local anesthetic solution into the abscess cavity.** The increased pressure within the cavity will cause more discomfort to the patient and may cause the local anesthetic solution or the abscess contents to be forcefully expelled if there is an opening in the skin.

Additional anesthesia is accomplished by performing a field block (**Figure 109-6**).[13] Inject local anesthetic solution subcutaneously around the periphery of the abscess (**Figure 109-6A**). Inject local anesthetic solution deep to the abscess in a fan-like pattern (**Figure 109-6B**).

Systemic analgesia (i.e., procedural sedation) is usually required since it is quite difficult to obtain adequate anesthesia of an abscess locally. Refer to Chapter 129 for the complete details of procedural sedation. Patient-administered nitrous oxide, with or without supplemental narcotic analgesics, is an alternative to procedural sedation. Refer to Chapter 128 for the complete details of nitrous oxide anesthesia. Obtain an additional signed informed consent for the procedural sedation or the nitrous oxide administration. **The procedure should be conducted under general anesthesia in the Operating Room if adequate anesthesia cannot be obtained and pain limits the procedure.**

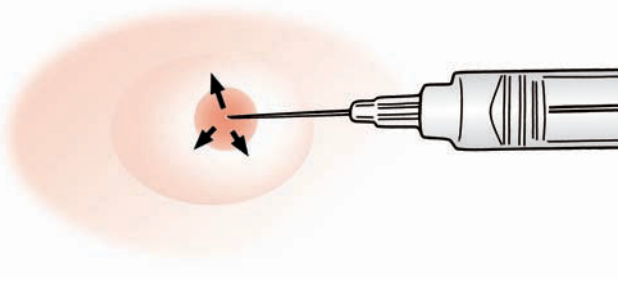

FIGURE 109-5. Subcutaneous infiltration of local anesthetic solution. The needle and syringe are held parallel to the skin. The needle is inserted into the subcutaneous tissue overlying the pilonidal abscess. Infiltrate the local anesthetic solution as the needle is withdrawn. The skin should blanch (shaded area) if injected properly.

TECHNIQUE

Incise the skin over the area of maximum fluctuance with a scalpel blade. A 10% recurrence rate after drainage of chronic abscesses through a vertical incision lateral to the midline has been reported.[14] This may be due to better healing of wounds that are off the midline. Thus, some authors and Colorectal Surgeons recommend that the incision for an acute abscess be off the midline if the abscess can be drained adequately through the incision (**Figure 109-7A**). Extend the incision the length of the abscess to allow for proper drainage. A full-thickness, thin ellipse of skin can be removed to prevent premature closure of the skin edges. Approximately 40% of pilonidal abscesses will be cured from simple incision and drainage alone.[15] It is not necessary to perform more radical excision procedures in the Emergency Department.

It is important that loculations be lysed and the area thoroughly drained to minimize recurrence. Several methods can be used to lyse adhesions within the cavity. A gloved finger may be used to bluntly break up the adhesions. Hemostats can be inserted and spread within the abscess cavity. A useful technique employs a 4×4 gauze square clamped in a hemostat and swirled inside the abscess cavity to break adhesions and remove debris (**Figure 109-7B**). This technique aids in removing hair and the infected lining of the cyst. Irrigate the abscess cavity with normal saline.

Loosely pack the cavity with ribbon gauze. Packing the cavity too tightly may cause ischemia to the surrounding tissue, delays healing, and is uncomfortable for the patient. The purpose of the packing is to keep the skin edges from adhering before the cavity closes. Cover the incision with a simple bandage composed of gauze and adhesive tape. A thick layer of absorbent gauze will soak up any continued drainage.

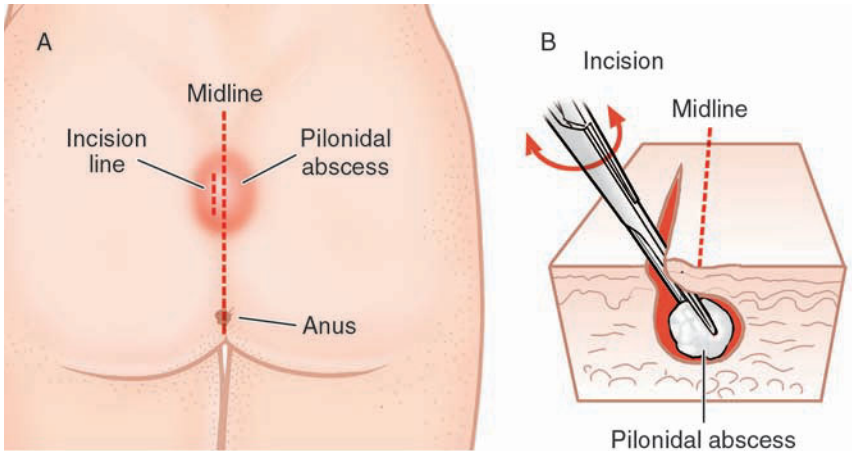

FIGURE 109-7. Incision and drainage of a pilonidal abscess. **A.** An incision is made lateral to the midline and overlying the abscess cavity. **B.** A hemostat with gauze clamped in the jaws is inserted into the abscess cavity and rotated to break loculations and remove debris.

AFTERCARE

Antibiotics are generally unnecessary to treat a simple abscess when there is no cellulitis surrounding the wound.[16] No data could be found on the optimal duration of antibiotic treatment if the overlying skin is cellulitic. The conventional 7 to 10 day course of antibiotics is probably adequate. Likewise, no studies could be found regarding treating patients with diabetes, cardiac valve disease, those who have hardware in their body, or those who are immunocompromised and have a pilonidal abscess. These patients are at risk for infectious complications and it is advised that they be treated with oral antibiotics.

There is a disparity in the literature regarding the bacteriology of pilonidal abscesses. *Staphylococcus aureus* is the most commonly found bacteria and, surprisingly, *Escherichia coli* is rarely found.[17] A report in children recovered primarily anaerobes from pilonidal cysts.[18] *Escherichia coli* was the most common aerobe cultured from this series. **In light of these conflicting results, and in the event that antibiotics are deemed necessary, coverage for skin flora as well as aerobes and gram-negative organisms would be advised.** A combination of a first-generation cephalosporin or penicillinase-resistant penicillin along with metronidazole or clindamycin is recommended. **Keep in mind the ever increasing rates of community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) infections.** Consider prescribing clindamycin, doxycycline, or trimethoprim-sulfamethoxazole if CA-MRSA is a potential pathogen.[19]

Instruct the patient to change the gauze dressing as often as necessary to keep the outside of the dressing dry. The patient should return for follow-up in 48 hours for a wound check and removal of the packing. If the wound is large, or there is not a clear open tract for continued drainage, reinsert new packing upon follow-up. Incisions that remain open do not require repacking. Advise the patient to have the packing changed every 24 to 48 hours, depending upon the amount of drainage. Decrease the amount of packing each time to allow the wound to heal from the base outward. The patient should thoroughly wash the wound with soap and water in the shower or take a sitz bath each time the packing is removed. It is helpful to let the stream of shower water run inside the wound to aid in wound irrigation. After showering, the patient should dry the area thoroughly. Discontinue the packing once the wound is well granulated and there is no concern that the skin edges will adhere to each other. The patient must continue to clean the wound thoroughly every day until it is fully healed. Healing may take several weeks depending upon the size of the abscess cavity. Instruct the patient that they must return to the Emergency Department if they develop a fever, increased pain, or increased redness of the skin surrounding the abscess. Patients often have pain in the first 2 to 3 days after the incision and drainage. This can be controlled with nonsteroidal anti-inflammatory drugs and supplemented with occasional narcotic analgesics.

Inform the patient that incision and drainage in the acute care setting is not definitive treatment and that the condition may recur. Arrange for follow-up with a Surgeon who can provide wound care as well as definitive therapy if surgery is required. Definitive treatment of a chronic pilonidal abscess or sinus still remains controversial among Colorectal Surgeons. Options include wide excision with primary closure, wide excision with secondary closure, or marsupialization.[2]

Educate the patient about their role in the prevention of a recurrence. Recurrence may be prevented with meticulous hygiene and periodic shaving of the area.[10,13] Instruct the patient on the methods for meticulous hygiene in the area, even after the wound has healed. Repeated trauma to the area should be avoided. This includes exercises such as sit-ups and leg lifts, and prolonged periods of sitting.

COMPLICATIONS

Pilonidal disease may return, even with radical and extensive surgical excision procedures. **Thus, recurrence is to be expected and the patient alerted of this possibility.** Rarely, pilonidal lesions progress to necrotizing fasciitis. Proceed cautiously with patients who are diabetic or otherwise immunocompromised as they are at risk for widespread infections. Those with systemic signs and symptoms are best admitted for treatment. Necrotizing fasciitis is a surgical emergency and requires extensive operative debridement, systemic antibiotics, and intensive supportive care.

Rarely, a nonhealing pilonidal infection may be a pilonidal sinus malignancy.[20] Squamous cell carcinoma has been described to arise from chronic sinus tracts. This emphasizes the importance of follow-up for all patients with pilonidal sinus disease.

Other complications include infection and tissue injury. The incision and drainage procedure can result in a subsequent cellulitis, endocarditis, fasciitis, meningitis, myositis, sacrococcygeal osteomyelitis, or septicemia. The sharp and blunt dissection can injure underlying or adjacent structures including blood vessels, the coccyx, muscles, nerves, and tendons.

SUMMARY

Pilonidal disease is common in the young adult population and more prevalent in males. It is now widely accepted as being an acquired condition caused by hair that penetrates an irregular area of skin in

the sacral area. Pits occur in the skin that in turn lead to cysts in the subcutaneous tissue. Patients may present with asymptomatic pits noted incidentally, as chronically draining sinuses, or an acute painful abscess. No treatment is necessary for asymptomatic patients. Nontender sinuses may be referred for surgical treatment. Abscesses should be drained expeditiously under adequate analgesia and anesthesia. Antibiotics are not indicated unless the patient has surrounding cellulitis or is immunocompromised. Recurrences are common and patients must be referred for follow-up with a Surgeon who can provide wound care as well as surgical treatment for chronic cases.

110 Perianal Abscess Incision and Drainage

Maggie Ferng and Ryan C. Headley

INTRODUCTION

Anorectal infections are common problems presenting to the Emergency Department. Understanding anorectal anatomy is essential to make a diagnosis, institute proper treatment, and anticipate complications. Failure to diagnose and treat an extensive abscess may be life threatening. It is imperative to obtain a surgical consultation if one is unsure of the extent of an abscess.

Anorectal infections occur mostly in the third or fourth decade of life. Perianal abscesses are two to three times more common in men than women.[1] Male predominance is even more pronounced in the pediatric population.[2] In one series, all patients under 2 years of age were males, while 60% of the children greater than 2 years were males.[2] The increased incidence of perianal infection in males may be related to androgen conversion in the anal glands.[3] In infants, deep anal crypts are associated with perianal abscesses.[4]

Abscesses may completely resolve after a proper incision and drainage procedure. However, 50% recur or develop a chronic epithelialized tract or fistula-in-ano. Abscesses and fistulas are different sequelae of the same process.[5]

ANATOMY AND PATHOPHYSIOLOGY

Knowledge of the anatomy of the region is important to understand the pathophysiology of anorectal infections (**Figures 110-1 & 110-2**). Columnar epithelium transitions to squamous epithelium at the columns of Morgagni at the level of the dentate line. Semilunar folds of epithelium called anal valves connect the inferior borders of the anal columns. At the base of each anal valve is an anal crypt, into which opens the ducts of the anal glands. The anal glands secrete mucous to aid in the evacuation of feces. The anal glands are located in the space between the internal and external anal sphincter muscles. Most anorectal infections begin in this intersphincteric space due to blockage and resultant infection of the anal glands.[6]

The spread of an infection is determined by the anatomy of the anorectal region. There are five anatomic spaces into which an infection can spread (**Figure 110-3**).[5] The perianal space is located at the area of the anal verge. The ischiorectal space, which is continuous with the perianal space, extends from the levator ani muscle to the perineum. The intersphincteric space lies between the internal and external anal sphincter muscles. It connects inferiorly with the perianal space and superiorly with the rectal wall. The supralevator (or pelvirectal) space is located superior to the levator ani muscle and is bounded superiorly by the peritoneum. The rectum forms its medial border and the pelvic wall forms the lateral boundary. The deep postanal space is located between the tip of the coccyx and the anus. It courses through the superficial external anal sphincter and the levator ani. The superficial postanal space lies posterior to the anal verge and is subcutaneous. The retrorectal space is high in the pelvis. It occupies the area between the distal rectum and the sacrum.

Most anorectal infections begin in the intersphincteric space. Natural barriers are broken down by formation of an abscess and the infection can spread to contiguous spaces. Abscesses are classified according to their location. Perianal abscesses are common,

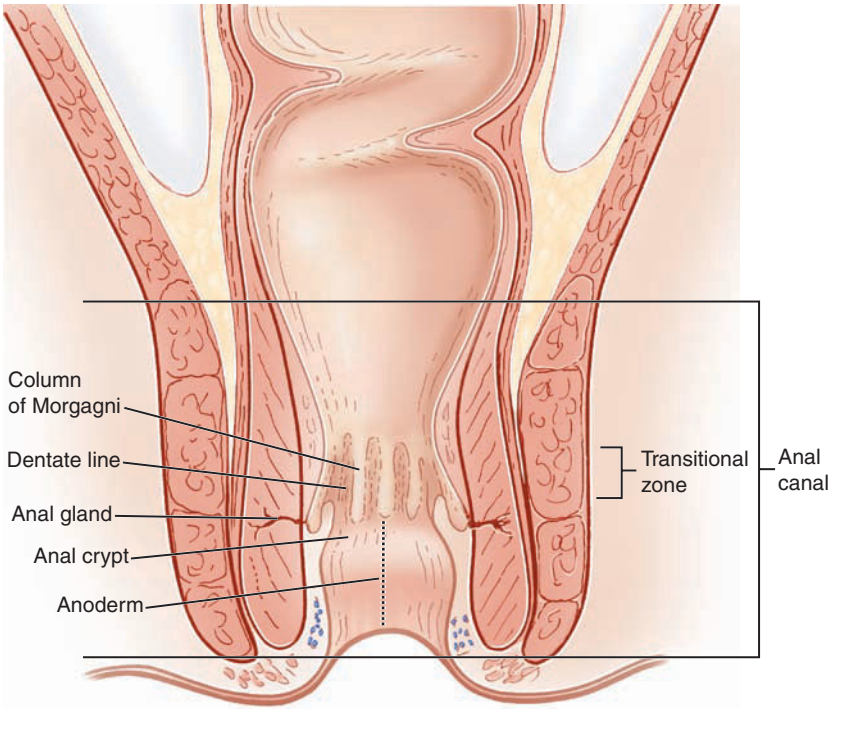

FIGURE 110-1. The anatomy of the anal canal.

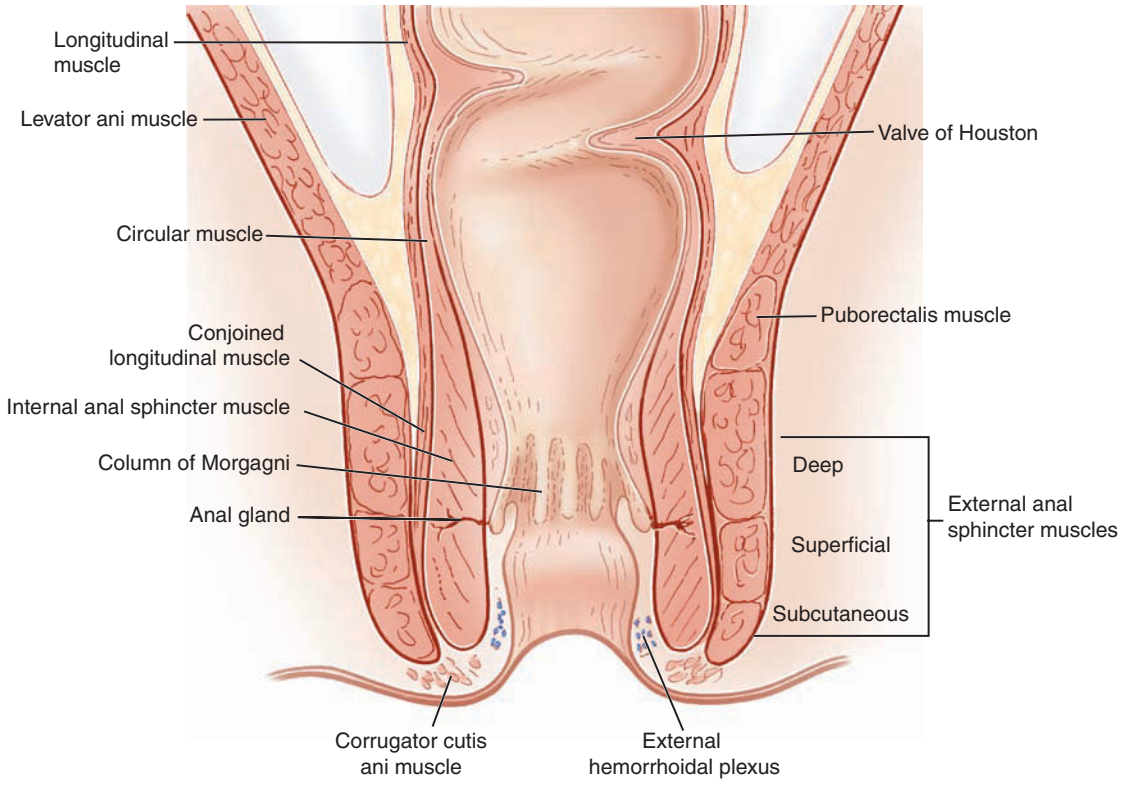

FIGURE 110-2. The major supporting structures of the anal canal.

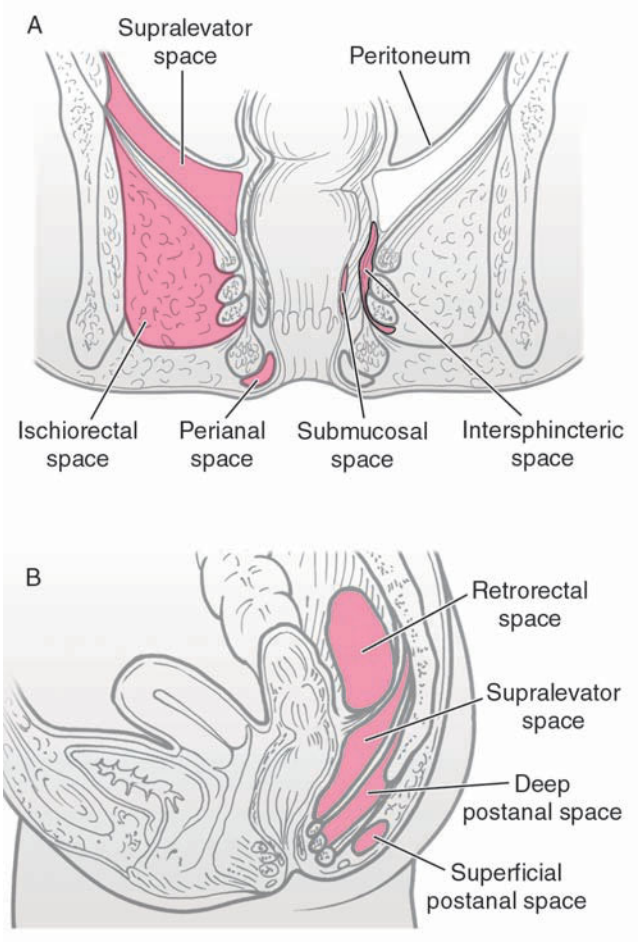

FIGURE 110-3. The anorectal spaces. **A.** Coronal section through the pelvis. **B.** Sagittal section through the pelvis.

ischiorectal abscesses occur less frequently, and supralevator abscesses are least common.[7] Bilateral involvement may occur when an infection spreads circumferentially via the deep postanal space, resulting in a horseshoe abscess.

Patients with anorectal abscesses present with buttock pain and swelling. There is, occasionally, spontaneous drainage from the abscess site. Symptoms depend upon the location of the abscess. Patients with perianal infections have anal pain that increases with defecation or sitting. Pain associated with deeper infections may be atypical. Patients with supralevator abscesses may have deep rectal pain, gluteal pain, dysuria, or other urinary symptoms.

Erythema, swelling, and fluctuance are often present at the abscess site. The location of the swelling and fluctuance of a perianal abscess is at the anal verge. Ischiorectal space infections track farther from the anus onto the buttock. Supralevator and intersphincteric abscesses may have minimal or no external signs.[8] **The diagnosis of perianal cellulitis is highly suspect. These patients have either an anorectal abscess or Fournier's Gangrene until proven otherwise. Patients with gluteal pain and a small amount of erythema in the perianal area have a deep-seated abscess until proven otherwise.**

A digital rectal examination is necessary as intersphincteric, deep postanal, and submucosal abscesses may be palpated but often cannot be appreciated on external examination. **A superficial digital examination of the anal canal alone is inadequate for detection of some abscesses. The gloved finger must extend into the rectum seeking tenderness and a mass.** Unfortunately, digital rectal exam may fail to detect some deep abscesses due to patient discomfort. If unable to obtain an adequate exam due to pain or if a deep abscess is suspected, obtain a CT scan of the pelvis with rectal and intravenous contrast.

A fistula-in-ano represents the chronic phase of an unhealed perianal abscess. Fistulas may form due to persistent obstruction of the anal gland or inadequate drainage of an abscess. The tract eventually becomes epithelialized with glandular tissue. Fistulas may also form

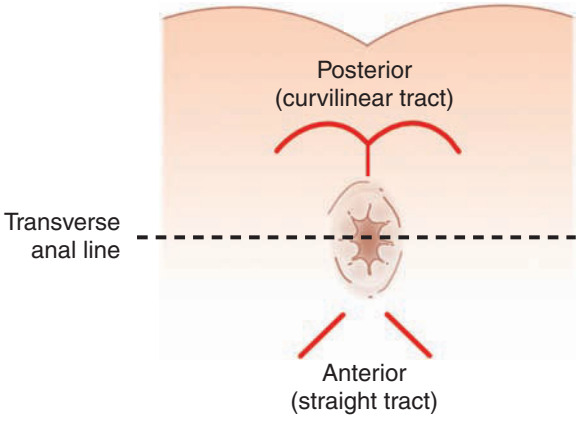

FIGURE 110-4. Goodsall's rule.

as a result of epithelialization by cells derived from the transitional zone of the anal canal and thus may be unrelated to persistent anal gland disease.[9] Patients with a fistula-in-ano will often give a history of a previous abscess in the same area that was either drained surgically or spontaneously. Patients may complain of chronic drainage from the site or subacute pain.

Physical examination of a fistula-in-ano reveals an external opening with scant drainage and visible surrounding granulation tissue. Digital rectal examination may reveal an indurated cord-like structure beneath the skin within the anal canal. The internal opening may be palpable along the dentate line. Pus may be expressed externally or from within the anus upon palpation of the fistulous tract.

The greater the distance from the anus that the external opening is located, the more complex is the fistulous tract. Goodsall's rule describes the likelihood of the location of fistulous tracts and the internal opening based upon the location of the external opening (**Figure 110-4**). Anterior external openings tend to communicate in a linear fashion with the internal opening in the anal canal. Fistulas with posterior external openings tend to communicate in a curvilinear fashion with the internal opening.

Patients with multiple or recurrent fistulas require evaluation of the bowel for Crohn's disease. This is particularly true if associated with chronic diarrhea or cramping, both of which suggests inflammatory bowel disease. Recurrent fistulas may be indicative of tuberculosis or a sexually transmitted disease such as lymphogranuloma venereum. **It is imperative that these patients be referred to a Surgeon who is experienced in managing anorectal disease.**

INDICATIONS

Incision and drainage is the treatment for an anorectal abscess. Uncomplicated perianal abscesses and submucosal abscesses may be drained in the Emergency Department. Management of deeper or more extensive abscesses should be in consultation with a Surgeon. Use caution in draining abscesses. The ischiorectal space is quite large, particularly in the obese patient, and adequacy of drainage is not assured except under general anesthesia. It is not uncommon for an abscess to have a small erythematous and swollen area on the buttock overlying an extensive and deep abscess. Attempts at drainage in the Emergency Department may be inadequate.

Perianal disease is commonly encountered in the HIV-infected patient. Complication rates were noted to be high in the past and a hands-off approach was espoused. However, more recent data suggest that those patients with a relatively preserved immune system may safely undergo standard surgical drainage. Small perianal abscesses may be drained in the Emergency Department. Consult a General or Colorectal Surgeon for those patients with late-stage HIV disease. Infections are more likely to be extensive and anorectal sepsis is more common because these patients have poor wound healing.[10]

CONTRAINDICATIONS

Most small, uncomplicated perianal and submucosal abscesses can be drained in the Emergency Department. **A General or Colorectal Surgeon should drain all other types of anorectal abscesses. Caution is urged when an abscess is on the buttock for it may manifest an ischiorectal abscess.** Patients with bleeding disorders, taking anticoagulants, or thrombocytopenia should be managed by a Surgeon. Consult a Surgeon if the infection is extensive or if the extent of the abscess cannot be determined. Surgical consultation is also necessary for patients with purulent drainage from inside the anus. Internal findings may indicate that the patient has an intersphincteric or a supralevator abscess; the full extent of which can be determined only under general anesthesia. The procedure should be conducted by a surgeon under general anesthesia in the Operating Room if adequate anesthesia cannot be obtained and pain limits the procedure.

Patients with fever or toxicity should be admitted to the hospital for parenteral antibiotics, incision and drainage in the Operating Room, and observation. Anorectal infections occasionally progress to necrotizing fasciitis, a true surgical emergency. Physical examination findings in such cases may initially be minimal except for systemic signs or symptoms. Patients who are immunocompromised or with late-stage HIV infection should be referred to an experienced Surgeon due to the higher complication rate and increased risk of extensive infection.

Chronically draining fistulas without an acute infection should be referred to a General or Colorectal Surgeon for care. Patients with purulent drainage from the anus, even if there is no significant tenderness, should be examined under general anesthesia as they may still have an internal abscess along with a fistulous tract.

EQUIPMENT

- Gown, face mask, and gloves
- Povidone iodine or chlorhexidine solution
- 10 mL syringe
- 25 or 27 gauge needle, 2 in. long
- Local anesthetic solution with epinephrine, lidocaine, or bupivacaine
- #11 scalpel blade on a handle
- #15 scalpel blade on a handle
- Curved hemostat
- 4 × 4 gauze squares
- 10 to 16 French mushroom (de Pezzer) catheter, optional
- Adhesive tape
- Feminine napkin, optional
- Normal saline
- 18 gauge angiocatheter
- 20 mL syringe
- 2-0 nylon suture
- Needle driver
- Scissors

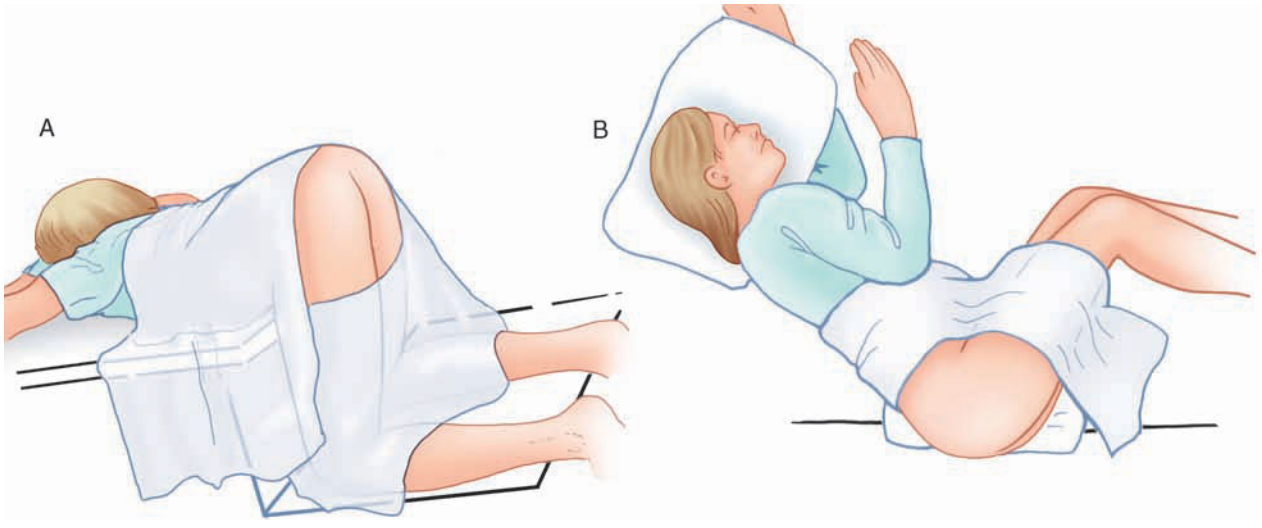

FIGURE 110-5. Patient placement. **A.** Prone on a proctoscopy table. The patient may also be placed prone on a gurney. **B.** The lateral knee-chest position.

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. The postprocedure care should be explained as well. Document the discussion of the risks and benefits of the procedure. Obtain an informed consent for the procedure. Wear a face mask, gown, and gloves for the entire procedure. The injection of local anesthetic solution can force abscess contents to shoot out. Incision of a tense abscess can also result in contamination.

The best visualization of the sacral region, particularly in obese patients, occurs with the use of a proctoscopic examination table, if available (**Figure 110-5A**). Place the patient prone on a gurney or on the proctoscopy table. Alternatively, place the patient in the prone or lateral knee-chest position on a gurney or examination table to expose the affected area (**Figure 110-5B**). Apply benzoin solution to the buttocks and allow it to dry. Apply adhesive tape to the buttocks and tape them open (**Figure 110-6**). Clean any dirt and debris from the skin overlying the abscess or cyst. Apply povidone iodine or chlorhexidine solution and allow it to dry. Shave the surrounding area, if the patient is hirsute, to aid in the application of the dressing after the procedure.

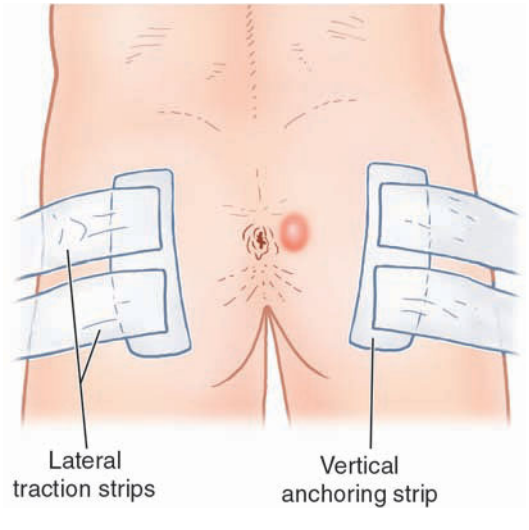

FIGURE 110-6. Exposing the abscess.

ANESTHESIA

Local anesthesia should be administered, recognizing that it is often difficult to obtain complete anesthesia by direct infiltration of an abscess. Local anesthetics are weak acids and are less effective in the acidic environment of an abscess. The skin over the abscess cavity usually becomes insensate, but anesthesia of the abscess cavity itself is not possible. The pain caused by injection of the local anesthetic solution is related to the rate that the anesthetic is injected and the force necessary to inject it. **Inject the local anesthetic solution slowly through a small-bore needle (25 or 27 gauge) as the needle is withdrawn through the dermis.** The needle bore will create a passage through the subcutaneous tissue as it is inserted that enables the local anesthetic solution to be infiltrated slowly and with less discomfort.

Hold the syringe horizontal in reference to the skin surface. Inject 3 to 4 mL of local anesthetic solution intradermally over the dome of the abscess (**Figure 110-7**). The skin will blanch if the injection is given properly. **Do not inject the local anesthetic solution into the abscess cavity.** The increased pressure within the cavity will cause more discomfort to the patient and may cause the solution to be forcefully expelled if there is an opening in the skin.

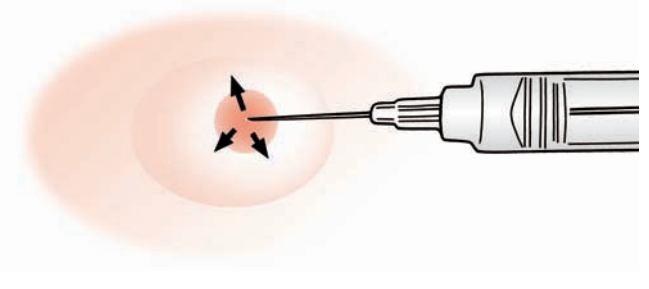

FIGURE 110-7. Subcutaneous infiltration of local anesthetic solution. The needle and syringe are held parallel to the skin. The needle is inserted into the subcutaneous tissue overlying the abscess. Infiltrate the local anesthetic solution as the needle is withdrawn. The skin should blanch (shaded area) if injected properly.

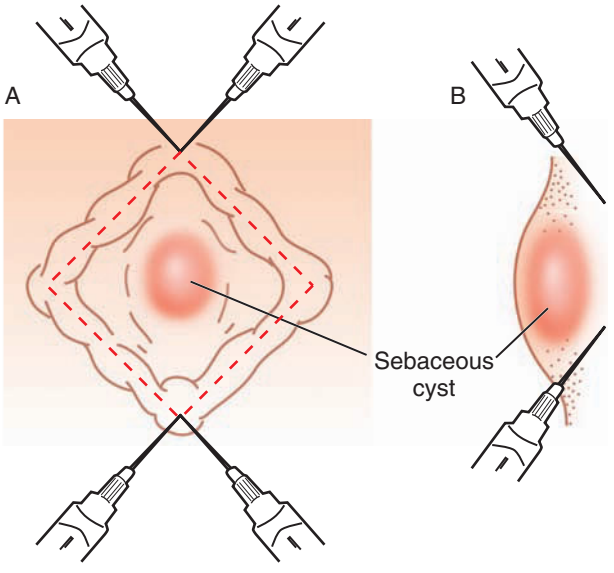

FIGURE 110-8. Field block anesthesia. **A.** Local anesthetic solution is infiltrated subcutaneously on all four sides of the abscess. **B.** The local anesthetic solution is infiltrated deep to the abscess cavity in a fan-like pattern.

Additional anesthesia is accomplished by performing a field block (**Figure 110-8**). Inject local anesthetic solution subcutaneously around the periphery of the abscess (**Figure 110-8A**).[11] Inject local anesthetic solution deep to the abscess in a fan-like pattern (**Figure 110-8B**).

Systemic analgesia (i.e., procedural sedation) is usually required since it is difficult to obtain adequate anesthesia of an abscess locally. Refer to Chapter 129 regarding the details of procedural sedation. Self-administered nitrous oxide, with or without opioid supplementation, is an alternative. Refer to Chapter 128 regarding the details of nitrous oxide anesthesia. Obtain an additional informed consent for the procedural sedation or nitrous oxide procedure. **The procedure should be conducted by a surgeon under general anesthesia in the Operating Room if adequate anesthesia cannot be obtained and pain limits the procedure.**

TECHNIQUES

INCISION AND DRAINAGE OF PERIANAL ABSCESSES

Make a stab incision with a #11 scalpel blade in the skin overlying the area of fluctuance to decompress the abscess. **Make the incision as close to the anus as possible so that if a fistula forms, its size will be limited.** This maneuver will minimize the length of a fistulotomy, should it become necessary, in the future. Extend the incision with the #11 scalpel blade or a #15 scalpel blade in a full-thickness elliptical pattern along the length of the abscess cavity or the area of fluctuance (**Figure 110-9A**). Remove the ellipse

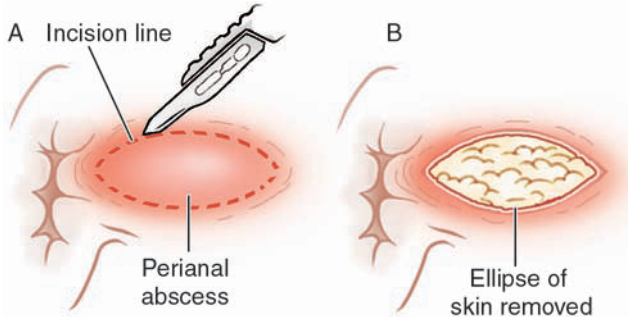

FIGURE 110-9. Drainage of a perianal abscess. **A.** An elliptical incision is made in the skin. **B.** The ellipse of skin is removed to prevent premature closure of the skin edges.

of skin (**Figure 110-9B**). A full-thickness ellipse of skin is excised to prevent premature closure of the skin edges. Some prefer to make a cruciate incision over the abscess and excise the edges (**Figure 110-10**).[5] Both of these techniques delay cutaneous healing while the abscess is decompressing and allow it to drain freely without the need for packing.

A linear incision is acceptable instead of the above incisions, but is not recommended for a perianal abscess. The body location and excessive skin often result in premature closure before the cavity has healed. A linear incision requires repeated packing at 24 to 48 hour intervals to prevent premature closure. The area is difficult to access by the patient to pack the cavity. The pain of repeated packing often results in noncompliance. It is also difficult for the patient to wash out the cavity in the shower or bathtub.

It is important that loculations be lysed and the area thoroughly drained to minimize recurrence. Several methods can be used to lyse adhesions within the abscess cavity. A gloved finger may be used to bluntly break up the adhesions. Hemostats can be inserted and spread within the cavity. A useful technique employs a gauze 4 × 4 square clamped in a hemostat and swirled inside the abscess cavity to break adhesions and remove debris. Irrigate the cavity with normal saline.

It is not necessary to pack an incised and drained perianal abscess that has been incised by removing a full-thickness skin ellipse or a cruciate incision. Consider temporarily packing the abscess cavity in the Emergency Department to control any hemorrhage. Remove the packing before discharging the patient to reassess the need for further hemorrhage control. Cover the wound with a thick layer of absorbent gauze to soak up continued drainage. A feminine napkin may also be used to absorb drainage and obviates the need for taping the dressing in place.

CATHETER DRAINAGE OF PERIANAL ABSCESSES

Another method used to drain perianal abscesses, and preferred by some Colorectal Surgeons, is catheter drainage. The mushroom or

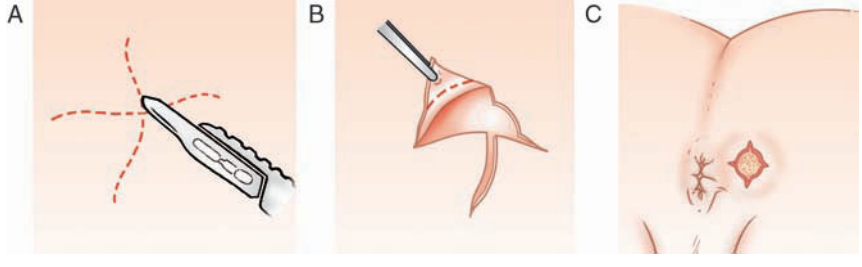

FIGURE 110-10. Drainage of perianal abscess employing a cruciate incision. **A.** The cruciate incision is made over the abscess. **B.** Excision of the skin flap edges. **C.** The final appearance.

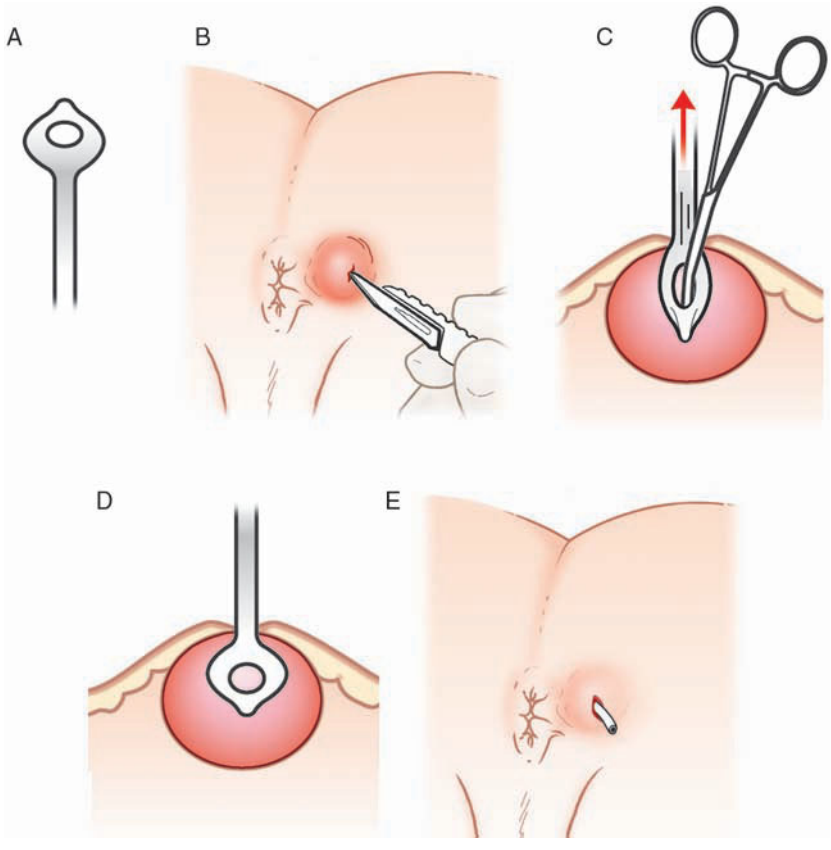

FIGURE 110-11. Catheter drainage of an abscess. **A.** The mushroom (de Pezzer) catheter. **B.** A stab incision is made over the area of maximal fluctuance. **C.** Place the tip of the hemostat through the side hole to stretch the tip of the catheter. Insert the stretched catheter through the stab incision. **D.** Remove the hemostat to expand the head of the catheter so that it remains within the abscess cavity. **E.** The catheter is cut so that it protrudes 2 to 3 cm from the skin incision.

de Pezzer catheter has a tunnel through a solid mushroom-shaped tip (**Figure 110-11A**).[12] Make a stab incision with a #11 scalpel blade over the anal side of the area of fluctuance (**Figure 110-11B**). Insert a hemostat into the abscess cavity. Open and close the jaws of the hemostat to lyse any adhesions and express the pus. Flush the abscess cavity with normal saline using an 18 gauge angiocatheter on a 20 mL syringe.

Insert a 10 to 16 French latex mushroom catheter using a hemostat to stretch the tip so that it will fit through the incision. Place the tip of the hemostat through the hole in the mushroom catheter. With one hand holding the hemostat, use the other hand to pull on the tubing to stretch the mushroom tip and enable it to fit into the abscess cavity (**Figure 110-11C**). Insert the stretched mushroom tip into the abscess cavity (**Figure 110-11C**). Release the traction on the hemostat once the catheter tip is within the abscess cavity and the mushroom shape will be restored (**Figure 110-11D**). Remove the hemostat from the abscess cavity.

Suture the catheter in place. Place a single simple interrupted stitch using 2-0 nylon adjacent to the stab incision. Leave both ends long, tie the suture knots, and do not cut the suture. Pass the needle through the catheter as it exits the skin incision. Tie the needle end of the suture to the tail end of the suture to secure the catheter. Cut off the excess suture. Cut the catheter so that it protrudes only 2 to 3 cm from the incision (**Figure 110-11E**). Apply a dressing of gauze squares or a feminine napkin.

Many Colorectal Surgeons prefer the catheter method. On subsequent visits they can assess the wound for the presence of a fistula without removing the catheter. Hydrogen peroxide can be infused through the catheter. Bubbles seen escaping from an opening within the anal canal are diagnostic for a fistula. Hydrogen peroxide is also used to produce an ultrasound interface that facilitates the definition of a fistulous tract and the internal opening.[5] The smaller stab incision takes less time to heal than the larger incision and drainage wound.

SUBMUCOSAL ABSCESSES

The majority of submucosal abscesses may be drained in the Emergency Department. The procedure requires the use of an anoscope to visualize the abscess. Refer to Chapter 70 for the complete details regarding the use of an anoscope. Make a superficial stab incision in the abscess with a #11 scalpel blade. Gently insert a hemostat and lyse any adhesions. Remove a small ellipse of the mucosa to allow the abscess to drain. Arrange follow-up with a Colorectal Surgeon within 24 hours.

AFTERCARE

Antibiotics are generally unnecessary to treat a simple abscess when there is no cellulitis surrounding the wound.[13] No data could be found on the optimal duration of antibiotic treatment if the overlying skin is cellulitic. The conventional 7 to 10 day course of antibiotics is likely adequate. Likewise, there is no data in the literature regarding the treatment of patients with diabetes, cardiac valve disease, those who have hardware in their body, or those who are immunocompromised with antibiotics for a perianal abscess. These patients are at risk for infectious complications. It is advised that they be treated with antibiotics. Bacteriology of anorectal abscesses is polymicrobial, with coliforms and anaerobes predominating.[14] Recommended antibiotics include an extended spectrum β-lactams, a second- or third-generation cephalosporin with metronidazole or clindamycin, or a newer fluoroquinolone with metronidazole or clindamycin.

The patient may change the gauze dressing as often as necessary to keep the outside of the dressing dry. Instruct the patient to return for follow-up in 48 hours for removal of packing if placed and a wound check. The patient may begin sitz baths or showers 24 hours after the procedure. They should thoroughly clean the wound with soap and water at least once a day until the wound is fully healed. It

is helpful to let the stream of shower water run inside the wound to aid in irrigation. Healing may take several weeks depending upon the size of the abscess. Additional measures to aid in healing and comfort include stool bulking agents and stool softeners. Pain can be controlled with nonsteroidal anti-inflammatory drugs supplemented with occasional narcotics analgesics.

Advise the patient that the condition is likely to recur. They must be referred to a General or Colorectal Surgeon who is experienced in the management of anorectal infections. Inform the patient that they may require an operation to prevent future recurrences. Instruct the patient to immediately return to the Emergency Department if they develop a fever, increased pain or redness to the area, or a foul-smelling discharge.

COMPLICATIONS

Perianal abscesses may recur or a fistula may form. Recurrence is more likely if the patient has had abscesses in the same location in the past. Occasionally, anorectal infections progress to necrotizing fasciitis. Patients with any systemic signs and symptoms require surgical consultation, hospital admission, parenteral antibiotics, and a drainage procedure.

Complications associated with the incision and drainage procedure are rare. A linear incision or too small of an incision can result in premature skin closure, incomplete healing of the cavity, and recurrence. Too large of an incision can result in delayed healing. An overly aggressive incision can damage adjacent structures. Postprocedural bleeding is rare.

SUMMARY

Anorectal infections are commonly seen in the Emergency Department. They are thought to be due to obstruction and subsequent infection of the anal glands that in turn form an abscess. Small perianal abscesses and submucosal abscesses can safely be drained in the Emergency Department. A digital rectal examination may aid in determining the extent of an abscess. A General or Colorectal Surgeon should manage patients with fever, signs of toxicity, evidence of a deep or extensive infection beyond the perianal area, or who are immunocompromised. Be alert that abscesses with maximum fluctuance on the buttock are more likely to have ischiorectal extension, are more complex, and greater in size. Perianal abscesses must be drained expeditiously to prevent their spread. Approximately 50% of anorectal abscesses will develop a fistulous tract. Patients require referral for follow-up with a General or Colorectal Surgeon who can provide wound care as well as manage chronic cases.

111 Sebaceous Cyst Incision and Drainage

Carlos J. Roldan

INTRODUCTION

Sebaceous cysts are common, present with a very benign evolution, may be located anywhere on the body, and frequently become infected. They are most commonly found on the face, neck, and trunk. Sebaceous cysts are usually asymptomatic unless they become infected. The Emergency Physician must be acquainted with the principles involved in treating infected sebaceous cysts, particularly if they are located on cosmetically important areas such as the face.

ANATOMY AND PATHOPHYSIOLOGY

Sebaceous cysts are the result of obstruction of sebaceous gland ducts. They are freely mobile, slow growing, round shaped, painless, and located in the subcutaneous tissues. The cysts are made of a thin white capsule filled with a thick, cheesy, and keratinous material. Their size is variable and ranges from less than a quarter of an inch to more than 2 inches. These keratin-containing lesions are usually seen in young and middle-aged adults in relation to a pilosebaceous follicle.[1] Sebaceous cysts may be present for many years before infection occurs. Physical examination often reveals a subcutaneous mass that is fluctuant and tender. The overlying skin may appear normal or erythematous.

The initial treatment of choice of an infected sebaceous cyst is incision and drainage. The sebaceous material is too thick to allow for spontaneous drainage and it must be expressed. **The sebaceous cyst will likely recur, however, unless the capsule of the cyst is removed.** Patients may have the initial incision and drainage performed in the Emergency Department with follow-up at some later date to remove the cyst capsule. Alternatively, the cyst capsule may be removed at the time of the initial incision and drainage.

INDICATIONS

Incision and drainage in the Emergency Department is indicated whenever a patient presents with a tender sebaceous cyst consistent with an abscess. The procedure will relieve the patient's pain. Antibiotics without drainage are ineffective in treating abscesses.[2] The vast majority of infected sebaceous cysts may be drained in the Emergency Department, clinic, or office setting. A noninfected sebaceous cyst may be removed electively and for cosmetic purposes in the clinic or office setting by a Primary Care Provider or a Surgeon.

CONTRAINDICATIONS

There are no absolute contraindications to the incision and drainage or removal of an infected sebaceous cyst. Caution is advised in those patients with bleeding disorders, taking anticoagulants, or with thrombocytopenia. Incision and drainage is preferred if the overlying skin is cellulitic. The capsule can be removed at a later time. Extremely large abscesses or those in which adequate anesthesia is not possible should be managed in the Operating Room by a General Surgeon or Plastic Surgeon. The procedure should be conducted under general anesthesia in the Operating Room if adequate anesthesia cannot be obtained and pain limits the procedure. Refer patients with noninfected sebaceous cysts to their Primary Care Physician, a General Surgeon, or a Plastic Surgeon for removal.

EQUIPMENT

- Gown, face mask, and gloves
- Povidone iodine or chlorhexidine solution
- 10 mL syringe
- 25 or 27 gauge needle, 2 in. long
- Local anesthetic solution, with or without epinephrine
- #11 scalpel blade on a handle
- #15 scalpel blade on a handle
- Curved hemostat
- Iris scissors
- Ribbon gauze, plain or iodinated

- 2 × 2 gauze squares
- Adhesive tape
- Sterile saline
- Nylon sutures for skin closure, various sizes
- 3-0 Vicryl suture
- Needle driver

PATIENT PREPARATION

Explain and document the risks, benefits, and potential complications of the procedure to the patient and/or their representative. The postprocedure care should be explained as well. Obtain an informed consent for the procedure. Obtain an additional informed consent for the procedural sedation or nitrous oxide procedure if it applies. Wear a face mask, gown, and gloves for the entire procedure. The injection of local anesthetic solution can force abscess contents to shoot out. Incision of a tense abscess can also result in contamination.

Antibiotic resistance is a growing concern. The incision and drainage of a simple and noncomplicated skin abscess does not require antibiotic therapy.[3,4] The incision and drainage procedure may release bacteria into the circulation. Consider the use of preprocedural intravenous antibiotics in those patients suspected or known to be immunocompromised, a history of prosthetic heart valve replacement, a history of artificial joint replacement, or signs of systemic toxicity.

Clean any dirt and debris from the skin overlying the abscess or cyst. Apply povidone iodine or chlorhexidine solution and allow it to dry. Apply drapes to delineate a procedural field and absorb any material or blood that escapes from the abscess cavity.

ANESTHESIA

Recognizing that it is often difficult to obtain, local anesthesia should be considered the first choice. Direct infiltration of the skin and soft tissues in a fan-like pattern surrounding an abscess or "field block" provides sufficient anesthesia to tolerate the procedure (**Figures 111-1A & B**).[5] Local anesthetics are weak acids and less effective in the acidic environment of an abscess and should not be directly injected in the abscess cavity. The pain caused by injection of the local anesthetic solution is related to the rate that the anesthetic is injected and the force necessary to inject it. Inject the local anesthetic solution slowly through a small-bore needle (25 to 30 gauge) as the needle is withdrawn through the dermis. The needle bore will create a passage through the subcutaneous tissue as it is inserted that enables the local anesthetic solution to be infiltrated slowly and with less discomfort.

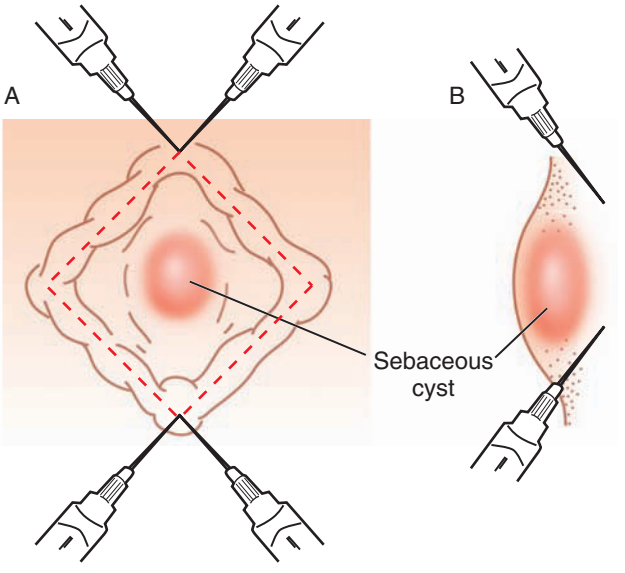

FIGURE 111-1. Field block anesthesia. **A.** Local anesthetic solution is infiltrated subcutaneously on all four sides of the infected sebaceous cyst. **B.** Local anesthetic solution is infiltrated deep to the infected sebaceous cyst in a fan-like pattern.

Hold the syringe horizontally in reference to the skin surface. Inject 3 to 4 mL of local anesthetic solution intradermally over the dome of the abscess (**Figure 111-2**). The skin will blanch if the injection is given properly. The increased pressure within the cavity will cause more discomfort to the patient and may cause the solution to be forcefully expelled if there is an opening in the skin therefore some practitioners prefer to skip this step. Alternative anesthesia could be accomplished with regional or individual nerve blocks when the abscess is located in an anatomical area of innervation.

Systemic analgesia (i.e., procedural sedation) is strongly recommended in the pediatric population, it may occasionally be required as well in adults when a field anesthesia has suboptimal results. In rare occasions, the procedure should be conducted under general anesthesia in the Operating Room if adequate anesthesia cannot be obtained and pain limits the procedure.

TECHNIQUES

INCISION AND DRAINAGE

Make a stab incision with a #11 scalpel blade in the skin overlying the area of fluctuance (**Figure 111-3A**). The incision should be

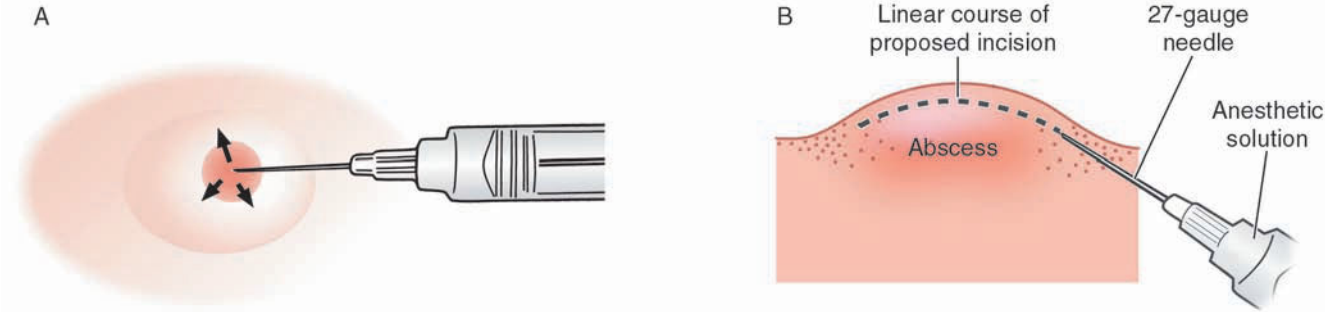

FIGURE 111-2. Subcutaneous infiltration of local anesthetic solution. The needle and syringe are held parallel to the skin. The needle is inserted into the subcutaneous tissue overlying the infected sebaceous cyst. Infiltrate the local anesthetic solution as the needle is withdrawn. The skin should blanch (shaded area) if injected properly. **A.** Superior view. **B.** Lateral view.

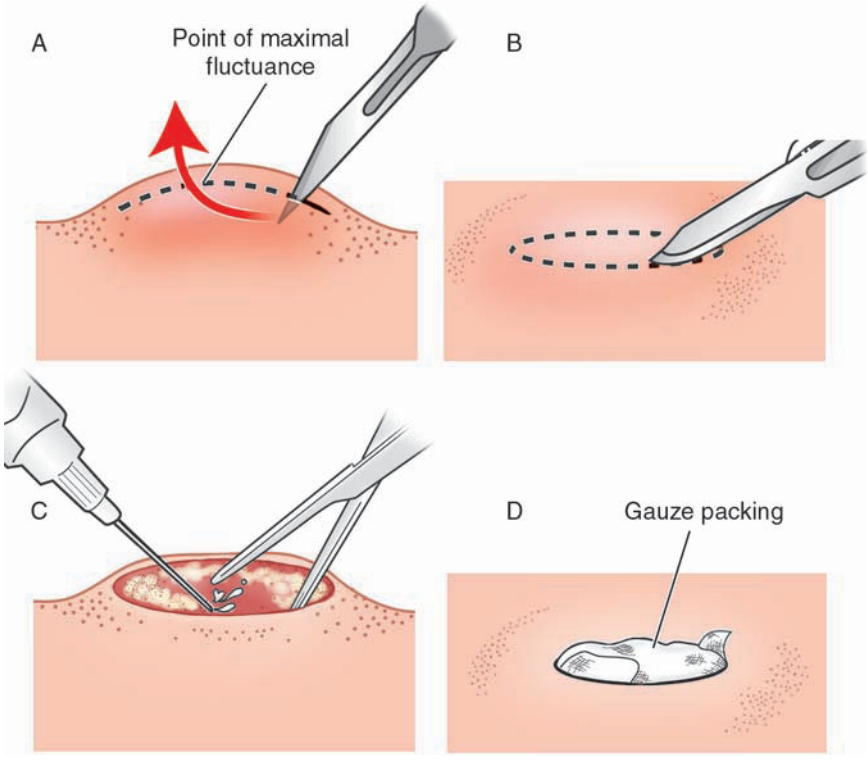

FIGURE 111-3. Incision and drainage of an infected sebaceous cyst. **A.** A straight incision to drain the abscess. **B.** An elliptical incision to drain the abscess. **C.** The wound is irrigated with sterile saline. Pockets of purulent material are opened with the hemostat. **D.** The wound is packed open.

parallel to any lines of tension to produce the least conspicuous scar, particularly in cosmetically important areas such as the face. Extend the incision the length of the fluctuant area with a #11 or #15 scalpel blade unless the abscess is in a cosmetically important area. A linear incision is adequate, although some advocate a cruciate incision (**Figure 110-10**). The cruciate incision results in greater scarring, however, and probably is not necessary. An elliptical incision can be performed in noncosmetically important areas (**Figure 111-3B**). The purpose of the elliptical incision is to remove a full thickness wedge of tissue so that the wound will remain open. **Limit the length of the incision on cosmetically important areas to 3 to 4 mm.** This is just large enough to drain the abscess.

Express the pus and the sebaceous material. It is too thick to drain spontaneously. It is important that loculations be lysed and the area be thoroughly drained to minimize recurrence. Insert a hemostat and spread the jaws within the cavity (**Figure 111-3C**). Useful technique employs gauze clamped in the jaws of a hemostat and swirled inside the abscess cavity to break adhesions and remove debris. Irrigate the cavity with normal saline (**Figure 111-3C**).

Loosely pack the wound cavity with ribbon gauze or gauze squares to prevent the skin edges from closing prematurely if a linear incision was made (**Figure 111-3D**). Cruciate and elliptical incisions do not require packing of the wound. Cover the wound with a bulky gauze dressing to soak up continued drainage.

INCISION AND DRAINAGE WITH PRIMARY CYST REMOVAL

The entire sebaceous cyst, including the capsule, can be removed at the time of the incision and drainage with a simplified technique.[6] Make an incision in the skin overlying the center of the sebaceous cyst. Extend the incision to be slightly longer than the diameter of the sebaceous cyst. **Do not cut into the dermis or subcutaneous tissues.** Sharply dissect the sebaceous cyst free of the surrounding subcutaneous tissues with an iris scissors. The delineation between the thin, shiny, white capsule and the surrounding tissues is very obvious. **Do not puncture the capsule of the sebaceous cyst.** Doing so and spilling some of the contents sets up a nidus for subsequent infection or reformation of the sebaceous cyst. Start at both ends of the incision and free the cyst circumferentially. Once the sides of the cyst are free from the surrounding adipose tissue, gently grasp the top of the cyst with a hemostat or forceps and gently elevate it. Dissect the inferior border of the cyst free until it can be removed. Irrigate the wound with at least 200 mL of normal saline solution. Allow the cavity to heal by granulation. Alternatively, close the pocket with 3-0 Vicryl deep sutures and approximate the skin edges with nylon sutures.

The cyst capsule can often rupture when attempting to remove it intact. If this occurs, express the contents as if incising and draining an abscess. Gently flush the cyst cavity with normal saline. Grasp the shiny, cut edges of the capsule with a hemostat. Gently elevate the cyst capsule edges and dissect the complete cyst capsule free from the surrounding adipose tissue. Irrigate the wound with at least 200 mL of normal saline solution. Allow the cavity to heal by granulation. Alternatively, close the pocket with 3-0 Vicryl deep sutures and approximate the skin edges with nylon sutures.

Submit the complete cyst and capsule or the ruptured capsule for pathologic diagnosis in a sterile container. Several pathologic conditions can mimic a sebaceous cyst. This includes adenomas, adenocarcinomas, dermoids in children, and melanomas. Preauricular tender masses can be parotid gland tumors.

This technique results in fewer days to heal, less pain for the patient, and less scarring than with incision and drainage alone.[6] This was not a blinded study and no other studies could be found to verify their results. The researchers noted that primary resection (average of 50 minutes) takes longer than simple incision and drainage (average of 10 minutes). This may limit its use in the Emergency Department.

AFTERCARE

Antibiotics are generally unnecessary to treat a simple abscess unless there is cellulitis of the skin surrounding the wound.[2] No data could be found regarding patients with an abscess who are diabetic, have cardiac valve disease, who have hardware in their body, or who are immunocompromised. These patients are at risk for infectious complications. It is advised to cover these patients with antibiotics. Likewise, there is no data on the optimal duration of antibiotic treatment. The conventional 7 to 10 day course of antibiotic coverage is probably adequate.

Bacteriology of cutaneous abscesses remote from the rectum usually show aerobic skin flora, with *Staphylococcus* and *Streptococcus* being the most common etiologies.[4] Antibiotics recommended are a first-generation cephalosporin, a penicillinase-resistant penicillin, or a newer fluoroquinolone. Prescribe clindamycin, doxycycline, or trimethoprim-sulfamethoxazole if methicillin-resistant *Staphylococcus aureus* is suspected as the etiology.[7]

Instruct the patient to change the gauze dressing as often as necessary to keep the outside of the dressing dry. Patients should have scheduled follow-up in 48 hours for a wound check and removal of the packing. The packing should be removed in 24 hours if the wound is on the face. If the wound is large, reinsert the packing upon follow-up. Incisions that remain open or that have an elliptical or cruciate incision do not require packing. Advise the patient to change the packing every 24 to 48 hours, depending on the amount of drainage. Decrease the amount of packing each time to allow the wound to heal from the base outward. The patient should thoroughly wash the wound with soap and water in the shower each time the packing is removed. It is helpful to let the stream of shower water run inside the wound to aid in wound irrigation. Discontinue the packing once the wound is well granulated and there is no concern that the skin edges will adhere to each other. The patient must continue to clean the wound thoroughly every day until it is fully healed.

Healing may take one to several weeks depending upon the size of the abscess cavity, the patient's age, and any comorbidities. Instruct the patient to return to the Emergency Department immediately if they develop a fever, increased pain, or worsening redness of the skin surrounding the abscess. Pain relief can be provided with nonsteroidal anti-inflammatory drugs. Occasionally, narcotic analgesics may be required in the first 24 hours after the procedure.

Inform the patient that incision and drainage in the acute care setting is not definitive treatment and that the condition is likely to recur unless the cyst is removed. Refer the patient to a physician who can provide wound care as well as remove the cyst capsule.

COMPLICATIONS

Sebaceous cyst infections may spread if the wound is inadequately drained. Attention must be paid to underlying anatomical structures, such as cranial nerve VII, when draining facial abscesses to avoid complications caused by inadvertently incising these structures. Incomplete removal of the cyst wall or spillage of the cyst contents sets up a nidus for future infection and/or recurrence of the sebaceous cyst. A linear incision or too small of an incision can result in premature skin closure, incomplete healing of the cavity, and recurrence. Too large of an incision can result in delayed healing and significant scarring. Postprocedural bleeding is rare.

SUMMARY

Infected sebaceous cysts are commonly seen in the Emergency Department. They are thought to be due to blockage of the ducts of sebaceous glands that subsequently become infected and form an abscess. Most cutaneous abscesses can be drained in the Emergency Department. Consult a Surgeon for those patients with large abscesses who require drainage in the Operating Room. Patients with signs of fever or toxicity should be admitted for parenteral antibiotics, incision and drainage, and observation. Refer patients to a physician who can provide wound care as well as definitive excision of the sebaceous cyst.

112 Hemorrhage Control

Christopher Freeman and Eric F. Reichman

INTRODUCTION

Control of external hemorrhage from an injury is a priority of basic first aid, beginning with the first responder in the prehospital setting and continuing with Emergency and Trauma Physicians in the resuscitation suite. Bleeding from extremity wounds is common. Most extremity bleeding is a minor inconvenience for the busy Emergency Physician in the crowded Emergency Department, prolonging wound closure and complicating wound healing. However, major exsanguinating extremity hemorrhage can be a life threat. Hemorrhage from extremity injuries was a leading cause of death in the Vietnam War and Operation Desert Storm.[1,2] Hemorrhage remained the leading cause of death in Operation Iraqi Freedom and Operation Enduring Freedom; however, torso hemorrhage was the leading cause of death.[3] **Methods for rapid and effective control of bleeding are essential in managing traumatic injuries and optimizing wound management.**

ANATOMY AND PATHOPHYSIOLOGY

Hemostasis is the first biological response to injury.[4–6] Hemostatic platelet plugs form at the ends of transected vessels within seconds of traumatic disruption of the skin. Fibrin fibers gather about the platelet plug within minutes. This fibrin mesh becomes part of an early matrix that initiates wound healing.[4]

Hemostasis is also the first priority in wound management for the Emergency Physician caring for traumatic wounds. **Control of bleeding is necessary to establish hemodynamic stability and prevent further blood loss.** Hemostasis is the first step in preparing for wound closure. Inadequate hemostasis with hematoma formation impairs wound healing, increases the risk of wound infection, leads to tissue ischemia, and results in hypertrophic scars.[7,8] Large hematomas may cause delayed wound dehiscence.

Bleeding from wounds may be superficial or deep. Superficial wounds, such as abrasions, avulsions, or simple lacerations involve damage to the epidermis, dermis, and subcutaneous tissue. Bleeding from most superficial wounds is predominantly from capillaries, small veins, or arterioles. Wounds deep to the fascia involve larger vessels and are typical of deep puncture or stab wounds, gunshot wounds, or major crush injuries. The approach to the bleeding wound will depend upon the nature of bleeding (e.g., large vessel vs. small, discrete source vs. diffuse), the site of injury, and its association with other major organ injury.

INDICATIONS

The immediate control of excessive bleeding is always a priority and should occur during the first contact with the patient. All bleeding must be controlled. Exsanguinating hemorrhage must be

immediately controlled. All other bleeding can wait until the ABC's and life-threats are addressed. The timing and selection of specific measures to isolate and treat the bleeding source will depend upon the management priorities of each patient. A simple compressive dressing or tourniquet may be used as a first-line measure to control bleeding in a multiple trauma patient. Measures that are more definitive may be taken early to identify and treat the specific injury if it is isolated.

CONTRAINDICATIONS

There are no absolute contraindications to any particular technique to control bleeding. The Emergency Physician should choose the technique best suited to the individual situation. An impressive wound should not distract or divert attention away from other injuries that may be less dramatic but more immediate life threats. **The simplest and most effective techniques should be used to control hemorrhage when faced with multiple injuries.**

EQUIPMENT

Pressure Control

- Blood pressure cuff
- Sterile 4 × 4 gauze pads
- Elastic bandage

Wound Manipulation

- Hemostats
- Needle driver
- Assorted suture
- Scissors
- Sterile saline
- 20 mL syringes
- 10 mL syringes
- 18 gauge needles
- 27 gauge needles

Anesthetics

- Lidocaine, with and without epinephrine
- Bupivacaine, with and without epinephrine
- 18 gauge needles
- 27 gauge needles
- 10 mL syringes

Wound Cautery

- Silver nitrate ($AgNO_3$)
- Electrocautery unit
- Monsel's solution (20% ferric subsulfate solution)
- Drysol (30% aluminum chloride solution)

Vasoconstrictors

- Epinephrine, 1:1000
- Cocaine, 1% to 4%
- Tetracaine, epinephrine, and cocaine (TEC) solution

Topical Hemostatic Agents

- Gelfoam
- Surgicel
- Cellulose
- Dry gelatin
- Thrombin
- Microfibrillar collagen
- Cyanoacrylate
- Various agents as listed in the techniques section

Miscellaneous Supplies

- Povidone iodine or chlorhexidine solution
- Penrose drain
- Finger tourniquet
- Hemoclips
- Hemoclip applicator
- Bone wax
- Raney scalp clips and applier

PATIENT PREPARATION

Control of hemorrhage is the priority. Attention to wound preparation should not delay definitive action to control bleeding. Obtain intravenous access and a type and crossmatch for blood products in any patient with active bleeding and hemodynamic compromise while applying direct pressure to the bleeding site. Explain the procedures to the patient while preparing for and performing the procedures. A local anesthetic can be administered prior to significant wound manipulation if the injury is minor and the patient is stable. Contaminated wounds should be irrigated free of foreign bodies and debris and the surrounding area cleaned with an antiseptic solution (i.e., povidone iodine or chlorhexidine). Refer to Chapter 92 for the complete details of wound cleansing and preparation.

TECHNIQUES

DIRECT PRESSURE

The quickest and easiest method to stop bleeding is the application of direct pressure to the bleeding site.[9–11] Poor lighting may prevent the exposure and visualization necessary to identify discrete bleeding sites in the prehospital setting. A compressive dressing may be the best option to control bleeding. Unfortunately, most compressive bandages apply too little pressure over too wide an area and act more like a sponge than a pressure dressing. Significant blood loss can be hidden within a bulky dressing.

Explore a bleeding wound as soon as lighting is sufficient and circumstances allow. Even brisk bleeding frequently has a few discrete sources that can be easily managed once identified. Direct pressure over bleeding vessels allows time for a platelet plug to form and gives a chance for the body's natural mechanisms of hemostasis to take place. Apply pressure over arterial wounds for 10 to 15 minutes to control most bleeding. Apply pressure to a proximal artery to impede arterial inflow and control, or slow, the bleeding when wound exploration is not practical.[12,13]

TOURNIQUETS

The use of tourniquets for extremity hemorrhage has received a great deal of attention throughout history. In reality, tourniquets are seldom necessary to control hemorrhage, even in major crush wounds, amputations, and in wilderness settings.[14] Direct pressure is more effective and causes less tissue ischemia. Tourniquets may be required to control bleeding and free rescue personnel to attend to other concerns if there is significant bleeding in a mass

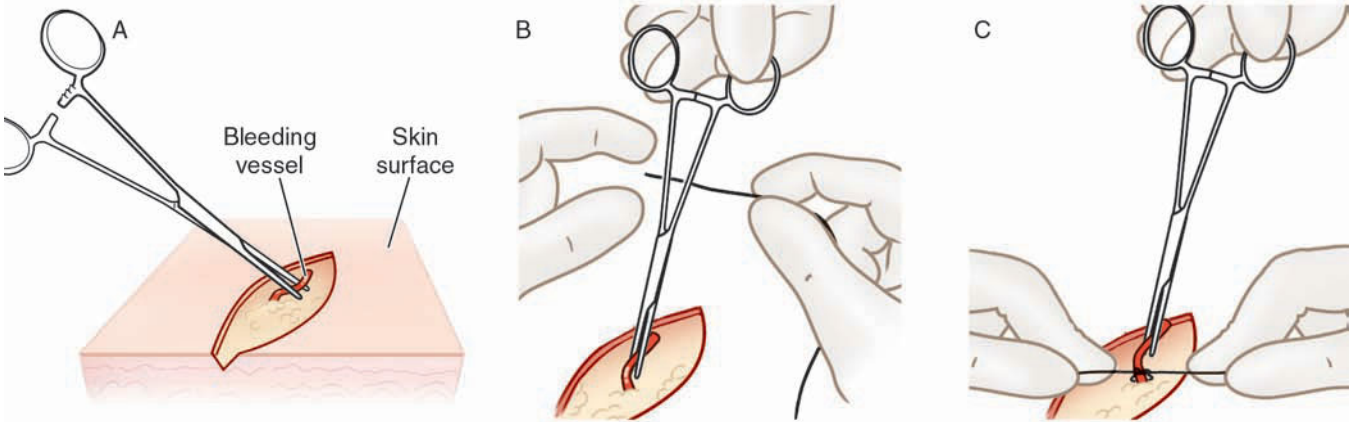

FIGURE 112-1. Control of the bleeding vessel that is visualized. **A.** Clamp the cut end of the vessel with a hemostat. **B.** Wrap a suture ligature about the base of the vessel. **C.** Tie and secure the suture around the base of the bleeding vessel.

casualty disaster. Tourniquets should be used as a last resort when other methods fail and the patient's life is in jeopardy.[12,14] Some of the currently available tourniquets include the Combat Application Tourniquet (Composite Resources, Rock Hill, SC), the Special Operations Forces Tactical Tourniquet (Tactical Medical Solutions, Anderson, SC), and the Emergency and Military Tourniquet (Delfi Medical, Vancouver, Canada).

There is no definitive time period to safely apply a tourniquet. There is a risk of limb ischemia and eventual limb loss any time a tourniquet is used. It is generally accepted that 2 hours is a safe time period.[38–40] Beyond this time, it is believed that permanent muscular or neurologic injury may occur. However, a tourniquet has been safely applied for up to 6 hours without permanent complications.[40–42] Use the minimal tourniquet pressure necessary to maintain hemostasis. Release the tourniquet periodically and reassess the extremity. **It is best to limit the use of a tourniquet for the minimum time required to temporarily be lifesaving and until definitive care can be received.**

BALLOON CATHETERS

Physicians have been using balloon catheters to tamponade exsanguinating bleeding from deep wounds or wound tracks. These devices were not specifically designed for this purpose, but used as an improvised technique to temporarily tamponade the hemorrhage. Devices used have included Fogarty catheters, Foley catheters, and Sengstaken–Blakemore tubes. These devices are blindly placed in the wound and inflated to tamponade bleeding from vascular and solid organ injuries.

Tourniquets specific for deep wound hemorrhage are being developed. These devices may be used when conventional external methods (e.g., clotting agents, direct pressure, and tourniquets) do not control the hemorrhage. This group of devices are inserted into the wound or wound track and inflated to tamponade the bleeding. One of these devices is the Tournicath (CardioCommand, Tampa, FL). These devices have not yet been fully evaluated for use in the prehospital setting or in the Emergency Department.

SUTURE LIGATION

Thoroughly inspect briskly bleeding wounds. Place a blood pressure cuff proximally and inflate it until a dry bloodless field is obtained. Large vessel bleeding will first become apparent as the cuff pressure is slowly dropped. Large and intermediate-sized vessels will need to be ligated or oversewn for effective control. Familiarity with the vascular supply to the extremities will help the Emergency Physician anticipate major arterial injuries and look for likely bleeding sources. **Whenever a transected vessel is seen, the other end should be searched for.** A retracted artery in spasm will likely bleed later and should be actively sought and ligated.

Bleeding vessels that can be visualized should be ligated with suture (**Figure 112-1**). Grasp the cut end of the bleeding vessel with a hemostat (**Figure 112-1A**). Pass an appropriate sized suture around the vessel (**Figure 112-1B**). Use absorbable sutures that do not lose their tensile strength too soon (e.g., Vicryl, Monocryl, and PDS). Tie and secure the suture around the base of the bleeding vessel (**Figure 112-1C**). Gently release the hemostat from the blood vessel.

Cut blood vessels, especially arteries and arterioles, often retract into the tissue and are difficult to visualize. A suture can be used to control the bleeding (**Figure 112-2**). Place a figure-of-eight stitch (**Figure 112-2A**) or a pursestring stitch (**Figure 112-2B**) to encompass the blood vessel. These sutures are simple, quick, and easy to place.

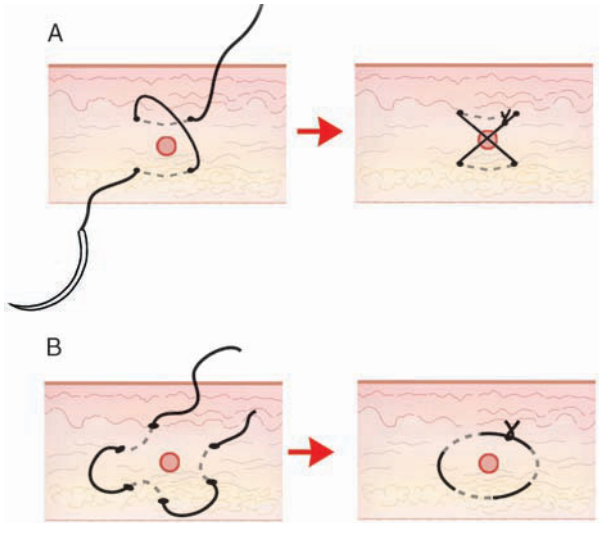

FIGURE 112-2. Control of a bleeding vessel deep or embedded in tissue. **A.** The figure-of-eight stitch. **B.** The pursestring stitch. Note that both of these stitches are not tied tightly for the sake of clarity. In real use, both of these stitches will be tied tightly to seal the bleeding vessel.

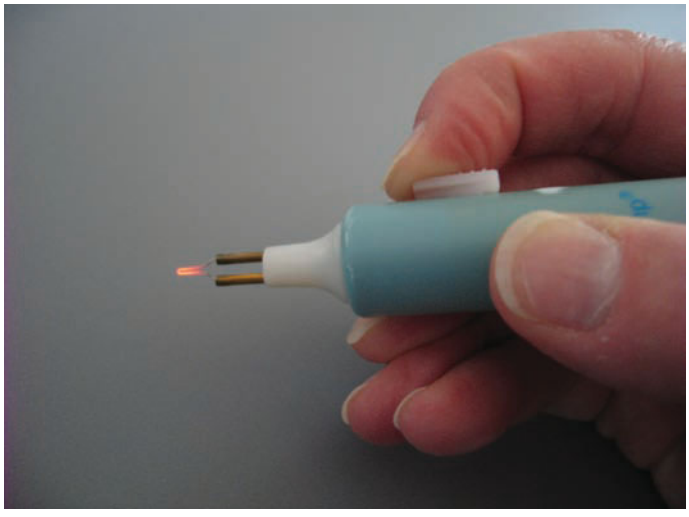

FIGURE 112-3. The battery-powered electrocautery device.

CAUTERY

Place a blood pressure cuff proximally and inflate it until a dry bloodless field is obtained. Small bleeding vessels will be identified as the inflated blood pressure cuff pressure is gradually reduced. The most likely source of significant bleeding from small vessels are from veins and dermal arterioles. Venous bleeding usually stops with direct pressure alone. Dermal arterioles tend to resist direct pressure and cause persistent oozing from the wound edges. Blood vessels are best identified by picking up the wound edge and inspecting the dermis. These bleeding vessels can be effectively treated with electrocautery or chemical cauterization.

Electrocautery is surprisingly easy and effective against aggressive bleeding from small vessels less than 2 mm in diameter.[9] Handheld battery-driven electrocautery units use a heated electrode to deliver a thermal burn to the tissue and char the ends of vessels (**Figure 112-3**). They are simple to use, inexpensive, and stocked in most Emergency Departments. More versatile electrosurgical units, such as the Bovie and Hyfrecator, are extremely effective coagulators.[15] Unfortunately, they are not routinely available in most Emergency Departments.

Chemical cauterization with silver nitrate ($AgNO_3$) is an effective alternative. The silver nitrate is a dark material that is provided on the end of a wooden applicator stick, resembling a large matchstick (**Figure 112-4**). Rub the silver nitrate over the cut end of the vessel.

FIGURE 112-4. The silver nitrate ($AgNO_3$) applicator.

It forms an insoluble precipitate with tissue protein to form an artificial clot or an eschar that occludes the vessel lumen. Silver nitrate cannot be used on briskly bleeding vessels as it will coagulate the blood and not the vessel. The cut vessel must not be bleeding or just oozing for silver nitrate to coagulate the tissue.

The reduced silver nitrate salts stain the tissue it contacts black. Most of the black silver salts are resorbed by the body over several weeks. There is the possibility of permanent staining or tattooing of the skin. Thus, do not use silver nitrate on light skin individuals or close to the skin surface in cosmetically sensitive areas. Minimize tissue contact with silver nitrate to prevent damage to the underlying tissue.

Two topical solutions can be used for chemical cauterization. Monsel's solution is a 20% ferric subsulfate solution that is thick and dark brown to black in color. Like silver nitrate, it can permanently stain or tattoo the skin. Drysol solution is a 30% aluminum chloride solution that is colorless. It will not stain or tattoo the skin. Drysol solution may not be as effective as Monsol's solution for cauterization. Both of these solutions are applied to a relatively dry or slightly moist area with a cotton-tipped applicator.

Briefly apply the electrocautery or chemical cautery directly to the bleeding source. Neither technique will work well unless the field is dry. This can be achieved with the use of suction, the wound can be dabbed dry with gauze or cotton-tipped applicators, or external pressure. More liberal use to the surrounding tissue will leave unnecessary damage and impair wound healing. Overzealous use of electrocautery and chemical cautery can cause unnecessary tissue necrosis and increase the risk of infection.

VASOCONSTRICTORS

Smaller bleeding vessels will usually constrict and eventually stop on their own once major vessels have been treated. If not, the use of local vasoconstrictors and topical hemostatic agents is effective.[16] Epinephrine is a convenient and effective vasoconstrictor.[17] It can be injected into the wound edges with local anesthetic or placed directly into the wound. Epinephrine and other vasoconstrictors should not be used in a finger, toe, ear, nose, or penis where ischemia may cause tissue loss. **Topical vasoconstrictors should be used with diligent attention to the total dose administered to avoid systemic side effects such as hypertension, tachycardia, and seizures.**

Commonly available local anesthetic solutions containing epinephrine that are available in the Emergency Department include lidocaine and bupivacaine. Inject 1 to 2 mL of local anesthetic solution containing epinephrine into the tissue surrounding the bleeding vessel, cover the wound with saline-moistened gauze, and apply external pressure for 2 to 4 minutes. **Use caution and aspirate prior to the injection to ensure that the solution is not being injected intravascularly.** Alternatively, spray 1 to 2 mL of 1:1000 epinephrine or epinephrine containing local anesthetic solution over the wound surface with a 25 gauge needle, cover the wound with a sterile saline-moistened gauze, and apply external pressure for 2 to 4 minutes.[18]

A more dilute epinephrine solution can be used in larger wounds to minimize potential side effects. Solutions as dilute as 1:100,000 to 1:1,000,000 are used to control the brisk bleeding that accompanies tangential burn wound excision and graft donor sites.[19] Topical cocaine (1% to 4%) is a potent vasoconstrictor commonly used on mucous membranes. Combinations of 0.5% tetracaine, 1:2000 epinephrine (adrenalin), and 11.8% cocaine (TEC) are used for topical anesthesia and hemostasis in pediatric wounds.[20] Apply 1 to 2 mL of these solutions directly into the wound followed by an occlusive dressing.

TOPICAL HEMOSTATIC AGENTS

This group of agents has seen most of the recent innovation in hemorrhage control. Most of these agents were originally developed for operative hemostasis. There use has expanded into the Emergency Department. More and more hemostatic agents are being developed for hemorrhage control outside the operating room or for life-threatening hemorrhage when other standard agents have failed. Topical hemostatic agents used in the Emergency Department include cellulose, dry gelatin, thrombin, microfibrillar collagen, cyanoacrylate, inorganic, and polysaccharide-based agents. **Injudicious reliance on hemostatic agents should not replace a methodical approach to wound care and a meticulous search for bleeding vessels.**

Oxidized cellulose (i.e., Surgicel) or dry gelatin (e.g., Gelfoam, Surgifoam) based agents can be used to provide hemostasis in wounds when there is diffuse oozing, especially where a small amount of blood impedes wound closure and jeopardizes a cosmetic outcome. These agents provide a matrix for platelet deposition and aid hemostasis.[7,16] Troublesome wounds can be treated with these agents and covered with a pressure dressing. After a few minutes, the dry field can be approximated with sutures. Another option is to simply leave the hemostatic agent in the wound, close the wound, and apply a pressure dressing. These techniques will be effective for many wounds. These substances are not free of complications. Absorbable gelatin in a wound can produce excessive granulation tissue and fibrosis. Cellulose can cause a foreign body reaction.

In cases where the bleeding persists, topical thrombin or microfibrillar collagen (e.g., Avitene, Instat, Helistat) may be useful hemostatic agents in these problematic cases.[16] Apply topical thrombin in powder form, or diluted with saline and sprayed on the wound. Concentrations of 100 units/mL are usually effective. Concentrations of 1000 to 2000 units/mL can be used if the bleeding is severe. Alternatively, microfibrillar collagen can be used to encourage platelet aggregation. Both thrombin and microfibrillar collagen are expensive and are not usually supplied outside the Operating Room. Their use should be restricted to the unusual patient with a coagulopathy or severe bleeding unresponsive to other measures.

Cyanoacrylate tissue adhesives are commonly used in the Emergency Department for wound closure. It is also a helpful adjuvant for hemostasis. In simple wounds where cyanoacrylate is used for wound closure, it forms an occlusive dressing that provides hemostasis. There is little human data demonstrating the hemostatic activity of cyanoacrylate. It has been shown to promote clot formation, decrease bleeding time, and decrease rebleeding in porcine models for epistaxis and femoral arterial injury.[21,22] It is important to note that cyanoacrylate works best in a dry, bloodless field that can be obtained by a combination of direct pressure, irrigation, and temporary tourniquet use. Hemostasis was achieved in a porcine arterial hemorrhage model in 90% of the animals after temporary tourniquet placement, irrigation, and cyanoacrylate application via spray.[22] Given the occlusive nature of cyanoacrylate, the wound can remain uncovered after its application, allowing for easier recognition of rebleeding if it occurs.

A relatively new area in topical hemostasis is the management of life-threatening bleeding in the nonoperative setting. This has focused on hemostatic dressing and agents, which when applied, lead to rapid hemorrhage control. These products are placed in the wound, covered with gauze, and pressure is then applied. More definitive management can be planned after hemostasis is achieved. These agents fit into two broad categories, inorganic and polysaccharide-based hemostatic agents.

The inorganic hemostatic agents include Quickclot (Z-Medica, Wallingford, CT) and Woundstat (TraumaCure, Bethesda, MD). Quickclot is a zeolite powder that adsorbs water and produces an exothermic reaction, releasing heat into the surrounding tissue.[23] The exact composition is proprietary, but the company states that it contains no biological or botanical substances. It is available as a loose powder and granular beads in a meshwork fabric. While zeolite provided hemostasis in some animal models, there were mixed outcomes and the exothermic reaction can cause temperatures in excess of 212°F or 100°C, leading to thermal tissue injury.[24,25] A new formulation now produces heat of approximately 105°F or 40.5°C to reduce the potential for thermal injury. This may limit Quickclot's clinical use. Woundstat is a smectite nonmetallic mineral that is composed of sodium, calcium, and aluminum silicates. It adsorbs water without producing an exothermic reaction, concentrates blood products, and promotes hemostasis. It is available as granular powder that is packed into wounds. Woundstat use demonstrated decreased blood loss and improved survival compared to Quickclot in animal studies.[26,27]

The polysaccharide-based agents are classified as *N*-acetylglucosamines containing glycosaminoglycans and microporous polysaccharide hemispheres. The data supporting the use of these agents are limited, mostly derived from animal studies with multiple differing models making direct comparison between the products difficult. *N*-Acetylglucosamine glycosaminoglycans are a complex polysaccharide derived from marine microalgae or crustacean shells in the form of chitin or chitosan.[24] These agents are thought to provide hemostasis through multiple mechanisms including tissue adhesion, attraction of circulating red blood cells, and vasospasm.[28] *N*-Acetylglucosamine-based agents include Hemcon and ChitoFlex (Hemcon Medical Technologies, Portland OR), Celox (SAM Medical Products, Portland OR), and Modified Rapid deployment Hemostat (Marine Polymer Technologies, Danvers, MA). Hemcon is available as a coated bandage. Celox is available as granules, granules in a disposable bag, coated flexible gauze, and in a plunger for deep application. Modified Rapid deployment Hemostat is available as a coated gauze. Hemcon, one of the best studied agents, has demonstrated mixed results in animal studies but has favorable reports from its limited use with the United States military.[29] A limited study of 10 trauma patients with intraabdominal injuries achieved hemostasis in 90% of the patients with Modified Rapid deployment Hemostat.[30]

Microporous polysaccharide hemispheres are derived from potato starch. The agent in this class is Traumadex (Medafor, Minneapolis, MN). Traumadex functions as a sponge, dehydrating the blood, concentrating the blood constituents, and promoting clot formation.[24] It is available as a powder and an impregnated bandage. Similar products are available as a spray and plunger for deep application. It performed better than a standard dressing in a swine model of lethal hemorrhage, but worse than both Hemcon and Quickclot.[31]

Dry Fibrin Sealant Dressing (DFSD) is composed of clotting proteins purified from donated blood and plasma. The DFSD is a multilayered dressing composed of fibrin, calcium chloride, thrombin, and an absorbable mesh. The dressing combines with blood to become activated and adhere to the tissues. These DFSD's require special handling and are very expensive, both of which will limit its use in the Emergency Department.

The limited human evidence, case reports, and small studies make comparison of the various hemostatic agents difficult. The application of these agents is simple. Determining which of these agents to use is difficult. It is likely that one or more of these products will become a useful adjunct in topical hemostasis in the early phase of trauma management in the Emergency Department.

The Defense Advance Research Projects Agency (DARPA) is looking into novel methods of hemorrhage control for the battlefield.

They are in the process of developing a wound dressing with an embedded ultrasound device that would be tuned at the resonant frequency of blood. The ultrasound would emit and focus high-power energy toward the bleeding site and stimulate coagulation. If practical and effective, its use can be expanded to the prehospital environment and the Emergency Department.

WOUND CLOSURE VERSUS PACKING

The wound can be approximated, a pressure dressing applied, and the limb elevated when oozing cannot be controlled by any other method. Alternatively, the wound can be packed with saline-moistened gauze until better hemostasis is achieved. Obtain a coagulation profile in anyone with persistent diffuse bleeding. If a correctable coagulopathy is identified, the wound can be approximated after the coagulopathy is corrected.

ALTERNATIVE TECHNIQUES

The general techniques discussed above apply to bleeding from most sites. There are a number of techniques applicable to specific anatomic sites.

THE HAND

Hand injuries pose special problems. Strict hemostasis is necessary to examine the wound and identify any associated damage to tendons, nerves, and joint capsules. A tourniquet can be placed to exsanguinate the extremity and facilitate wound inspection. Elevate the limb and wrap it with an elastic bandage to "milk" the venous return toward the heart. Apply a blood pressure cuff to the forearm or arm and inflate it above the systolic blood pressure. This prevents arterial inflow while minimizing the backflow from venous engorgement to reliably provide a bloodless field.

A digital tourniquet may expedite the examination if the injury is confined to a single digit.[32,33] A number of methods are effective. A Penrose drain can be wrapped about the base of the finger and secured with a hemostat (**Figures 104-3 & 112-5A**). Mark a 0.25 in. Penrose drain with two lines placed 26 mm apart. Stretch the Penrose drain about the base of an average adult finger until the lines meet. Clamp the Penrose drain with a hemostat to generate a sufficient but safe pressure.[32] An alternative is to use a surgical glove with the fingertip cut off and rolled down to leave a tight band at the base of the digit (**Figures 104-4 & 112-5B**). Use a glove size larger than what would typically fit the patient for general use to avoid generating excessive pressure.[32] Disposable, preformed, rubber digital tourniquets are commercially available (**Figures 104-5, 104-6, and 112-5C**).[34] Refer to Chapter 104 for a more complete discussion of digital tourniquets. These tourniquets exsanguinate the digit and prevent arterial inflow. **Tourniquets should be applied for no more than 20 to 30 minutes to avoid injury to the digital nerves.**

Hemostasis is important but should not be pursued without regard to the surrounding tissues. **Hand wounds should not be explored or probed deep to surface structures. Blind exploration or clamping is never advised.** Probing and clamping can damage small nerves and other structures. **Vasoconstrictors, such as epinephrine, should not be used on the digits.** Consult a Hand Surgeon if wounds require deep exploration, a digital artery is injured, or hemostasis is difficult to achieve.

THE SCALP

Scalp wounds frequently occur in association with other major intracranial, spinal, thoracic, and intraabdominal injuries. Control of scalp bleeding is frequently not the first priority in the multiple trauma patient, although continued brisk bleeding from the scalp can contribute to hemorrhagic shock.[35] Techniques for vascular control of the damaged scalp should be simple, fast, and not interfere with the ongoing assessment and treatment of other injuries.

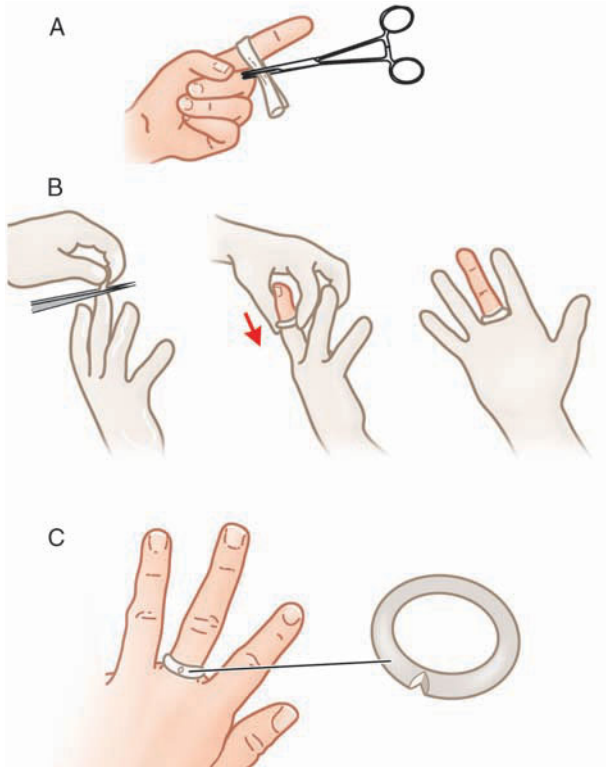

FIGURE 112-5. Finger tourniquets. **A.** A Penrose drain wrapped about the base of the finger provides effective hemostasis. **B.** A finger of a surgical glove has been cut and rolled down the finger. **C.** A commercial finger tourniquet.

A few techniques can help gain rapid control of scalp bleeding with a minimal investment of time or personnel (**Figure 112-6**). The fastest and most effective method is the application of Raney scalp clips (**Figure 112-6A**). These have been used for years by Neurosurgeons performing craniotomies.[36] **Scalp clips should only be used on the thick skin of the scalp. Use elsewhere can crush and devitalize thin skin or damage subcutaneous structures.** If these are not available, apply hemostats at the wound edges where the bleeding is brisk (**Figure 112-6B**). Inject local anesthetic solution with epinephrine into the wound edges to constrict smaller vessels. A Penrose drain can be wrapped about the head as a temporary tourniquet (**Figure 112-6C**).[12] A last method is to place a figure-of-eight suture, simple running sutures, mattress sutures, or surgical staples to temporarily close the wounds and achieve hemostasis. A more definitive closure can be performed after the patient has been stabilized.

The use of Raney clips can be cumbersome. This is especially true if the Emergency Physician has little or no experience with the system. It requires a special applier, individually loading the clips on the applier, and manipulating the clips. A much simpler system is a Raney clip gun (**Figure 112-7**). The clips are preloaded in a magazine that snaps into the clip gun. A clip is applied by touching the tip of the gun to the scalp edge and squeezing the handle. The clip gun then ejects and applies a clip, loads the next clip, and is set to apply the next clip. The process and technique of applying a clip is similar to using a skin stapler. The clip gun is much easier, quicker, and simpler to use than the traditional method.

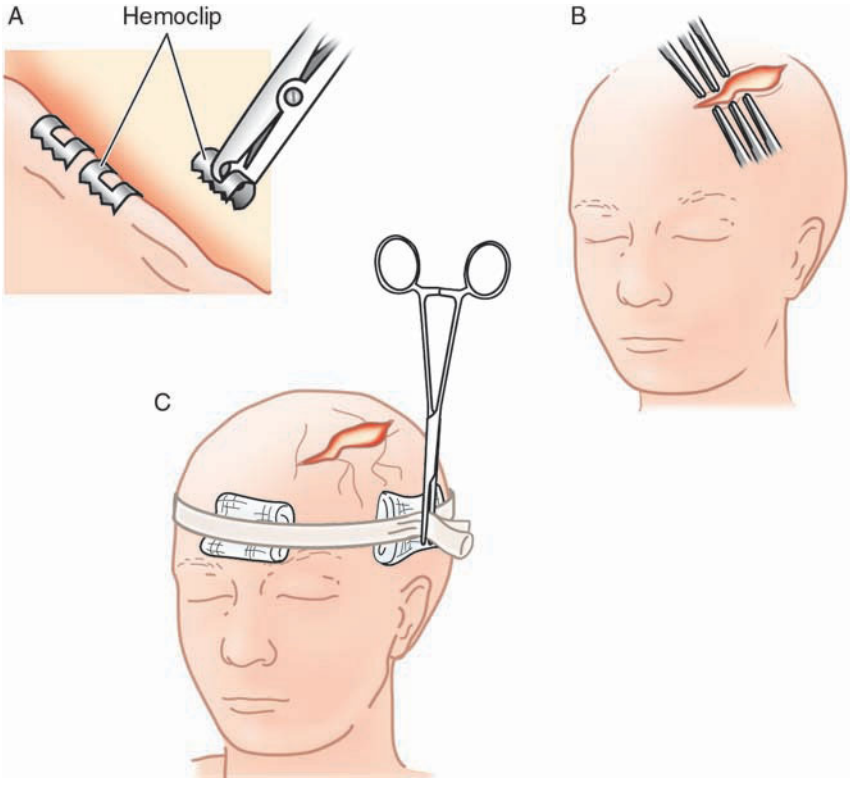

FIGURE 112-6. Hemorrhage from scalp wounds can easily be controlled. **A.** Hemostatic Raney scalp clips seal the wound edge. **B.** Hemostats applied about the edge of the wound. **C.** A Penrose drain wrapped about the head.

MAJOR EXTREMITY INJURY

Amputations, major crush wounds, soft tissue avulsions, and fractures of the extremity may present with active bleeding. Diffuse bleeding from muscle and soft tissue may be difficult to localize and treat. Immobilize the extremity and apply direct pressure if discrete bleeding sites cannot be identified. Reduction of long bone fractures and immobilization of soft tissue injuries can stabilize the damaged tissue and minimize blood loss. The application of a MAST suit or air splint may stabilize bony fragments and tamponade active bleeding.[37] Consider the application of a topical hemostatic agent such as Hemcon, QuickClot, or Traumadex. These conservative and simple measures can dramatically reduce ongoing blood loss.

FIGURE 112-7. The Medtronic Clip Gun Kit (Medtronic Neurosurgery, Goleta, CA). It contains the clip gun, three magazines preloaded with Raney-type clips, a clip remover tool, and an instruction manual.

EXPOSED BONE

Exposed bone will tend to ooze. This can be especially troublesome in amputations and crush wounds. Bone wax can tamponade these sites and temporarily halt the bleeding until more definitive action can be taken. Open a sterile package of bone wax and hold it in a sterile-gloved hand to warm it up and make it more pliable. Remove a piece of the bone wax and mold it over the end of the broken bone. Firmly push the bone wax into the bone to seal the edges. **Use care to prevent lacerating your glove and finger, resulting in a potentially significant bloodborne pathogen exposure.** Possible complications associated with the use of bone wax include granulomatous reactions, infection, and interference with osteogenesis. An alternative to bone wax is Ostene (Ceremed Inc., Los Angeles, CA), a water-soluble alkylene oxide copolymer that dissolves within 24 hours.

ARTERIAL INJURIES

Puncture wounds, open fractures, amputations, and deep lacerations may be complicated by arterial injuries. These may be obvious if they present with dramatic pulsatile bleeding. However, the elastic recoil of arteries frequently causes the damaged vessel to retract deep within the wound, only to rebleed after wound closure. Recurrent pulsatile bleeding and deep hematoma formation are characteristics of unrecognized arterial injuries. This is particularly true of puncture wounds where the damage may be deep and not visible to the examiner's eye. These wounds may require angiography, embolization, or wound exploration to identify the source if they rebleed despite local measures.

ASSESSMENT

The ideal goal in wound care is to achieve a dry bloodless field without compromising the vitality of the tissue. Simply controlling the hemorrhage and preserving life is the goal in major trauma victims. Expediting wound closure and preventing hematoma formation is a more modest goal for minor injuries.

AFTERCARE

A healthy wound is proof of adequate hemostasis. Routine wound care should verify a healthy incision line and the absence of a hematoma or an infection. Refer to Chapters 92 through 96 regarding the details of wound care and repair.

COMPLICATIONS

The techniques in this chapter are all safe and effective when used as described. Complications occur when the described techniques are used in excess or in the wrong setting. The specific complications of each technique are discussed under each specific section in this chapter.

SUMMARY

There are a number of techniques available for the control of hemorrhage. A methodical approach to the bleeding wound will optimize the outcome. Simple measures should be used first and progressive systematic steps taken until hemostasis is achieved. All bleeding eventually stops! The goal is to halt the bleeding before irreparable harm occurs.

113 Trigger Point Injections

Danielle Campagne

INTRODUCTION

Musculoskeletal pain is a significant health problem for the North American population.[1–9] Such pain affects between 10% and 20% of the population and is a major cause of morbidity.[1] It is estimated that approximately half of the chronic pain complaints result from a musculoskeletal origin.[2] It is hypothesized that myofascial trigger point (MTrP) injections may alleviate much of this pain. It is imperative that the Emergency Physician perform a thorough history and physical examination, with an emphasis on the neurological and orthopedic examination to exclude other causes of musculoskeletal pain.[3]

ANATOMY AND PATHOPHYSIOLOGY

The etiology and pathogenesis of MTrPs have yet to be elucidated. Likewise, the precise mechanism by which MTrP injections inactivate the trigger point is unknown. Researchers do agree that acute trauma or repetitive microtrauma appears to lead to the development of a MTrP.[6] The risk for a MTrP is increased when other factors are present, including poor physical conditioning, poor posture, and prolonged bending.[7] MTrPs mostly affect the muscle groups used to maintain posture (i.e., muscles of the neck, shoulders, and back). When the head and neck region is affected, the patient may present with a tension headache or temporomandibular joint pain.[6]

MTrPs are hyperirritable points located within a taut band of skeletal muscle or fascia.[2] When these points are compressed, they may cause referred pain, local tenderness, and autonomic changes.[2] Pain may be localized or diffuse. It can be described as burning, dull, sharp, or some combination of these. Autonomic changes associated with a MTrP include dizziness, edema at the site, lacrimation, piloerection, salivation, and tinnitus. The compression of a MTrP can further lead to muscle spasm, stiffness, shortening, and fatigue.[1] This may progress to impaired muscle coordination, reduced muscle strength, and decreased range of motion.[1]

DIAGNOSIS OF MTrPs

The diagnosis of a MTrP relies on the following criteria: a tender spot with an underlying taught band, pain on palpation of the tender spot, and a local twitch response (i.e., a transient local contraction of skeletal muscle fibers in response to palpation or needling).[3] While the data on clinical outcomes provide no definitive answer, the best outcomes appear to occur in patients who exhibit a local twitch response with palpation.[4] The current literature provides no pathophysiologic explanation for this result. There are no laboratory, pathology, or radiology studies to identify or verify a MTrP.

Identifying the palpable, taut band is critical in locating the MTrP. The MTrP can be identified by flat palpation, snapping palpation, pincer palpation, and/or deep palpation. Flat palpation uses a fingertip to slide across the skin over the affected muscle to find the MTrP (**Figure 113-1**). The taut band may be felt under the sliding fingertip. Snapping palpation uses the tip of the index finger to pluck the skin in an attempt to feel the underlying taut band. This motion is similar to plucking a guitar string. Pincer palpation uses the dominant thumb and index finger to firmly grasp the skin and

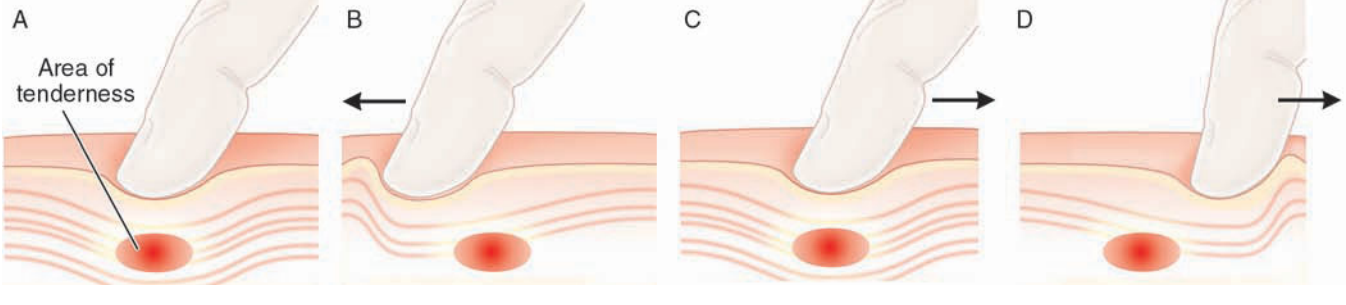

FIGURE 113-1. Flat palpation to identify a MTrP or taut band. **A.** The index finger pushes down over the MTrP or taut band. **B.** The index finger rolls off the tender spot and pushes the skin to one side. **C.** The index finger pushes the skin back to the tender spot to feel the taut band. **D.** The index finger rolls off the tender spot and pushes the skin to the opposite side.

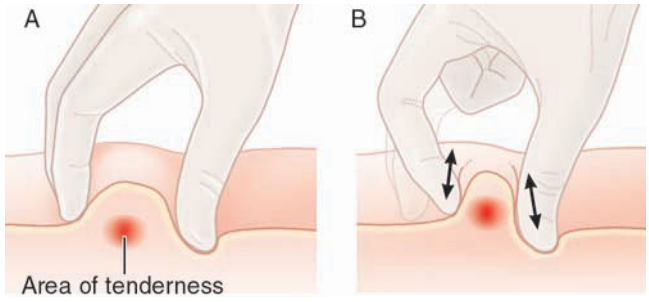

FIGURE 113-2. Pincer palpation to identify a MTrP or taut band. **A.** The skin, subcutaneous tissue, and muscle are grasped between the thumb and index finger. **B.** The fingers are moved back and forth (*arrows*) to feel the taut band as it is rolled between the fingertips.

muscle as a unit and roll it to identify the taut band (**Figure 113-2**). Deep palpation can be used to identify a deep MTrP or a superficial MTrP in an obese patient. Use the tip of the index finger to press slowly and deeply to reproduce the patient's symptoms and identify the MTrP.

Studies have utilized a variety of injectant fluids and solutions during injections of MTrPs including sterile water, sterile saline, local anesthetic solutions, corticosteroid suspensions, ketorolac, and botulinum toxin.[1] No specific fluid or solution has demonstrated a clearly superior clinical outcome. Rather, it appears that the optimal injectant fluid or solution varies by Physician preference. The duration of pain relief has been found to last longer than the duration of action of the injectant. A recent meta-analysis of eight randomized and controlled clinical trials examined the type of injectant used and the resulting effect on symptom relief.[1] The authors concluded that the injection of either lidocaine or botulinum toxin provided greater symptom relief than placebo (i.e., dry needling alone). No particular injectant was more efficacious than any other injectant. This finding is consistent with the general medical literature on the topic, which is still in its infancy, and provides no clear indication of effectiveness. More research is required in this area.

NONINVASIVE MTrP MANAGEMENT

Numerous noninvasive techniques have been used to treat a MTrP.[2,5,8] One of the more common techniques uses spray vapocoolant (e.g., ethyl chloride) in combination with passive muscle stretch to relax the taut band. Ischemic compression therapy is the application of pressure to the MTrP to produce ischemia and ablate the MTrP. Digital pressure is applied and increased until the taut band relaxes. A deep pressure or stroking massage can be used to stretch the affected muscle and relax the taut band. Physical therapy can stretch and relax the affected muscles. Transcutaneous electrical stimulation units with the electrodes placed over the MTrP can be used to stimulate and relax the underlying muscle. Ultrasound can transmit heat and vibration to a superficial MTrP with the goal of muscle relaxation.

INDICATIONS

MTrP injections have been advocated for points of muscle pain that are not assisted by noninvasive therapy such as ischemic compression therapy, massage, physical therapy, spray vapocoolant, transcutaneous electrical stimulation (TENS), and ultrasound.[8] There is no emergent indication for a MTrP injection in the Emergency Department.

TABLE 113-1 Determining Isolated MTrPs Versus MTrPs Associated with Fibromyalgia

Characteristic	Isolated MTrPs	Fibromyalgia
Sexual predilection	None	Female
Pain and tenderness	Local or regional	Generalized and widespread
Muscle tissue	Taut bands palpable	Soft, no taut bands palpable
Muscle range of motion	Stiff and decreased	Normal
MTrPs	Few, discrete, and localized	Many and widespread
Immediate response to injection therapy	Resolution of symptoms	Poor or none

Source: Data from Simmons et al.[2]

CONTRAINDICATIONS

Contraindications to MTrP injections are similar to other injection procedures. This includes the presence of a local or systemic infection, malignancy, anticoagulation therapy, a bleeding disorder, or a dermatologic condition over the injection site.[5] Relative contraindications include allergies to local anesthetic agents, patients with needle phobias, and uncooperative patients.

It is important to differentiate between a patient with one or more isolated MTrPs and fibromyalgia (**Table 113-1**). **A patient with fibromyalgia can have multiple MTrPs. Do not perform MTrP injections in a patient with fibromyalgia.** The injection may worsen their pain.

EQUIPMENT

- Sterile gloves
- Povidone iodine or chlorhexidine solution
- Alcohol swabs
- Sterile gloves
- Gauze 4 × 4 squares
- 25 or 27 gauge, 1.5 in. needle for superficial trigger points
- 25 or 27 gauge, 2 in. needle for deeper trigger points
- 3 or 5 mL syringe
- Injection solutions:
  - Lidocaine without epinephrine
  - Bupivacaine without epinephrine
  - Sterile water
  - Sterile normal saline
  - Botulinum toxin A, 20 units or 0.4 mL (50 U/mL) (Botox, Allergan, Irvine, CA) diluted to 1 mL with normal saline
- Ultrasound machine with a 5 to 7.5 MHz probe
- Ultrasound gel

PATIENT PREPARATION

Explain the risks and benefits of the procedure to the patient and/or their representative. Obtain an informed consent, either signed or verbal, with adequate documentation to support the latter method. Place the patient in a comfortable position on a gurney with the MTrP(s) exposed. Ideally, the muscle with the MTrP(s) positioned so that it is relaxed. Identify the MTrP site(s). Clean the skin of any dirt and debris. Use ultrasound to ensure there are no neurologic, tendinous, or vascular structures in the area that can be injured

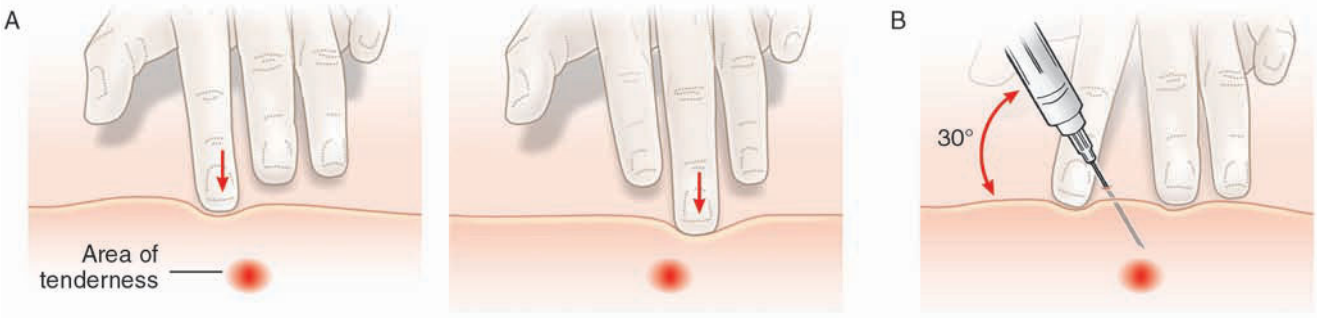

FIGURE 113-3. Identifying and securing the MTrP or taut band. **A.** Push with the index finger and middle finger, alternating between the fingers, to identify and isolate the MTrP or taut band. **B.** Compress the skin with both fingers to secure the MTrP or taut band and inject it.

by the MTrP injection. Mark the MTrP skin site with a pen. Apply povidone iodine or chlorhexidine solution over the injection site(s) and surrounding skin and allow it to dry. Follow aseptic technique for the injection procedure.

Prepare multiple 3 or 5 mL syringes armed with a 25 or 27 gauge needle and containing the injection solution. The editor recommends local anesthetic solution as the injectant in the Emergency Department. The number of syringes to prepare depends upon the number of MTrP sites to be injected and the volume injected at each site.

TECHNIQUES

INJECTION TECHNIQUE

Reidentify the MTrP site. Use the nondominant index and middle fingers to locate and isolate the MTrP or taught band (**Figures 113-3A & B**). Insert the needle into the skin approximately 1 cm away from the MTrP or taught band, at a 30° angle to the skin, and aimed at the MTrP or taut band. Advance the needle into the MTrP or taut band. **Insert the needle briskly, but also in a controlled manner.** Use a "fast in, fast out" approach to elicit a local twitch response when the tip of the needle hits the MTrP or taut band.[8] Aspirate to ensure that the tip of the needle is not within a blood vessel. Inject the solution within the syringe.

Common practice is to inject between 0.5 and 2.0 mL total per MTrP.[5] This volume can be injected into the one location of maximal tenderness or numerous sites in a fanlike pattern within the MTrP (**Figure 113-4**).[9] Once the injection is completed, withdraw the needle to the skin surface but do not completely remove it from the skin. Allow the injection solution to work for up to a minute. Reinsert the needle into the MTrP in a fanlike pattern until the local twitch response is no longer elicited or resisting muscle tautness is no longer palpable.[7] Completely withdraw the needle. Apply pressure over the injection site to prevent bleeding and hematoma formation. Instruct the patient to slowly and fully stretch the affected muscle group.[8]

DRY NEEDLING

The technique of dry needling involves inserting a needle into multiple sites within the MTrP or taut band without injecting any fluid or solution. This is similar to acupuncture. Insert the needle as described above. Withdraw the needle until the tip is just below the skin surface. Redirect and reinsert the needle in a fanlike pattern into a different location within the MTrP or taut band. Continue this process several times until the local twitch response is no longer elicited or resisting muscle tautness is no longer palpable.[7] Completely withdraw the needle. Apply pressure over the injection site to prevent bleeding and hematoma formation. Instruct the patient to slowly and fully stretch the affected muscle group.[8]

ASSESSMENT

The patient should experience relief of their symptoms after the injection. Passively and actively stretch the affected muscle in a slow manner to stretch it out. Apply digital compression to the injection site, the MTrP, and the taut band. If symptoms are still

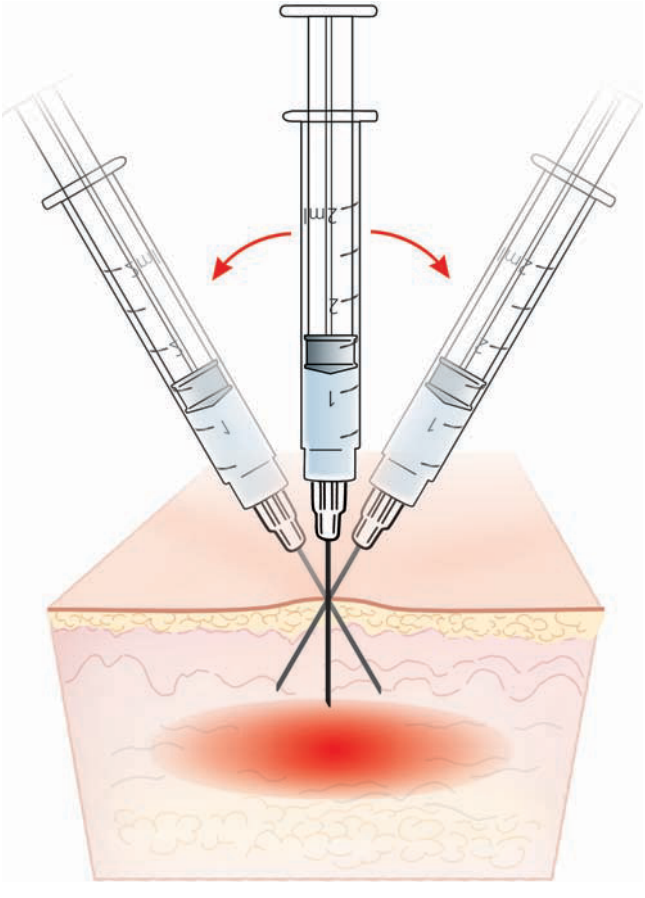

FIGURE 113-4. Injection of the MTrP or taut band. The needle is inserted through a single skin puncture and into multiple places within the MTrP or taut band in a fanlike pattern.

present, repeat the procedure with local anesthetic solution or by dry needling. Observe the injection site and apply pressure to control any bleeding.

AFTERCARE

Apply a simple adhesive bandage over the injection site. Postinjection soreness is expected and can be managed with acetaminophen or nonsteroidal anti-inflammatory drugs. Encourage the patient to use the affected muscle through its full range of motion, but avoid strenuous activity for 1 to 3 days after the injection. Instruct the patient to return to the Emergency Department immediately if they develop fever, chills, swelling at the injection site, redness at the injection site, or any drainage from the injection site.

COMPLICATIONS

The complications are the same as any injection procedure, including infections and needle breakage. An allergic reaction to the injection fluid or solution is possible. Treat this as any other allergic reaction. A thorough history may prevent an allergic reaction to the injectate. Never aim the needle at an intercostal space to prevent an iatrogenic pneumothorax.[7] Hematoma formation following injection can be minimized with proper technique and the application of pressure over the soft tissue after the needle is withdrawn.[2] Never inject the patient when they are standing or sitting in a chair. Ensure that the patient is always on a gurney and the side rails are upright to prevent injury if the patient becomes vasovagal or experiences syncope. Injury and inadvertent injection to adjacent structures can be avoided by knowing the local anatomy and using ultrasonography before the injection to identify adjacent structures.

SUMMARY

MTrP injections can be performed in the Emergency Department. They are simple, quick, and effective to manage a patient's pain. The efficacy of MTrP injections has not yet been established. However, MTrP injections may serve as part of a treatment plan to offer quick relief of myofascial pain when other noninvasive therapies have been unsuccessful.

114 Escharotomy

Michael A. Schindlbeck

INTRODUCTION

Few injuries have the same capacity for physical destruction and emotional devastation as do thermal burns. They are relatively common presentations that often require resource-intensive management. The preceding decade saw nearly 500,000 burn injuries per year receiving medical care in the United States. Over 40,000 of these patients required inpatient treatment for their injuries, and up to 25% of these injuries were work related. The associated expenses are staggering. The mean hospital stay was in excess of 1 week and at an average cost over 50,000 dollars per admission. Over this same 10-year period, an average of over 4000 individuals per year died as a result of burn-related injuries. Fires and burns now represent the fifth leading cause of unintentional injury deaths in the United States.[1] Conversely, less than 6% of the above patients who were admitted to a recognized burn center subsequently died as a result of their injuries.[2–4] **These data underscore the need for rapid and effective emergency care focused on facilitating the successful transfer of these patients to specialized burn centers.** The initial management of these patients invariably falls upon the Emergency Department. The Emergency Physician needs to be well versed in the recognition of acute thermal injuries, their associated complications, and their appropriate treatment.

Thermal injuries have the potential to affect any body surface, both internally and externally, that a heated medium comes into contact. The overall depth and degree of injury is multifactorial. It is also typically proportional to the temperature of the source medium, its unique specific heat, the actual rate of energy transfer, and the overall duration of tissue exposure. This chapter focuses on the skin and its response to burn injuries.

ANATOMY AND PATHOPHYSIOLOGY

Skin exposure to any significant heat source results in a spectrum of pathophysiological responses. An initial coagulation necrosis occurs as thermal energy is transmitted directly into living tissue. These cells subsequently die and lyse, spilling their intracellular contents and increasing the surrounding interstitial oncotic pressure. These processes serve to trigger a secondary edematous reaction in the surrounding tissues. Cellular breakdown releases a host of generalized inflammatory markers including histamines, prostaglandins, cytokines, and interleukins. These agents further exacerbate the localized edematous reaction via vasodilation and increased capillary permeability.[5]

Burns involving over 20% of a patient's total body surface area (TBSA) can result in secondary injury extending beyond the locally involved tissues. The previously described inflammatory outburst can become significantly large enough to produce a systemic pathophysiologic response of internal fluid shifts and external fluid losses. Inadequate fluid resuscitation can result in tissue hypoperfusion and multisystem organ dysfunction. Moreover, a secondary systemic inflammatory response syndrome (SIRS) can further complicate the clinical course of patients whose burns involve greater than 30% TBSA. This frequently results in widespread intravascular hemolysis, acute renal failure, and acute lung injury.[6,7] A global hypermetabolic state tends to accompany these injures. When greater than 30% to 40% of a patient's TBSA is involved, secondary catecholamine release can raise the resting metabolic rate approximately two to three times above baseline. The consequent catabolic tissue breakdown further exacerbates the emerging multisystem organ dysfunction.[5,8] These burns are associated with significant morbidity and mortality. Survivability rates are indirectly proportional to the TBSA involved. Of special note is the loss of a protective functioning epidermis as severe and overwhelming infection becomes a significant potential complication in those who survive beyond the initial resuscitative period.[9] Systemic organ failure from the "burn sepsis" continues to be a leading cause of death in these individuals.

Burns are classified based upon the overall depth of injury sustained. First-degree burns are limited solely to the epidermal layer. They typically present as a tender erythematous region of skin. This redness arises as the underlying dermal capillaries dilate in response to the overlying injury. Deeper tissues are not directly involved and the capillary walls remain intact. This explains the blanchable nature of these burns on physical examination. Blistering of the skin, indicating involvement of the underlying dermis, is not seen with first-degree burns. Classic examples include flash burns and sunburns. Despite extensive surface area involvement, these burns

do not generally illicit the systemic pathophysiologic response described above. Do not include first-degree burns when calculating the overall TBSA affected.

Second-degree burns are the partial thickness injuries. These burns extend into but not through the dermis. They are subdivided into superficial second-degree and deep second-degree burns. Superficial second-degree burns are typically moist to the touch, pink to reddish in color, blanchable with gentle pressure, and covered with tensely distended blisters. Cutaneous nerves, located in the uninvolved underlying deeper dermal layer, remain viable bestowing an exquisitely painful character to these burns. Conversely, deep second-degree burns involve the deeper reticular dermis and differ noticeably in appearance. They tend to be drier in texture and have a more blanched whitish complexion. These injuries tend to be less painful than their superficial counterparts due to destruction of the cutaneous nerves.

Full thickness burns involve the destruction of the entire epidermal and dermal tissues and are classified as third-degree burns. Coagulation necrosis imparts a dry leathery appearance to these burns. The overlying tissue is insensate secondary to the obliteration of the cutaneous nerves. The dermal proteins in third-degree burns are heated and tend to contract, facilitating the formation of a constrictive eschar of scar tissue. Rare scenarios where the tissue destruction extends through the dermis and into the underlying tissues (e.g., muscle, bone, and fascia) are categorized as fourth-degree burns. These injuries are catastrophic in appearance and tend to result in extensive tissue loss.[10]

Burn injuries can generate an extensive redistribution of fluids into the interstitial spaces. Aggressive fluid resuscitation will help to limit the consequent invariable hypoperfusion but does nothing to limit further leakage of fluids into the interstitium. This third spacing can lead to significant elevations in the localized hydrostatic pressures in tissues already constricted by an extensive overlying eschar. Impairment in regional lymphatic and venous drainage further exacerbates this adulteration of the local pressure gradient. Eventually, the normal arteriolar perfusion pressure will be overwhelmed and result in distal tissue hypoperfusion. Distal tissue necrosis can progress to limb loss if the burn occurs on an extremity. Swelling and scarring can result in the loss of a functional airway if the burn occurs over the neck. Burns occurring across the torso can produce an abdominal compartment syndrome, progressing to intra-abdominal organ ischemia, impaired diaphragmatic excursion, and reduced cardiac output secondary to diminished venous return.[11–13] Significant thoracic burns can also impede the dynamic chest wall motions of respiration producing a further restrictive ventilation that can progress to respiratory failure.[14]

INDICATIONS

The general indication to perform an escharotomy is to limit the circulatory or respiratory insult caused by an overlying circumferential burn. These indications can also be present with a significant noncircumferential burn. The development of a significant restrictive physiology often requires several hours after the initial burn. Most patients could be successfully transported to a specialized burn center within this time span. Invasive means to assess compartmental pressures (Chapter 74) should not be undertaken at the expense of proper fluid resuscitation and preparation for transport. The Emergency Physician must maintain a high index of suspicion to limit any further injury to viable tissues. **Once the decision to perform an escharotomy is made, it should be performed without delay.** If possible and time permits, perform the escharotomy in consultation with the accepting burn center and/or Burn Surgeon.

Any signs and symptoms of limb hypoperfusion should be taken seriously. **A restrictive etiology should be considered only if hypoperfusion persists despite adequate volume resuscitation as hypovolemia is the most likely etiology of impaired tissue perfusion immediately after the burn injury.** Perform and document frequent and repeat physical examinations including an assessment of overall skin appearance, distal capillary refill, peripheral pulse checks, any motor deficits, and any sensory deficits. **Depending upon the presence of palpable pulses as the sole means to approximate compartmental pressures will grossly underestimate the need for decompression.**[15] Several methods are available to aid the Emergency Physician in frequently assessing for tissue hypoperfusion. Bedside arterial Doppler provides an easy means to gauge peripheral perfusion. It is concerning if any signs of a progressive reduction in arterial flow occurs. The absence of arterial flow on a bedside Doppler is an indication for emergent escharotomy. **Keep in mind that the presence of Doppler pulses does not necessarily indicate adequate perfusion.** Pulse oximetry provides another useful adjunct. A distal oxygen saturation of less than 95% in a circumferentially burned extremity has been shown to be an indicator for an emergent escharotomy.[16] Compartmental pressures can usually be measured quickly at the bedside. An intracompartmental pressure of ≥40 mmHg is an indication for an escharotomy. Consider an escharotomy for intracompartmental pressures between 25 and 40 mmHg. Refer to Chapter 74 regarding the complete details of compartment pressure measurement.

Significant burns to both the chest and abdomen can result in restricting ventilation. Respiratory distress is generally multifactorial in burn patients. A concurrent inhalation injury or secondary ARDS should be entertained in the differential diagnosis. **Early intubation and mechanical ventilation is essential in any burn patient exhibiting respiratory distress.** Mechanically ventilated patients with severe truncal burns, persistent arterial hypercapnia, and elevated peak inspiratory pressures (although often confounded by concurrent airway edema and secondary bronchospasm) are objective signs suggesting a significant restrictive respiratory physiology. An emergent escharotomy in these patients could be a lifesaving procedure.

Facial burns can result in eschar formation around the eyes and mouth. Measure intraocular pressure if an eschar surrounds the eye. Elevated intraocular pressure should be decompressed with a lateral canthotomy. Refer to Chapters 156 and 162 regarding the complete details of intraocular pressure measurement and a lateral canthotomy, respectively.

CONTRAINDICATIONS

No specific contraindications exist for performing an escharotomy provided the above indications are satisfied. Concern for possible medical futility should arise in those patients with no chance of salvageability, although this is very difficult to determine within the Emergency Department.

EQUIPMENT

- Glove, gown, and face mask
- Povidone iodine or chlorhexidine solution
- #10 scalpel blade on a handle
- Electrocautery unit, optional
- Gauze 4 × 4 squares
- Local anesthetic solution
- Needles and syringes

PATIENT PREPARATION

This procedure is considered life and/or limb sparing. Inform the patient for the need to perform an escharotomy, its risks and benefits, and the outcome if not performed. Document the discussion in the medical record. The patient's medical condition often precludes them from signing a consent form. Despite the fact that escharotomies are performed upon tissues previously destroyed by full thickness burns, some intermittent nerve function can persist. This may necessitate the use of local anesthesia and/or procedural sedation. If not contraindicated, administer some form of procedural sedation (Chapter 129) in the conscious patient for pain control as well as to limit the profound anxiety elicited by this procedure. Strict aseptic technique should be followed. Clean the skin of any dirt or debris. Apply dilute povidone iodine or chlorhexidine solution to the skin and allow it to dry. This procedure has the potential to introduce a devastating infection.

TECHNIQUES

Make the skin incisions along the proper plane with a #10 scalpel blade or an electrocautery unit. Electrocautery has the added ability to coagulate the potential bleeding encountered from inadvertently incised superficial subcutaneous vessels. **Limit the depth of the incision to the dermis.** Use extreme caution to avoid overaggressively extending these incisions too deeply and injuring the underlying deep investing fascia, muscles, and/or tendons. There is a pressure buildup underlying the constricting tissue. **A properly placed incision should elicit a rapid separation of the eschar exposing the underlying subcutaneous fat.** Carefully run a gloved fingertip along the incision lines to detect any residual connecting bands of tissue requiring further incision. To ensure an adequate release, continue the incision across the entire eschar and extending 1 to 2 cm into the unscarred tissue on either end. Cosmetic concerns are not a concern as the incised tissue will often require eventual skin grafting, provided the patient survives.

FACE ESCHAROTOMY

The face is commonly involved in burn injuries. Eschars can form on the face just as they can form on other areas of the body. A patient complaint of any visual disturbance or burns around the eye requires a thorough investigation. This includes measuring visual acuity, a topical fluorescein examination, a fundoscopic examination, and measurement of intraocular pressure. Refer to Chapters 153 and 156 regarding the complete details of these examinations. Elevated intraocular pressure may require a decompressive lateral canthotomy and cantholysis. Refer to Chapter 162 regarding the complete details of this procedure.

Perioral burns can form eschars. These eschars may limit or prevent mouth opening. An escharotomy may be required to aid in oropharyngeal suctioning and orotracheal intubation. Make the escharotomy incisions at the bilateral corners of the mouth and extending directly posterior (in the supine patient) and approximately 4 to 5 cm long (**Figure 114-1A**). **Make the incisions very superficial to prevent injury to the underlying facial artery, cranial nerves, superficial facial structures, and the parotid gland.**

NECK ESCHAROTOMY

Significant burns to the neck can result in the formation of a constrictive eschar that can compromise the airway. Make paired vertical incisions on the posterolateral surfaces of the neck from the mastoid process to the clavicle (**Figure 114-1A**). **Meticulous care and attention should be given to always remain posterior to the clavicular border of the sternocleidomastoid muscle.** This will avoid injury to the internal jugular vein, carotid artery, thyroid gland, trachea, and vagus nerve.

TORSO ESCHAROTOMY

Perform a thoracic escharotomy by extending bilateral vertical incisions from the lateral clavicle to the costal margins along

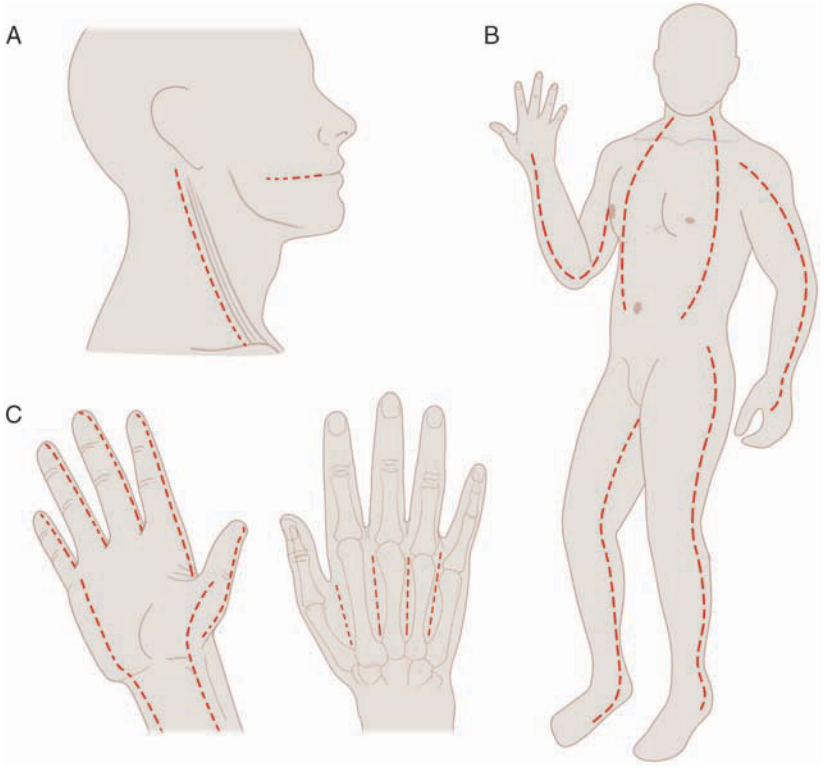

FIGURE 114-1. The location of incisions for escharotomies. **A.** The head and neck. **B.** The extremities and torso. **C.** The hand and fingers.

the anterior axillary lines (**Figure 114-1B**). Use caution in female patients to avoid incising directly through the breast tissue. Instruct an assistant to grasp the breast and move it medially to avoid the escharotomy incision line. In those patients whose burns also involve a significant portion of the abdominal wall, extend the thoracic incision inferiorly beyond the costal margins and across the entire eschar to ensure adequate decompression (**Figure 114-1B**). Make a horizontal bridging incision along the inferior costal margin in those patients whose burns extend from the thorax and onto the abdomen to support proper respiratory mechanics (**Figure 114-1B**).

Circumferential burns of the penis require an escharotomy to decompress the area and prevent ischemia. Distal ischemia can rapidly progress and produce significant tissue loss. Make bilateral incisions along the lateral margins of the body of the penis. **Meticulous care and attention should be given to avoid injuring the dorsally located neurovascular structures that lie between the 10 o'clock and the 2 o'clock position.**

UPPER EXTREMITY ESCHAROTOMY

Perform an upper extremity escharotomy on the medial and lateral aspects of the involved limb, extended along the line dividing the flexor and extensor surfaces (**Figure 114-1B**). Place the upper extremity supine to ensure adequate landmark identification. The areas surrounding joints are sites of severe potential restriction due to relatively tight tissue adherence. Use caution when extending the incisions across these locations. **Meticulous care and attention should be given to avoid the ulnar nerve along the medial surface of the elbow as it courses posterior to the median epicondyle and the superficial branch of the radial nerve along the lateral surface of the wrist as it courses superficially above the radius.** If the hand is involved, extend the forearm incisions to include the thenar and hypothenar eminences (**Figure 114-1C**). Further hand decompression can be accomplished by making vertical incisions down the four intermetacarpal grooves on the dorsum of the hand (**Figure 114-1C**). The fingers can be decompressed with linear incisions along the middle of the radial and ulnar surfaces, between the flexor and extensor surfaces (**Figure 114-1C**). In an attempt to limit the potential damage to a patient's grasping surfaces, incise the ulnar finger surfaces (radial surface on the thumb) and assess if this unilateral incision is sufficiently adequate to restore perfusion prior to automatically incising the corresponding opposing surface.[17]

LOWER EXTREMITY ESCHAROTOMY

The lower extremity should be approached in a similar manner, with incisions extending along the groove between the flexor and extensor surfaces (**Figure 114-1B**). **Meticulous care and attention should be given to avoid damaging the common peroneal nerve along the lateral knee as it courses superficial to the fibular head and the posterior tibial artery along the medial ankle as it courses posterior to the medial malleolus.** If the foot is involved, extend the incisions along the medial and lateral borders of the foot to the great toe and the fifth toe, respectively (**Figure 114-1B**). Decompress the toes in a manner similar to the fingers.

TECHNIQUE FOR PEDIATRIC PATIENTS

Pediatric patients have a higher surface area to volume ratio than does an adult. Consequently, burns pose a greater risk for significant external fluid losses and the rate of fluid resuscitation needs to be adjusted accordingly. More aggressive fluid resuscitation, however, increases the likelihood for pathologically significant elevations in the perfusion pressures of affected tissues. Infants and younger children depend to a greater extent upon diaphragmatic excursion and abdominal wall mobility for normal respiratory function. They are therefore more susceptible to significant respiratory compromise from extensive truncal burns. This necessitates that the treating Emergency Physician possesses both a high index of suspicion and the technical ability to intervene surgically. The patient preparation and escharotomy techniques are the same as in an adult.

ASSESSMENT

The response to an escharotomy should be almost immediate with the signs of improving distal perfusion of the extremities or improved ventilation. The distal extremity should demonstrate decreased pallor and return of a natural skin color, return of sensation, appropriate Doppler arterial flow, and appropriate pulse oximetry. Provided adequate respiratory mechanics, distal pulse oximetry readings should rapidly climb into a normal range.[18] **Lack of improvement in distal perfusion should alert the Emergency Physician to either an inadequate surgical decompression or an insufficient fluid resuscitation.** If there is no improvement in perfusion despite appropriately addressing these two concerns, consider an underlying intrafascial compartment syndrome that would require an emergent fasciotomy. Please refer to Chapter 74 regarding compartment pressure measurements and Chapter 75 for the details of performing a fasciotomy.

AFTERCARE

Continue routine burn care and fluid resuscitation as necessary. Manage any continued bleeding from the escharotomy incisions with the application of pressure or electrocautery. Cover the escharotomy incisions with sterile saline-soaked gauze and an outer dressing. Frequently reassess the patient to rule out the development of additional tissue ischemia or respiratory compromise that would indicate the need for further extension of the initial escharotomy incisions. Transfer the patient to a specialized burn center or an intensive care unit to continuously monitor and manage the patient.

COMPLICATIONS

As with any invasive procedure, bleeding can be a significant complication. This is rare when the escharotomy incisions are properly limited to the dermis. Bleeding can be extensive when an underlying subcutaneous vessel is incised. This is often complicated by the consumptive coagulopathy that frequently accompanies these burns. Electrocautery is an attractive option to limit such bleeding if encountered. Otherwise, direct pressure should generally suffice. Some blood vessels may require ligature for definitive hemostasis.

The burn-damaged epidermis can no longer function to protect deeper tissues from the external environment. Furthermore, the overlying eschar of necrotic tissue provides an ideal environment for uncontrolled bacterial colonization. Escharotomy incisions provide a direct route for bacterial penetration into susceptible subcutaneous tissues if sterile precautions are not properly maintained. This can result in catastrophic infection and burn sepsis.

Inadvertent injury of deeper structures such as blood vessels, nerves, and tendons can occur. This is preventable by controlling the depth of the incisions and not extending into and through the subcutaneous tissues. This is especially true when incising over high-risk areas as previously described.

Making an escharotomy incision on the fingers is controversial. There is little to no muscle at risk of ischemia in the fingers. The fingers primarily consist of bone, ligaments, subcutaneous fat, and

tendons. These structures are quite resistant to ischemia. A finger escharotomy can expose the metacarpophalangeal and interphalangeal joints, make them prone to infection, and require a subsequent fusion or amputation.

A final complication is the inadequate release of the overlying restrictive eschar. Ongoing tissue ischemia can lead to permanent disability from disfiguring muscle contractures, irreparable neurologic damage, or limb loss. Rhabdomyolysis can lead to life-threatening electrolyte abnormalities and acute renal failure. Several authors advocate extending the escharotomy incisions 1 to 2 cm beyond the eschar border into viable tissue. A secondary reperfusion injury can follow the primary decompression as blood once again streams into previously hypoperfused tissue. The consequent swelling can cause the formation of a secondary underlying intrafascial compartment syndrome.

SUMMARY

Thermal burns are frequently encountered injuries prompting patients to seek medical care. Their associated morbidity, mortality, and costs of treatment can be astronomical. Emergency Physicians often provide an essential role in the acute resuscitation and stabilization of these patients prior to their ideal transfer to a specialized burn center. Severe burns can destroy the natural elastic properties of skin and result in the formation of constrictive overlying eschars. If not recognized and treated, these eschars can result in catastrophic limb loss, airway compromise, or respiratory failure. When performed properly, an escharotomy can be a limb and life-saving procedure that, at the least, grants the patient a significant chance to undergo more specialized and definitive burn care.

Neurologic and Neurosurgical Procedures

115 Lumbar Puncture

Eric F. Reichman, Kevin Polglaze, and Brian Euerle

INTRODUCTION

Meningitis and subarachnoid hemorrhage (SAH) are serious life-threatening conditions. They require prompt and accurate diagnosis in the Emergency Department due to their significant morbidity and mortality. There are many diagnostic modalities available to the Emergency Physician to assist in the diagnosis. However, the lumbar puncture (LP) is still considered the gold standard. The LP is a procedure that is often performed in the Emergency Department to obtain information about the cerebrospinal fluid (CSF) to aid in the diagnosis of a variety of medical conditions. Knowledge about the proper indications, contraindications, various techniques, equipment, and recognition and treatment of its complications is vital to any Emergency Physician who performs this procedure. **An LP should be performed after a thorough neurological exam. Significant morbidity and mortality can result if the procedure is performed on the wrong patient.**

ANATOMY AND PATHOPHYSIOLOGY

While the entire cavity of the brain and spinal cord has a volume of approximately 1650 mL, CSF occupies approximately 150 mL of this volume. The brain literally floats in the CSF because the specific gravity of the CSF and brain are approximately the same. Approximately 500 mL (0.35 mL/min) of CSF is produced each day. Most (over two-thirds) of the CSF is produced by the choroid plexus within the lateral ventricles. Small amounts of choroid plexus can also be found in the third and fourth ventricles. Small amounts of CSF are secreted by the ependymal surfaces of the ventricles. A minimal volume of CSF is produced by the brain through the small perivascular spaces that surround the blood vessels entering the brain substance.

The flow of CSF through the ventricular system is rather simple (**Figure 115-1**). CSF produced in the lateral ventricles flows through the foramina of Monro into the midline third ventricle. It then passes through the Aqueduct of Sylvius into the fourth ventricle. From the fourth ventricle, the CSF flows into the cisterna magna via two lateral openings (foramina of Luschka) and one midline opening (foramen of Magendie). The cisterna magna is located beneath the medulla and cerebellum and is continuous with the subarachnoid space that surrounds the brain and spinal cord. The CSF then flows through the subarachnoid space to

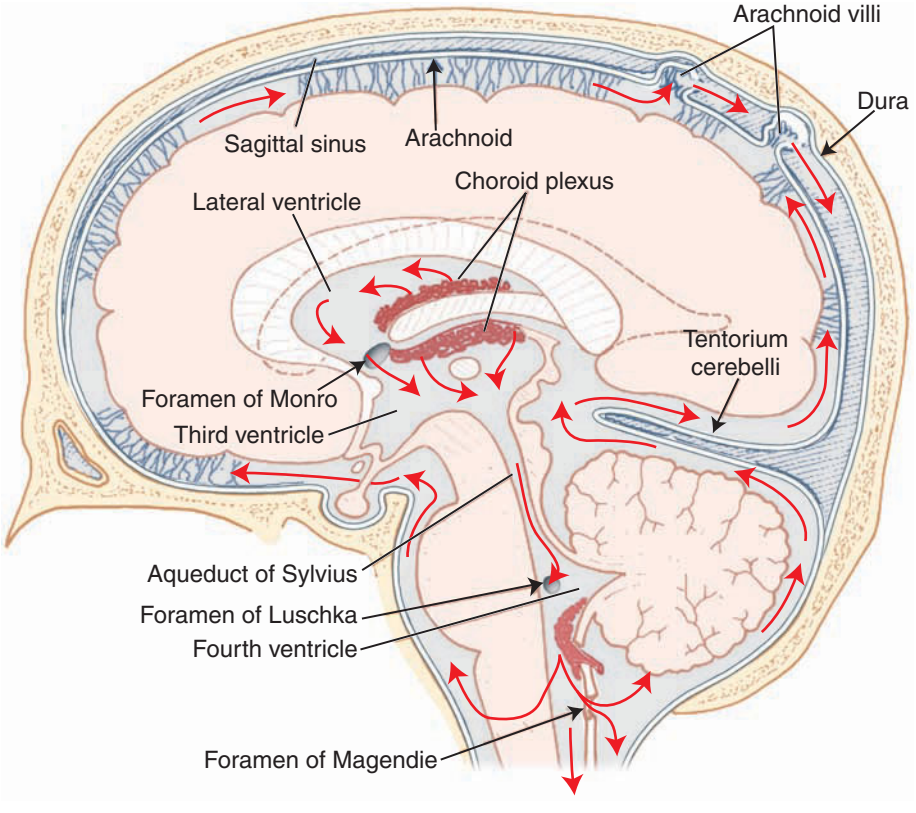

FIGURE 115-1. CSF circulation around the brain and upper spinal cord.

bathe the brain and spinal cord. The CSF is absorbed back into the venous system by way of arachnoid villi.

CSF pressure should average 130 mmH_2O when measured in the lateral decubitus position. It can range from 70 to 180 mmH_2O in a normal person. Since the CSF production rate is constant, the pressure is regulated by the rate of CSF absorption by the arachnoid villi that act as one-way valves into the venous blood of the dural sinuses. Certain disease states may impede reabsorption and lead to increased intracranial pressure (ICP).[1]

Familiarity with the anatomy of the spinal column is important when performing an LP. The anatomy will be briefly reviewed from superficial to deep as the spinal needle traverses the midline structures. The skin and subcutaneous tissue are the first layers encountered. These are followed by the supraspinous and intraspinous ligaments, located between the spinous processes of adjacent vertebrae. Deep to these ligaments is the thick ligamentum flavum that accounts for the characteristic "pop" that is described when performing an LP. The next layers encountered are the epidural fat, in the epidural space, followed by the dura mater, and finally the subarachnoid space.

When considering the lateral approach, there are subtle anatomic differences. The layers include skin and subcutaneous tissue followed by the paraspinal ligaments. The intraspinous ligament is less likely to be encountered with an extreme lateral approach, as this is a midline structure. The ligamentum flavum and deeper structures should be encountered in the same fashion regardless of the approach.

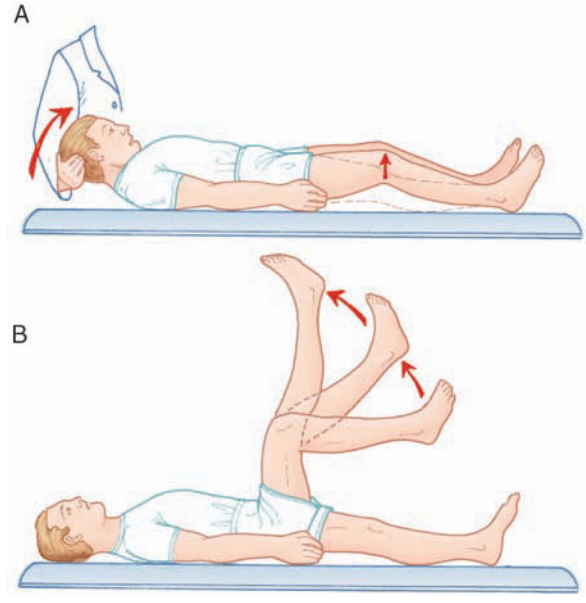

FIGURE 115-2. Physical examination of meningeal signs. **A.** Brudzinski's sign. Upon passive elevation of the head by the examiner, the patient complains of neck and low back pain, and may have involuntary flexion of the knees and hips suggesting meningeal irritation. **B.** Kernig's sign. Begin with the patient starting in a supine position with their hips and knees flexed 90°. Gradually extending the knee causes the patient to complain of neck or lower back pain.

INDICATIONS

There are many indications for performing an LP. The primary indications to perform an LP are the suspicion for a central nervous system infection, such as meningitis, or for a SAH. It may also be performed for the evaluation of new-onset seizures, to obtain CSF biomarkers, to relieve CSF pressure, and confirm the diagnosis of pseudotumor cerebri. Other indications include CSF evaluation for central nervous system diseases (e.g., Guillain–Barré, multiple sclerosis, and systemic lupus erythematosus), to confirm demyelinating or inflammatory diseases, to administer antibiotics or chemotherapeutic agents, to aid in radiologic imaging procedures (e.g., cysternography or myelography), and to diagnose meningeal carcinomatosis.

SUSPICION OF MENINGITIS IN ADULTS

An LP should be performed in adults when there is a clinical suspicion of a central nervous system (CNS) infection. While a fever is often present (most sources consider a fever >100.4°F or >38°C), it is not a dependable sign. Meningeal signs include nuchal rigidity, Kernig's sign, and Brudzinski's sign. Other signs of a possible CNS infection include a severe headache, photophobia, or a petechial rash. Unfortunately, these signs may or may not be present. This is especially true in the elderly, the young, or the immunocompromised patient. **An LP should be a routine procedure in febrile adults with an altered mental status and no source of fever.**

The most commonly looked-for signs of meningitis include the Kernig's sign and the Brudzinski's sign (**Figure 115-2**). Place the patient supine to test for these physical examination signs. Passively flex the patient's head until their chin touches the sternum. Flexion of the patient's hips and knees in response to the head flexion is known as the Brudzinski's sign (**Figure 115-2A**). The patient may also experience neck pain and resistance to flexion if meningitis is present. Passively flex one of the patient's legs to 90° at the hip and to 90° at the knee (**Figure 115-2B**). Passively extend the knee. Pain in the lower back or resistance to knee extension is known as the Kernig's sign.[2]

SUSPICION OF MENINGITIS IN CHILDREN

When evaluating the febrile infant, the decision of whether to perform an LP will be based on the clinical suspicion of meningitis, the age and appearance of the child, and whether an identifiable source of fever is present. The Emergency Physician will often be faced with a well-appearing febrile infant with no obvious source of fever. Until recently, many institutions managed all febrile infants less than 3 months old with a full sepsis workup (including LP) and admission to the hospital.

Guidelines based on an extensive literature review and a meta-analysis by an expert panel identify patients at low risk for serious bacterial infection (SBI), where LP and hospitalization may or may not be indicated.[3] Examples of serious bacterial infections include meningitis, sepsis, osteomyelitis, septic arthritis, urinary tract infections, pneumonia, and enteritis. Since clinical evaluation alone is inadequate to exclude serious bacterial infections in infants, it must be combined with laboratory studies that can define low-risk criteria. These criteria apply to nontoxic-appearing infants with reliable parents and prearranged follow-up. A more detailed discussion regarding the evaluation of the child with a fever is beyond the scope of this chapter.

It should be noted that any febrile child, regardless of age, who appears "toxic" should have an LP as an integral part of the sepsis workup. Certain bacterial infections have a high propensity for dissemination and systemic bacteremia. Examples include epiglottitis, buccal cellulitis, periorbital cellulitis, and septic arthritis. These children should also be considered for a LP in their evaluation and work-up.

IS AN LP INDICATED FOR THE FIRST FEBRILE SEIZURE?

The Emergency Physician will be faced with the decision of whether to perform an LP when evaluating infants and children with a first

febrile seizure. The American Academy of Pediatrics recommends that a LP be "strongly considered in infants less than 12 months of age" and "considered in children 12 to 18 months of age."[4] This is based on the lack of clinical signs and symptoms often associated with meningitis in this age group. For children over 18 months of age, an LP should only be performed if there is a clinical suggestion of meningitis. Clinical signs and symptoms that have been shown to correlate with the presence of meningitis include petechiae, nuchal rigidity, coma, persistent drowsiness, Kernig's or Brudzinski's sign, status epilepticus, and paralysis.[5]

Benign febrile seizures are those that occur in children 3 months to 5 years of age, are associated with a fever at the onset of an illness, have a single generalized seizure lasting less than 15 minutes in a child with normal psychomotor development, have no history of prior febrile seizures with this current illness, and have no evidence of an intracranial infection or acute neurological illness. These children generally appear well except for the fever and generally do not require a LP. This is based upon the level of Emergency Physician comfort in a nontoxic-appearing child.

Complex febrile seizures are those that do not meet the criteria of a benign febrile seizure. These children require a complete septic work-up including an LP. Criteria include seizures that begin focally, seizures lasting over 15 minutes, children with a prolonged postictal period, suspicious findings on physical examination, children less than 12 months of age, children already receiving antibiotics, children who have seen a Physician for an illness in the preceding 24 hours, or those who have had multiple seizures during a single period of illness. Seizures not associated with the onset of an illness have an increased risk of being due to meningitis or bacteremia. Children seizing upon presentation to the Emergency Department are considered to be seizing over 15 minutes or to have recurrent seizures. Suspicious findings on physical examination that suggest a complex seizure include rashes, petechiae, cyanosis, hypotension, abnormal respirations, increased or floppy tone, stiff neck, difficult to console, deviated eyes, doll's eyes, nystagmus, ataxia, photophobia, bulging or tense fontanelles, unable to fix and follow, or children that do not respond to voice or painful stimuli.

SUBARACHNOID HEMORRHAGE

A suspected SAH is the other common indication for an LP. The classic description of a SAH is the sudden onset of an excruciating headache ("thunderclap") during exertion that may or may not be associated with syncope, nausea, vomiting, diaphoresis, or meningeal signs. Physical examination findings may include nuchal rigidity, an altered level of consciousness, papilledema, retinal hemorrhage, third-nerve palsy, sixth-nerve palsy, bilateral lower leg weakness, nystagmus, ataxia, aphasia, or hemiparesis. Additional risk factors for a SAH include cigarette smoking, hypertension, alcohol abuse, a family history of SAH, polycystic kidney disease, connective tissue disorders, or sickle cell anemia.

It is estimated that 20% to 50% of patients with a SAH may have sentinel bleeds or small leaks that precede the major bleeding event. **It is important to diagnose a sentinel bleed because early management and intervention can improve the overall outcome for the patient. A sentinel bleed may precede a major SAH by hours, days, weeks, or months.**[6,7]

A CT scan of the head is often the first study used to investigate a patient complaining of the sudden-onset headache. The sensitivity of CT scan for SAH can range from 92% to 98% when performed within 24 hours of the onset of symptoms.[8–10] The sensitivity decreases markedly (about 76%) when performed 48 to 72 hours after onset of symptoms.[11–12] The head CT scan can be negative in the patient with a sentinel bleed.

An LP must be performed if the CT scan is negative and a SAH is still suspected.[10] The presence of xanthochromia or red blood cells in the CSF will confirm the presence of bleeding. While the CSF will usually confirm a SAH, it is possible that the LP may be negative despite a recent SAH if there has not been sufficient time for the red blood cells to migrate to the lumbar spine area. In this case, despite a negative head CT scan or a negative LP, a cerebral angiogram or follow-up LP in 12 to 18 hours should be performed.

CONTRAINDICATIONS

Knowledge of the contraindications to performing an LP is important. The Emergency Physician will often have to weigh the potential risks of performing the procedure with the benefits of obtaining the CSF. The decision must be made whether the procedure should be performed immediately or can be delayed until further studies are completed. Absolute contraindications to performing an LP include a cellulitis or abscess at the skin puncture site or signs and symptoms of increased ICP except for idiopathic intracranial hypertension (IIH, previously known as pseudotumor cerebri). The LP should be delayed in patients with an unstable airway, hypotension, shock, or status epilepticus until the patient has been stabilized. Hypoxemia, clinical deterioration, apnea, and cardiopulmonary arrest are reported complications of LP in unstable patients. Relative contraindications to performing an LP include the presence of a brain abscess, epidural or subdural fluid collection, brain tumors, and spinal cord tumors.

Note that antibiotics should not be delayed if meningitis is suspected and the LP must be delayed. If meningitis is highly suspected but the patient is unstable, treatment should be initiated with parenteral antibiotics and the LP delayed until the patient's condition is stabilized.

INCREASED ICP

An LP is relatively contraindicated in the presence of increased ICP.[13–15] This includes patients with space-occupying lesions (e.g., tumor or abscess), lateralizing signs such as hemiparesis on the physical examination, or when signs of uncal herniation are present (unilateral third-nerve palsy). Brain herniation or coning has also been reported in patients with meningitis and increased ICP. The sudden drop in ICP induced by an LP may precipitate a pressure cone or herniation.

Pseudotumor cerebri, now known as IIH, has been treated with a combination of medicines and repeated LPs to decrease ICP. Removal of CSF for IIH is a common diagnostic and therapeutic procedure in the Emergency Department. The use of LP in IIH is sometimes questioned. Many of these patients are obese, making an LP more difficult to perform, often requiring multiple attempts, and painful for the patient. The CSF removed reforms within a few hours, thus the LP provides only temporary relief of the patient's symptoms. Consult a Neurologist before performing an LP in the patient with IIH. An LP may be required to make the initial diagnosis of IIH, but may be unnecessary in the patient when the diagnosis has been made previously.

BRAIN ABSCESS

Patients with brain abscesses are at high risk for herniation.[16,17] Brain abscesses may present with a progressively worsening headache, low-grade fever, and the development of focal neurological signs (e.g., hemiparesis, papilledema, visual field deficits, and mild obtundation). Suspect a brain abscess in patients with a history of otic or paranasal sinus infection, orbital cellulitis, chronic pulmonary or

abdominal infection, endocarditis, congenital heart disease, recent dental procedures, dental abscesses, recent neurosurgery, craniofacial trauma, open skull fractures, or recent meningitis.

WHEN IS A CT SCAN INDICATED BEFORE AN LP?

It should be emphasized that increased ICP by itself is not necessarily a contraindication to an LP. ICP is usually mildly elevated in patients with IIH or meningitis.[18–20] A CT scan does not need to be routinely performed in straightforward cases of suspected meningitis in the patient with a normal neurological examination.[21–25] The inability to visualize the optic discs does not constitute a focal finding and, by itself, is not an indication for a head CT scan prior to an LP.[23] Despite this, there are occasional cases of herniation in patients with a normal CT scan.[13,14,19]

Most literature suggests that CT scans be performed prior to LP when patients are comatose or altered, have focal neurological signs, are HIV positive, have a progressively worsening headache, or have papilledema.[23–25] **The lack of papilledema is not always a reliable sign of normal ICP, as it often takes greater than 48 hours to develop papilledema.**[21] Papilledema may be absent in up to 15% of adults and up to 50% of children with early increased ICP.

The CT scan should be evaluated for mass lesions, shift of midline structures, or hydrocephalus due to obstructing masses, cisternal obstruction, and cerebral edema.[25] There are three findings that may predispose a patient to herniation if an LP is performed.[26] The first finding is midline shift. This suggests unequal pressures across the midline. The second finding is a loss of the suprachiasmatic and basilar cisterns. This suggests unequal pressures between the supratentorial and infratentorial compartments. The third finding is any evidence of a posterior fossa mass, obliteration of the superior cerebellar cistern, or obliteration of the quadrigeminal plate cistern caudal to the midbrain. These findings all suggest the presence of increased infratentorial pressure.

Do not delay the initiation of antibiotics if meningitis is suspected and a CT scan is indicated before performing an LP. Administer the antibiotics before the patient undergoes CT scanning. Several studies have shown that delays in the initiation of antibiotics are common in the Emergency Department. These delays are often Emergency Physician generated and result from the need for a CT scan prior to LP, waiting for LP results before administering antibiotics, and not giving antibiotics before a patient is transferred to the ward.[27–30]

COAGULATION DEFECTS

An LP is relatively contraindicated in patients with a coagulopathy. This includes hemophiliacs, those on anticoagulants, and patients with thrombocytopenia. An LP can result in a spinal epidural or subdural hematoma with subsequent spinal cord compression. Appropriate replacement of platelets and/or clotting factors should be undertaken prior to attempting an LP if the procedure can be delayed.[31] **The most experienced Emergency Physician should perform the procedure with a small gauge needle when an immediate LP is indicated in these patients.**

BACTEREMIA

Some sources list bacteremia as a contraindication to an LP, especially in children. While there is some suggestion that there may be an association between performing an LP in a bacteremic patient and the later development of meningitis, the risk of this is low. **An LP should not be withheld for fear of inducing meningitis.** The risk of delaying the diagnosis of meningitis clearly outweighs the small chance of causing meningitis with an LP.[32]

FIGURE 115-3. A commercially available LP kit.

EQUIPMENT

- Sterile gloves and gown
- Face mask and cap
- 1% lidocaine solution
- Povidone iodine or chlorhexidine solution
- LP needles, various gauges and lengths
- Topical anesthetic agent (e.g., EMLA), optional
- LP kit

Most of the equipment necessary for performing an LP is available in prepackaged, sterile, disposable, and single-patient use commercial kits (**Figure 115-3**). These kits usually contain a 20 gauge Quincke spinal needle, syringes, needles (25 gauge and 22 gauge) for local anesthesia, a manometer with a stopcock, sterile drapes, specimen tubes, 1% lidocaine, gauze, brushes for prepping the skin, and bandages. Some kits provide povidone iodine or chlorhexidine swab sticks whereas other kits have a small basin that needs to be filled. The Emergency Physician should become familiar with the kit used at their institution.

Additional supplies may be needed to perform the procedure without interruption. For example, some Emergency Physicians prefer a smaller gauge Quincke needle or a nontraumatic needle such as a Sprotte or Whitacre that are not often provided in the commercial kits (**Figure 115-4**). The use of a 25 gauge spinal needle is

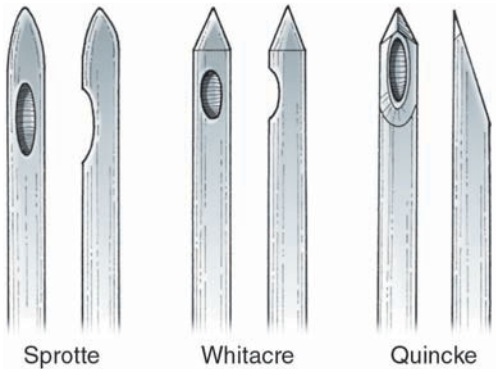

FIGURE 115-4. The three types of spinal needle tips. The standard Quincke needle has a sharp, beveled end. The Whitacre and Sprotte needles are designed to spread atraumatically, rather than cut dural fibers.

recommended as it causes a smaller puncture hole and less postprocedural headaches.[33–37] It has been suggested that atraumatic needles should be the standard when performing an LP.[38,39] In general, it is a good idea to have extra spinal needles, lidocaine, gauze, and skin antiseptic (e.g., povidone iodine or chlorhexidine solution) when performing an LP. There are numerous formulae to determine the LP depth and the length of the spinal needle required.[40,41] A reliable formula for estimating the required LP needle length is LP depth (cm) = 1 + [17 × (weight (kg)/height (cm))].[41]

There are subtle differences among the spinal needles commonly available (**Figure 115-4**). The standard Quincke needle has a sharp tip with a broad bevel at the end. The Whitaker and Sprotte needles have smaller tips with smaller diameter bevels. The bevel of the Sprotte needle is broader with a rounded tip so as to separate fibers of the dura as opposed to cutting through them. **Always remember to keep the bevel oriented parallel to the fibers of the dura when performing an LP regardless of needle style.**

PATIENT PREPARATION

Explain the risks, benefits, and complications of the procedure to the patient and/or their representative. Obtain a signed informed consent for the procedure. If the patient is a child or minor, ask the parents or caregivers whether or not they would like to be present for the LP.

There are a variety of different patient positions that can be used to perform the LP (**Figure 115-5**).[33,42,43] Knowledge and proficiency in more than one approach will be useful for the Emergency Physician, especially when encountering a difficult tap. The position of the patient will be chosen based upon the patient's body habitus, their ability to assume a position, their level of cooperativeness, and Emergency Physician preference.

The sitting position is more commonly used in adults than the lateral decubitus position. It is easier to identify the midline and palpate the spinous processes with the patient sitting (**Figure 115-5A**). The sitting position is particularly useful when patients are obese. While the LP can still be performed in the lateral decubitus position for obese patients, palpating the spinous processes and identifying the midline can be difficult. The measurement of hydrostatic pressure in the CSF is not accurate with the patient sitting. It gives a falsely elevated pressure reading.

The lateral decubitus position is often the most comfortable position for the patient (**Figure 115-5B**). Place the patient with their knees flexed, the upper back arched to spread the interlaminar spaces, and the neck slightly flexed. Ensure that the patient's shoulders, back, and hips are exactly perpendicular to the stretcher and

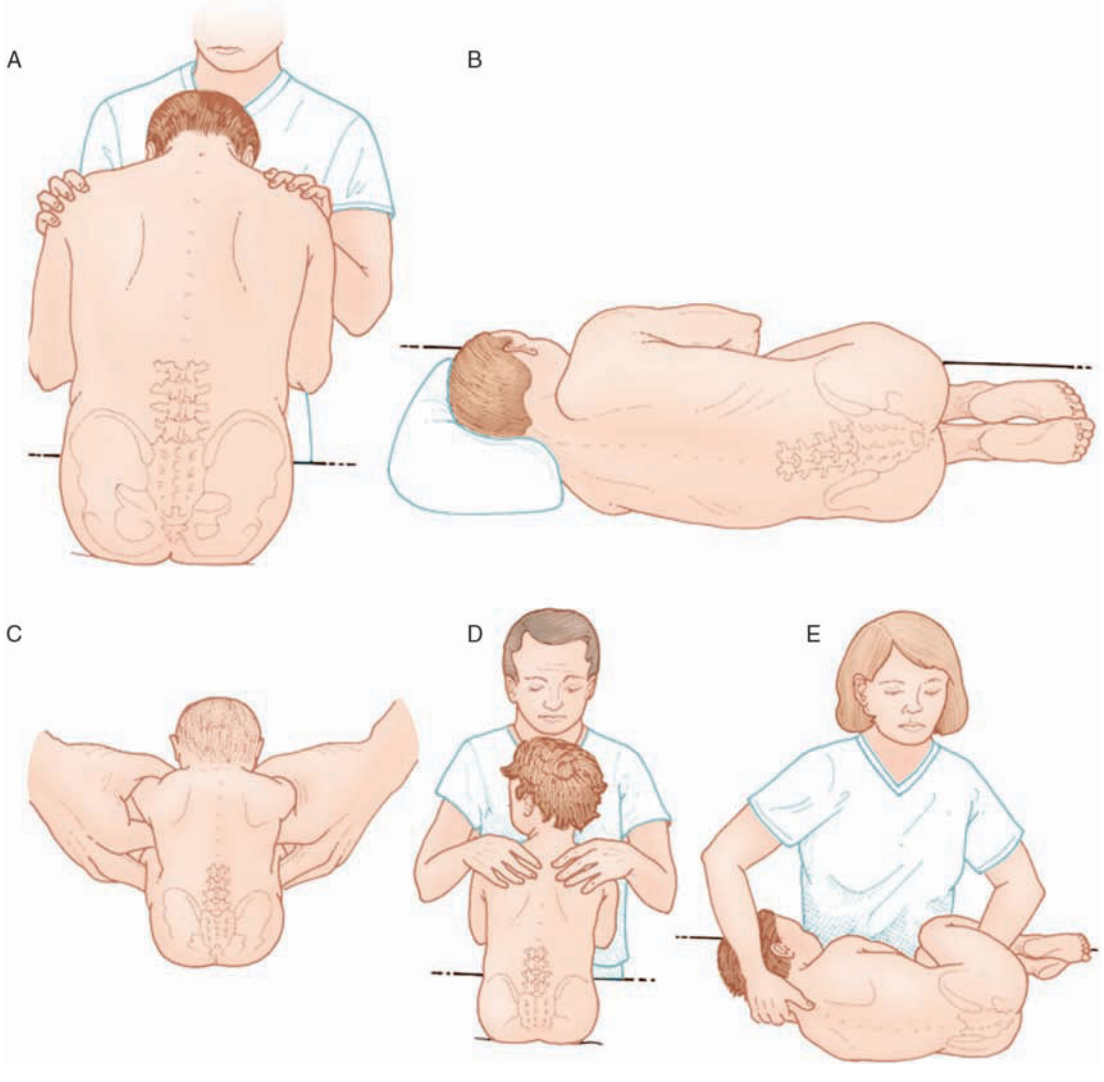

FIGURE 115-5. Patient positioning for an LP. **A.** An adult in the sitting position. **B.** An adult in the lateral decubitus position. **C.** An infant restrained in the sitting position. **D.** A child restrained in the sitting position. **E.** A child restrained in the lateral decubitus position.

floor. This will increase the chances of keeping the needle in the midline as it is introduced parallel to the surface of the stretcher. This is particularly important in infants and children where an assistant may be called upon to hold the patient in position. Severe neck flexion is not necessary and can lead to airway obstruction or lack of CSF flow.

Children can be placed in the sitting or lateral decubitus position. An assistant can easily maintain neonates and infants in the sitting position (**Figure 115-5C**). Toddlers and school-aged children can also often be maintained in the sitting position (**Figure 115-5D**). The lateral decubitus position can be used for any child (**Figure 115-5E**). **It is important to assess the child visually and with pulse oximetry during the procedure. These positions may cause improper neck flexion that can result in respiratory compromise, oxygen desaturation, hypoxemia, and anoxic encephalopathy.[44,45] The largest interspinous space is achieved with the patient sitting upright with their hips flexed, leaning forward, and with slight neck flexion based on ultrasonographic studies.[45–48]**

The subarachnoid space must be entered below the termination of the spinal cord that is situated at the lower level of L1 or the body of L2 (Figure 115-6). Identify by palpation the vertebral spinous processes in the midline and the posterior superior iliac spines. The patient can help to determine the midline.[179,180] Just ask them if the needle is in the midline. Another option is to draw a line between the spinous process of C7 and the gluteal cleft.[49] An imaginary line connecting the posterior superior iliac spines should intersect the midline at approximately the L4 spinous process or the L3-L4 interspace. One can select any of the spaces between L2-L3 and L5-S1 to perform an LP. Palpate the intended interspace before prepping the area. Some Emergency Physicians mark the site lightly with a pen or make a small indentation with the hub of a needle. Adjust the bed height so that you can sit in a comfortable position while performing the procedure.

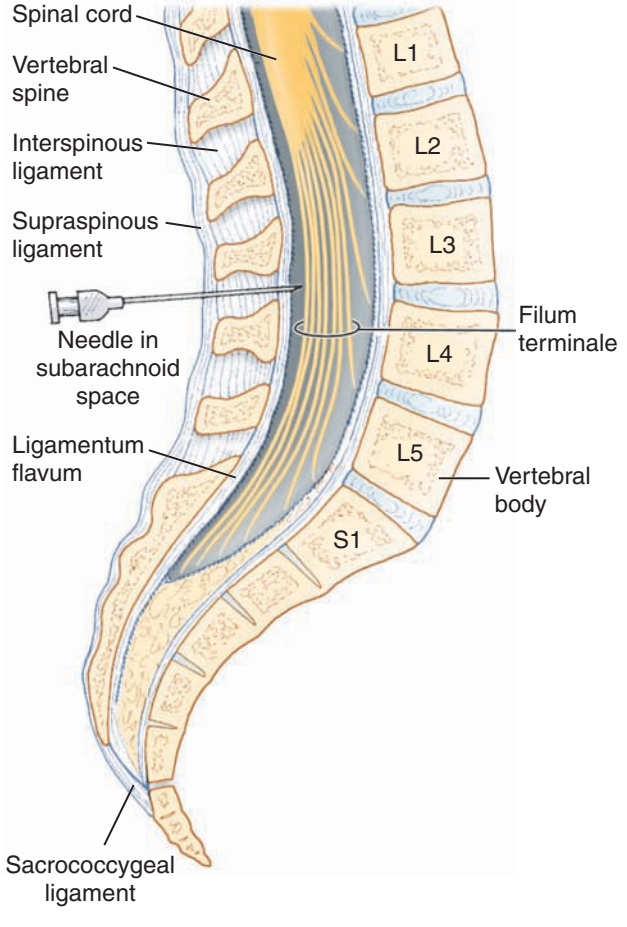

FIGURE 115-6. Midsagittal section of the lumbosacral region with a spinal needle in the L3-L4 interspace. The needle has penetrated the supraspinal ligament, the interspinous ligament, the ligamentum flavum, the dura mater, and the arachnoid mater.

Prepare the LP kit. Open the kit using sterile technique and place it on a bedside table. Place povidone iodine or chlorhexidine solution into the basin provided with the kit. Place any additional needles or supplies onto the sterile field. **This procedure requires strict aseptic technique. The Emergency Physician should don full sterile and personal protective equipment at this point.[50–52]** This should include sterile gloves, a sterile gown, a face mask, and a cap. Prepare the stopcock and manometer. The manometer is usually in two pieces that slide together. Insert the manometer into the vertical port of the stopcock. Turn the handle toward the outflow side of the stopcock. In general, the stopcock handle will occlude the port that it points to.

Prepare the patient's back. Clean the skin of any dirt and debris. Apply povidone iodine or chlorhexidine solution using a circular motion from the intended site of entry outward. Allow the solution to completely dry prior to inserting the spinal needle.[53] Chlorhexidine solution introduced into the spinal canal can result in arachnoiditis and neurotoxicity. Prepare an area of at least 10 cm in diameter. Most kits include a solid drape and a fenestrated drape. Place the solid drape between the patient's hips and the bed. Place the fenestrated drape with the adhesive side toward the patient's back and the opening centered at the desired level for the procedure.

Reidentify the anatomic landmarks. Place a finger over the desired interspace to use for the procedure. Place a skin wheal of local anesthetic solution subcutaneously over the desired interspace using a 25 gauge needle. Infiltrate and anesthetize the deeper tissue of the interspace along the projected needle track using the 22 gauge needle. **The infiltration of local anesthetic solution, unless contraindicated, should be used in all patients, including neonates and young children.** Local anesthetic makes it more likely the LP will be successful.[46,47,54]

Alternatively, a field block can easily be performed to produce anesthesia of the skin, interspinous ligaments and muscles, and the periosteum. The interspinous ligament and the periosteum are supplied by the recurrent spinal nerves branching off the nerve roots exiting the spinal canal at the same level. Inject local anesthetic solution into the interspinous ligaments, between the spinous processes superior and inferior to the intended puncture site, and on either side of the interspinous space (**Figure 115-7**).[33] A topical anesthetic (e.g., EMLA cream) may be applied over the interspace for 30 to 60 minutes prior to performing the LP if the patient is awaiting a CT scan of the head and antibiotics have been administered. Unfortunately, this only anesthetizes the skin and superficial subcutaneous structures. The patient will still require a local anesthetic injection.

It may occasionally be difficult for some patients to remain still and cooperative with the procedure. This can include anxious patients, those with an altered mental status, and small children. These patients may require an intravenous anxiolytic, nitrous oxide administration, or procedural sedation.

TECHNIQUES

LATERAL DECUBITUS POSITION AND MIDLINE APPROACH

Palpate the intended interspace. Introduce the needle in the middle of the interspace and parallel to the bed. **Orient the bevel of**

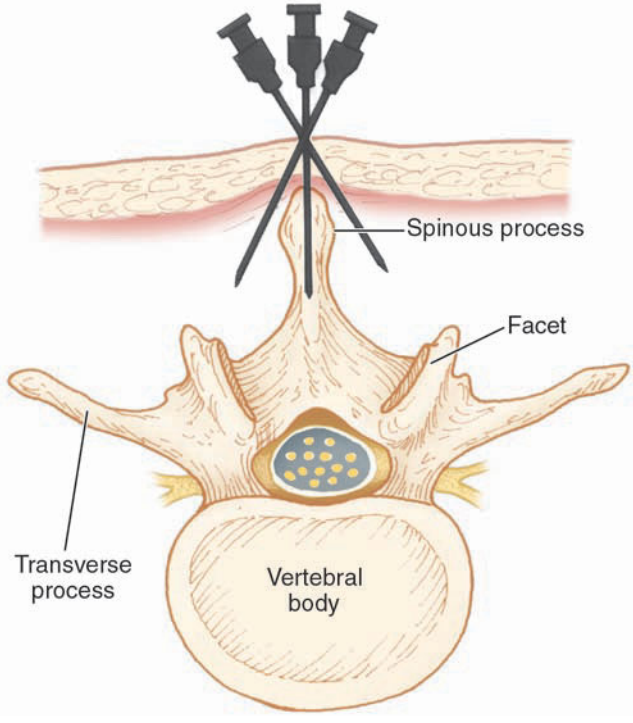

FIGURE 115-7. Field block for LP anesthesia.

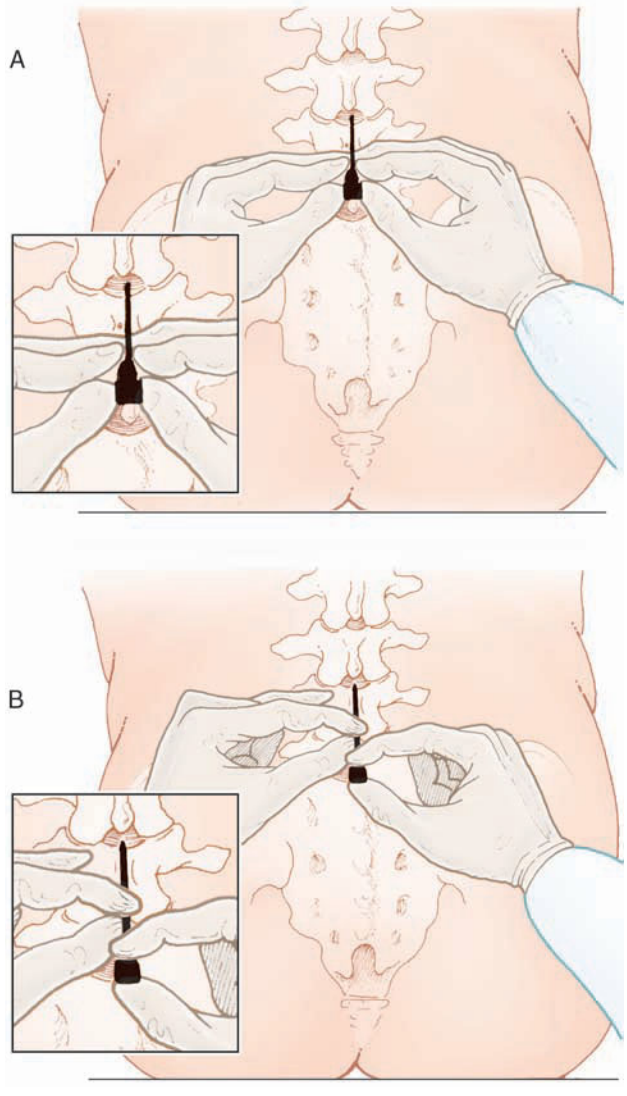

FIGURE 115-8. Two-handed techniques for spinal needle insertion. **A.** The index fingers guide the tip while the thumbs advance the needle. **B.** An alternative technique. One hand is placed at the needle tip and the other is at the base of the needle.

the spinal needle parallel to the longitudinal dural fibers to increase the chances that the fibers will be separated rather than cut by the tip of the needle.[55] This has been shown to decrease the incidence of postdural puncture headache.[56–58] The bevel should point up or down with the patient in the lateral decubitus position. Angle the needle 10° cephalad, or toward the umbilicus, and advance it slowly. The needle can be held between both index fingers and advanced with the thumbs (**Figure 115-8A**). Alternatively, it can be guided with a thumb and forefinger near the puncture site while the other hand holds the hub of the needle and advances it (**Figure 115-8B**).

Resistance will usually be felt as the needle penetrates the interspinous ligaments. Stop advancing the needle and remove the stylet frequently to check for the presence of CSF.[59] Many describe a characteristic "pop" that is felt when the needle enters the subarachnoid space. The commonly used Quincke needles often decrease or eliminate this sensation. It may also not be felt using atraumatic needles.[59] If bone is encountered, withdraw the needle to the subcutaneous tissue, confirm your landmarks, and readvance the needle in the midline. If bone is still encountered, redirect the needle slightly more cephalad and readvance it. Perform the procedure at a different level if still unsuccessful.

CSF should flow freely once the subarachnoid space is entered. The rate of CSF flow from the hub of the spinal needle may be slow. The flow rate can be increased by one of the following: ask the patient to Valsalva by gently coughing or bearing down, rotate the spinal needle 90°, or repeat the procedure with a larger bore spinal needle. Attach the stopcock and manometer directly to the needle. Alternatively, use the short extension tubing provided in most kits to connect the needle to the manometer. **Hold the hub of the needle firmly between the thumb and index finger and brace your hand against the patient's back when attaching or removing anything from the spinal needle.** This will prevent the needle from advancing or withdrawing. The stopcock handle should point posteriorly and CSF will begin to fill the manometer.

Ensure that the manometer hub remains at the level of the needle in order to get an accurate reading if using the extension tubing. Phasic changes with respirations should be noted as the manometer fills. Instruct the patient, or an assistant, to gently extend the patient's legs to decrease intraabdominal pressure and lower the reading. Normal opening pressure is 70 to 180 mmH_2O. Obtain the pressure reading once the CSF flow stops. Turn the stopcock handle toward the needle hub (or patient) to empty the contents of the manometer into the first tube for collection. To continue collection, remove the stopcock or simply remove the manometer and continue collection through the stopcock by pointing the handle toward the manometer port.

In general, 1.0 mL of CSF in each of the four tubes should be adequate to perform the CSF analysis. Collect 2 mL in each tube if cytology or antigen testing is necessary. **When the samples have been collected, carefully replace the stylet and remove the needle.**

There is disagreement regarding the use of the spinal needle stylet.[181] The literature notes an increased incidence of intraspinal epidermoid tumors after an LP if a stylet is not used. This led to the habit of leaving the stylet in place while inserting the spinal needle

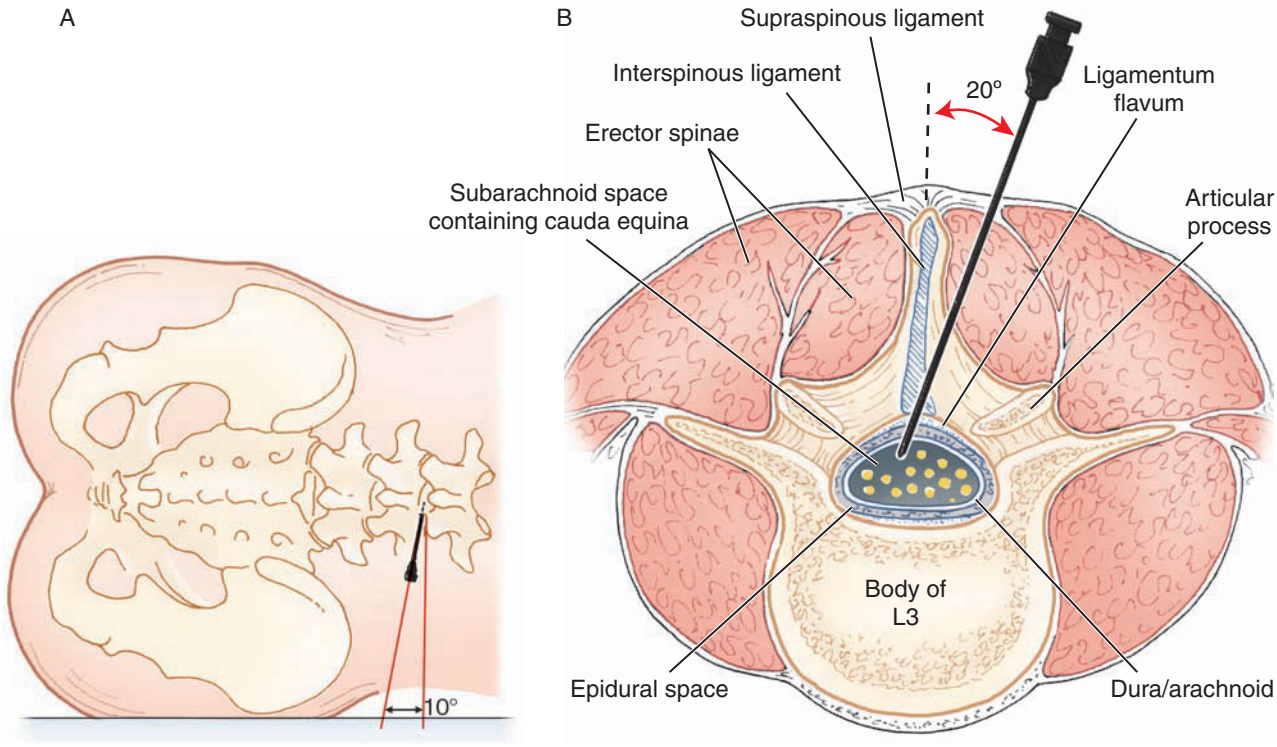

FIGURE 115-9. The lateral approach. **A.** If the patient is in the lateral decubitus position, insert the spinal needle approximately 2 cm below the midline and directed approximately 20° toward the midline, and 10° cephalad. **B.** Cross section of the spinal column showing the path of the spinal needle during the lateral approach. Notice that it avoids the calcified supraspinal and interspinal ligaments.

to prevent transferring epidermal cells into the spinal canal. Some now recommend removing the stylet after the tip of the spinal needle has been inserted past the epidermis.[46,60] This method has shown to result in a greater success rate when performing an LP.

Reinserting the stylet into the spinal needle is potentially problematic. Many will hold and stabilize the spinal needle with one hand and reinsert the stylet with the other hand. This risks a potential needlestick injury. The author inserts the stylet with one hand without using the other hand to stabilize the spinal needle. Reinserting the stylet prior to removal of the spinal needle has been shown to decrease the incidence of the post-LP symptoms of dizziness, headache, nausea, and tinnitus.[61] The method of using the stylet is left to Emergency Physician preference.

SITTING POSITION AND MIDLINE APPROACH

Place the patient sitting on the edge of the bed. Ask the patient to flex their lower back and lean forward onto some support, such as an assistant or bedside stand, in order to open the interlaminar spaces in the lumbar area. Orient the bevel of the needle laterally (to the left or right). The remainder of the procedure is the same as previously described.

LATERAL APPROACH

The lateral approach may be useful in avoiding the calcified supraspinous and interspinous ligaments often encountered in elderly patients. This approach may be performed with the patient in the lateral decubitus position or the sitting position. Though it is less commonly used than the midline approach, it is a good idea for the Emergency Physician to become familiar with this technique as an alternate approach if the midline approach has failed. This may prove easier in the patient who has had multiple previous midline LPs.

Position the patient and select an appropriate interspace. Cleanse, drape, and anesthetize the area as previously described. Insert the spinal needle 1.5 to 2.0 cm lateral to the midline. The needle can approach from either side (left or right) if the procedure is being performed in the sitting position. Approach from the inferior side if performing the LP in the lateral decubitus position (**Figure 115-9A**). Direct the needle 10° cephalad and approximately 20° to the midline. This angle will direct the needle through the erector spinae muscles and lateral to the supraspinous and interspinous ligaments. The needle will penetrate the ligamentum flavum, the dura, and then the subarachnoid space (**Figure 115-9B**). If bone is encountered, partially withdraw the needle and redirect it at the same angle toward the midline but slightly more cephalad. The remainder of the procedure is as described previously.

LP IN INFANTS AND CHILDREN

Performing an LP in an infant or child is similar to that of an adult. Place the patient in the lateral decubitus position or the sitting position. Place the neck in midflexion in the lateral decubitus position. **Severe flexion of the neck does not facilitate the procedure and can result in the lack of CSF flow or airway obstruction.**

Hypoxemia has been reported during LP in infants. The increased intraabdominal pressure caused by flexing the knees into the abdomen may lead to compression of the diaphragm, ventilation-perfusion mismatch, and hypoxemia.[62] For this reason, the sitting position or modified lateral decubitus position (hips only flexed to 90°) is preferred.[63] Preoxygenation with 100% oxygen via face mask for 2 to 5 minutes may prevent hypoxemia.[64] **Consider the use of continuous pulse oximetry in infants and young children undergoing an LP.**

Some authors advocate the use of a butterfly needle and using the tubing as a manometer to get a general idea of the opening pressure.

The use of nonstyletted needles, however, may occasionally result in the implantation of cells and a subsequent epidermoid tumor. In some low ICP syndromes, CSF may fail to flow during the procedure and gentle suction with a 1 mL syringe can be used.

Local anesthesia should be used in all patients, even in neonates. There is evidence that pain perception is present even in premature neonates.[65] The use of local anesthetic is often omitted in the neonate and young infant, possibly in fear of obscuring anatomical landmarks. Pinheiro et al. studied the success rate of LP in neonates given local anesthetic, the amount of struggling during lidocaine injection, and the amount of struggling during spinal needle insertion.[66] They found that local anesthesia did not alter the success rate of the procedure and led to a decreased amount of struggling during spinal needle insertion.

The use of a eutectic mixture of local anesthetics (EMLA) cream or similar topical anesthetic is common and effective for venipuncture in children. It also can be used successfully before LP in children and adults.[67,68] EMLA has been shown in some studies on adults to be more effective than lidocaine infiltration.[69,70] The major disadvantage of EMLA cream is that it requires application for a minimum of 30 minutes before the procedure is performed. In general, it is more effective if it stays on longer. It also does not anesthetize the deeper tissues and local infiltration is still required.

Procedural sedation is usually reserved for those children getting routine LPs for intrathecal chemotherapy. If absolutely necessary, procedural sedation can be used while performing a diagnostic LP. Procedural sedation should not be used unless the child has a normal mental status and is hemodynamically stable. The decision regarding procedural sedation must be considered on a case-by-case basis.

ULTRASOUND-GUIDED LP

For the past several decades, Anesthesiologists have been using ultrasound (US) to assist in various spinal procedures. More recently, Emergency Physicians have reported on the use of US to assist in performing an LP or to evaluate spinal anatomy.[71–75] Peterson and Abele described two patients in whom multiple attempts at landmark-guided LP were unsuccessful. US-guided LP was performed easily and was successful in each patient. The authors concluded that the technique has great potential as a time-saving tool.[73] Nomura and colleagues performed a randomized, double-blind study comparing LP using landmarks identified by palpation versus those identified by US.[75] The use of US significantly reduced the number of failures in all patients and improved the perceived ease of the procedure in obese patients. A group of Radiologists studied US guidance for LPs in children.[76] They found US superior to fluoroscopy as it allows three-dimensional guidance in real time and provides visualization of soft-tissue structures.

With the increasing availability of US machines in Emergency Departments, ultrasonography is more readily available to assist the Emergency Physician in performing many procedures including an LP.[71,72] US can visualize both superficial and deep tissue structures. Emergency Physicians who consider using US in assisting with an LP should be properly trained in the use and theory behind US before attempting to use it in the clinical setting.

There are three possible approaches to establishing the indications for the use of US to guide an LP. US guidance can be used for an LP when the traditional landmark-guided approach has failed. This approach may result in more patients having multiple attempts at an LP. US guidance can be used as the initial method in patients predicted to have a higher failure rate with landmark-guided LP. This includes patients with spinal landmarks that are difficult or impossible to palpate.[72,77,78] The landmarks are increasingly difficult to palpate in the body mass index (BMI) categories of overweight (BMI = 25 to 29.9) and obese (BMI ≥ 30) patients.[71] Under this approach, patients in whom an LP is not predicted to be difficult would have it attempted initially with the landmark palpation method, reserving US guidance for failures. The final approach uses US guidance initially for all patients, regardless of their BMI or the predicted ease of an LP.

US can be used to visualize structures and mark the point of needle insertion. It can also be used to visualize the deep soft tissue structures, allowing the Emergency Physician to estimate the depth that the needle needs to be inserted to enter the subarachnoid space.[79]

A high-frequency linear US probe is the transducer of choice. In patients with a higher BMI, the linear probe may not allow visualization to the depth required. In these cases, use a lower-frequency US probe, generally a curvilinear array. A pen or surgical skin marker is needed to mark the skin at the point of needle insertion. Surgical skin markers have the advantage of using scrub-resistant, non-smearing ink.

Both transverse and longitudinal midline images centered over the lumbar spine are utilized.[71,72] Ferre and Sweeney indicated a preference for the paramedian longitudinal view.[72] This view was felt to allow better visualization of deep soft tissue structures such as the ligamentum flavum and dura mater. In the transverse view, the spinous process causes a shadow that extends from near the top to the bottom on the monitor screen (**Figure 115-10**).[73,77] In the longitudinal view, the distal tips of the spinous processes are seen as a series of echogenic convexities (**Figure 115-11**).

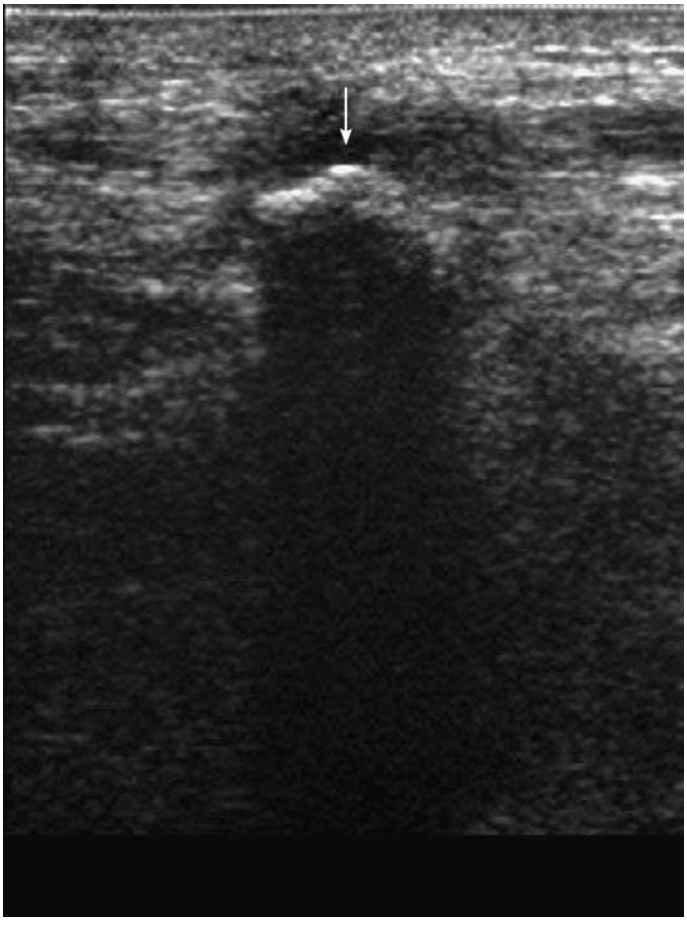

FIGURE 115-10. US image of the lumbar spine in the transverse view. The spinous process (*arrow*) causes a shadow that extends from the top to the bottom of the monitor screen.

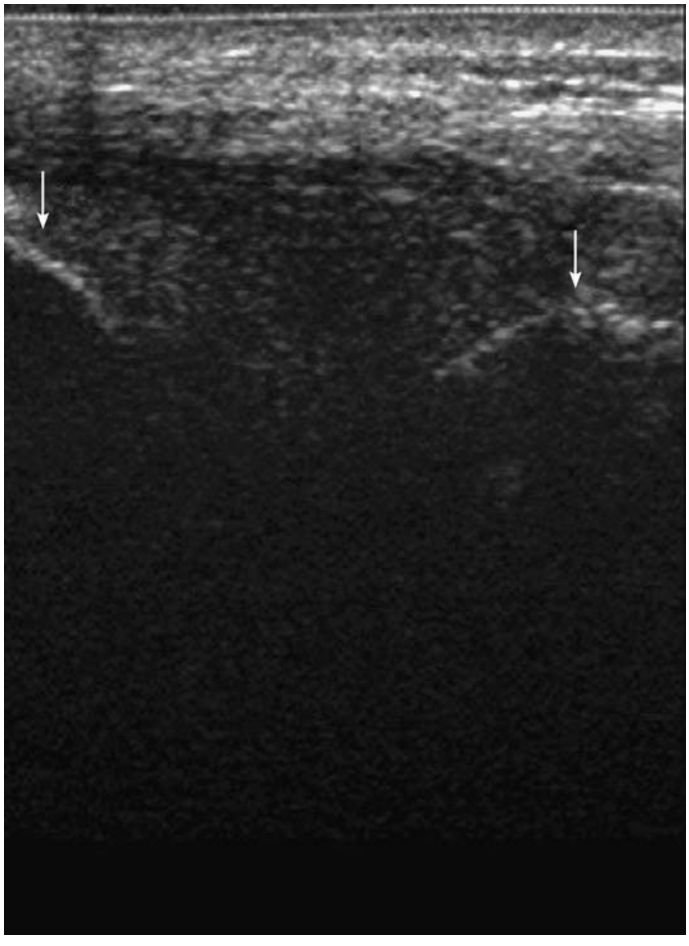

FIGURE 115-11. US image of the lumbar spine in the longitudinal view. The distal tips of the spinous processes are seen as a series of echogenic convexities (*arrows*).

Place the patient into the position they will be in during the LP, whether the lateral decubitus position or sitting upright. It is important that the patient be in the exact position, such as with spinal flexion and their knees drawn up, that will be used during the LP. **Any change in patient position between the time of the US and the LP could change the location of the landmarks and decrease the likelihood of success.**

Use US to locate the entry site of the spinal needle. Using the transverse view at the level of the iliac crests, move the US probe until the shadow caused by the spinous process is centered on the monitor screen (**Figure 115-10**). Use the skin marker to place a mark on each side of the US probe, exactly at its midpoint (**Figure 115-12**). When these two lines are connected, they will form a single line that marks the midline of the spine. Rotate the US probe 90° to a midline longitudinal view. Move the US probe until the tops of two adjacent spinous processes are seen, with the gap between them located in the center of the screen (**Figure 115-11**). Again, make two marks on the patient's skin, one on each side of the US probe at its midpoint (**Figure 115-13**). These two marks, when connected, will form a single transverse line that indicates the center of the gap between adjacent spinous processes.

Set aside the US probe. Connect the two pairs of skin marks to form two lines that intersect at a right angle (**Figure 115-14**). Their intersection marks the site of needle entry (**Figure 115-14**). Clean and prep the patient's skin and perform the LP as described previously.

FIGURE 115-12. The US probe is oriented transversely across the lumbar spine. A mark is placed on each side of the US probe's midpoint.

FIGURE 115-13. The US probe is oriented longitudinally along lumbar spine. A mark is placed on each side of the US probe's midpoint.

FIGURE 115-14. Two pairs of marks are obtained. Their intersection (purple dot) marks the spot for the spinal needle entry.

RISK FACTORS FOR TRAUMATIC OR UNSUCCESSFUL LP

There are numerous risk factors for obtaining a traumatic or unsuccessful LP.[60,80] It is important to recognize these, as traumatic or unsuccessful attempts may cause diagnostic ambiguity and lead to unnecessary antibiotic use, hospitalization, and patient discomfort. In the setting of a high likelihood of a difficult LP, steps may be taken to minimize patient discomfort and maximize the chance of a successful LP. Have the most experienced Emergency Physician perform the procedure. If there is a high likelihood of a traumatic LP and there is a high suspicion of a SAH, consider the use of US or fluoroscopic guidance. **Emergency Physicians should never delay administering antibiotics, or other potentially lifesaving treatment, because an LP may appear difficult.**

In adults, the inability to either visualize or palpate the spinous processes is predictive of a difficult LP. The inability to visualize the spinous processes is associated with an increased risk of a traumatic LP.[80] As described previously, the use of bedside US can assist in the identification of the spinous processes.

There are several risk factors in children associated with an unsuccessful or traumatic LP.[60] These include patient-related factors such as young age and inability to visualize the spinous processes, physician factors such as less experience performing LP, and procedural factors such as no local anesthetic use, patient movement, and advancement of the spinal needle with the stylet in place.[60]

Physicians have traditionally been taught to keep the stylet in place as the spinal needle is advanced into the subarachnoid space as this will avoid the introduction of epidermal cells into the subarachnoid space and the subsequent development of an epidermoid spinal canal tumor. However, the stylet-out technique has not been linked to this complication as long as the stylet is used as the needle penetrates the skin.[60] The greatest benefit of stylet removal appears to occur in young infants when the Emergency Physician is less likely to feel the spinal needle penetrate the dura. The stylet-out technique allows for continuous monitoring of penetration into the subarachnoid space by direct visualization for CSF return.

AFTERCARE

Clean the excess povidone iodine or chlorhexidine from the patient's back and apply a dressing or bandage to the puncture site. Immediately place the patient supine to decrease the potential for a postdural puncture headache (PDPH) and decrease the risk of local bleeding. Recumbent positioning will decrease the postural headache that sometimes follows LP, but it has not been shown to decrease the incidence of PDPH.

COMPLICATIONS

The use of proper technique is essential when performing an LP. It is also important that the Emergency Physician is aware of potential complications, how to recognize them, and how to manage the complications that can result from an LP. Refer to the article by Evans for a complete review of LP complications.[81] The PDPH is the most common complication and cerebral herniation is the most immediately life-threatening complication. Localized cellulitis, dural abscesses, discitis, and localized bleeding are also potential complications.

CEREBRAL HERNIATION

The most serious complication that may result from an LP is brain herniation or coning.[14] Theoretically, if a large pressure gradient exists between the cranial and lumbar compartments, herniation across the tentorial incisura or foramen magnum may occur after removal of CSF from the lumbar area. Patients with increased ICP secondary to intracranial mass lesions, cerebral edema, and acute hydrocephalus are at greater risk for cerebral herniation or coning. Herniation has also been known to occur in patients with meningitis. For many years, the role of LP in precipitating brain herniation has been the subject of debate. Several studies suggest that an LP is relatively safe in the patient with increased ICP.[82–84] However, each individual patient's risks and benefits must be considered before proceeding.

Herniation has resulted from an LP in patients with meningitis and SAH.[85–87] The actual role that an LP has in precipitating or facilitating the process of herniation is not known.[85] **Patients with decorticate or decerebrate posture, focal neurologic signs, or no response to pain should receive antibiotics but not a LP; this is true even in the face of a normal CT in suspected cases of meningitis.**[85,87] Deterioration after an LP has been reported in patients with a SAH. Fortunately, it is a rare outcome as a result of an LP. **A CT scan should be obtained before performing an LP if there is a suspicion for a SAH.**[88,89]

POSTDURAL PUNCTURE HEADACHE

The PDPH is the most common complication of an LP. It is thought to be the result of continued CSF leakage at the puncture site. The reason why this causes a headache is unclear.[90] It is thought that the lower CSF pressure induced by the leakage causes the brain to "sag." This leads to traction on pain-sensitive structures in the brain such as the dura, nerves, and bridging veins. Intracranial venous dilation and increased brain volume may lead to a neurohumoral response identified as pain.

The headache begins within 24 hours of the procedure in 65% of cases and within 48 hours in 90% of cases.[91] Delayed development of a PDPH 5 to 14 days after the procedure has been reported. The headache typically resolves within 7 days. It has been reported to last several months in rare individuals. The headache is usually located in the frontal or occipital area. It may vary in intensity. The PDPH is usually described as bilateral pressure that is throbbing or achy and improves with supine positioning. Associated symptoms may include nausea, vomiting, neck stiffness, auditory symptoms, and vestibular symptoms.[91]

The incidence of PDPH has been reported to be anywhere from 1% to 70%. The wide range is most likely due to the fact there are several identifiable risk factors that influence its development. Age and gender play a significant role.[91–93] The highest incidence occurs in 18 to 30 year olds. There seems to be a decreased incidence after the age of 60, the reason for which is unknown.

The type of needle and its diameter also influence the development of a PDPH.[34–38] This is based upon the amount of trauma and the size of the rent it makes in the dura. Smaller diameter needles and atraumatic needles lower the incidence of PDPH. However, a 22 or larger gauge needle must be used to determine the opening pressure and to collect samples in a timely fashion when performing a diagnostic LP.[94] The bevel orientation should be parallel to the longitudinal dural fibers when using a Quincke needle. This significantly reduces the incidence of PDPH.[58,95–97] The use of an atraumatic needle may also decrease the incidence of PDPH.[98,99] These needles are designed to separate rather than shear the dural fibers. Replacement of the stylet before removing the spinal needle has been shown to decrease the incidence of PDPH.[100] Repeated dural punctures have been associated with an increase in the incidence of PDPH.[101]

Other nonproven risk factors for a PDPH include psychogenic factors, the rapidity of CSF withdrawal, race, patient positioning, and hydration status. Bed rest for 24 hours was often widely

recommended. However, it has not been shown to decrease the incidence of PDPH.[102–104] Other studies have shown bed rest to increase the risk of PDPH.[105,106] Early ambulation does not increase the incidence of PDPH.[107] Dehydration was once felt to impair the patient's ability to produce CSF to compensate for the leaking CSF. Dieterich and Brandt found that the incidence of PDPH was independent of daily fluid intake.[108] They postulated that it is the closure of the dural defect and not the CSF loss that is the critical factor in the termination of the PDPH.

Supine positioning can provide some symptomatic relief for initial or mild PDPHs. A single 300 mg dose of oral caffeine may provide transient relief.[109] While offering no advantage over caffeine, an oral dose of theophylline can also be given. Administer 500 mg of intravenous caffeine, or 5 to 6 mg/kg of intravenous aminophylline, for more severe headaches. In the only study to date describing the use of intravenous caffeine, Sechzer and Abel reported an approximately 70% success rate in treating PDPH.[110] A more recent study suggests that intravenous caffeine administered prophylactically may minimize the incidence of PDPH.[111] There is some promise in the use of triptans.[112,113] The use of cosyntropin, an ACTH analog, has shown promise in the treatment of PDPH.[114,115] An occipital nerve block may resolve a PDPH.[116,117]

A more definitive but invasive treatment for the PDPH is the epidural blood patch.[118] This procedure is to be performed by an Anesthesiologist. It involves injecting 10 to 20 mL of autologous blood into the epidural space at the level of the previous LP. The blood acts to tamponade any further CSF leakage and allows healing of the dural rent. Epidural blood patching is successful in 85% of patients after one injection and about 98% of patients if a second blood patch is required.[119–121] Epidural blood patching should be performed no sooner than 24 hours after the LP. Complications of the blood patch include back pain, paresthesias, radiculopathies, and weakness; all of which are transient. A rare complication is the spinal subdural hematoma.[122] Other modalities for PDPH relief that have been used but not widely studied are epidural saline injections, dextrose injections, gelatin injections, and epidural morphine.

INFECTIONS

Local infections including cellulitis, abscesses (lumbar epidural or spinal cord), and discitis can result from an LP. Performing an LP through an area with a local infection, such as a cellulitis or an abscess, can introduce bacteria into the CSF and lead to meningitis. Contamination of the needle by airborne pathogens can also occur. **Always wear a sterile gown and gloves, a mask, and a cap while performing an LP.**[50] It is possible for the Physician's oral flora to contaminate the field and equipment, resulting in an iatrogenic meningitis.[50–52]

It was once thought that an LP could induce meningitis in a bacteremic patient. Further studies have shown this idea to be unfounded.[123–125] **Bacteremia is not a contraindication to performing an LP.** Proper cleaning and disinfecting of the skin, avoiding infected areas with the spinal needle, and using aseptic technique will minimize but not eliminate any risk of infection.

HEMORRHAGE

A traumatic LP is a common occurrence. Up to 72% of LPs have anywhere from 1 to over 50 red blood cells.[126] This is a common and usually uncomplicated occurrence in patients with a normal coagulation profile. Traumatic LPs can result in a spinal epidural or spinal subdural hematoma in patients with or without coagulation abnormalities.[127–131] Epidural hematomas most likely result from needle trauma to the internal vertebral plexus or radicular vessels (**Figure 115-15**).[126] The radicular vessels course down the length of each nerve root. It has been suggested that the bevel of the spinal

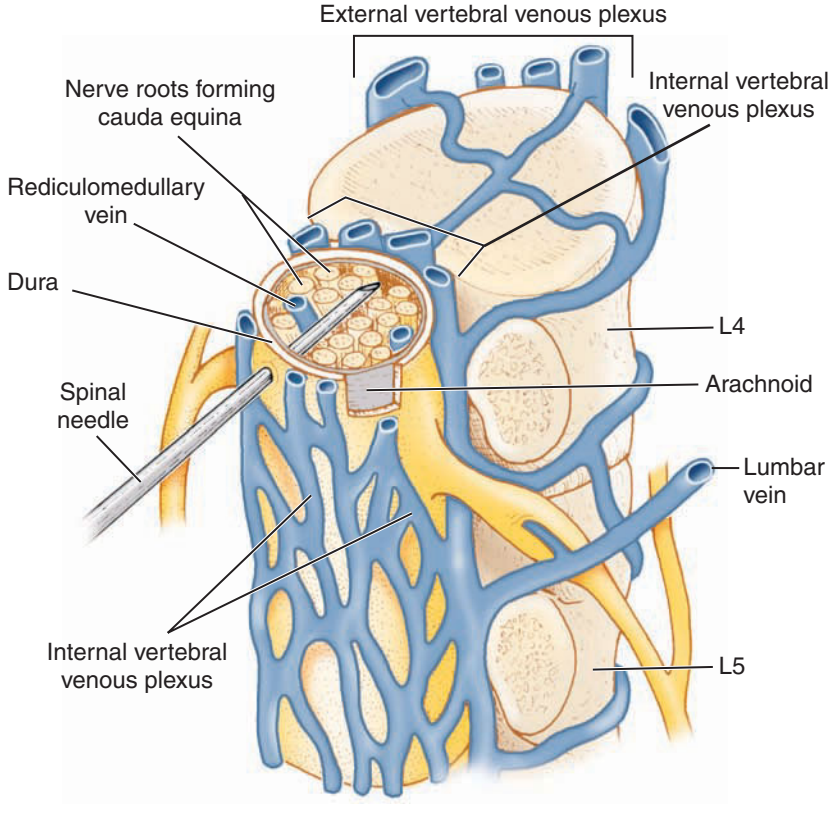

FIGURE 115-15. Illustration of the spinal cord and the potential sources of spinal needle-induced bleeding. Note, however, that the correct path of the spinal needle should usually avoid the internal vertebral venous plexus.

needle can induce trauma and bleeding to these vessels much like they produce paresthesias when touching the nerve roots. Spinal epidural hematomas, if large enough, can result in a cauda equina syndrome.[132]

Subdural or SAH is a rare but catastrophic complication in patients with or without a coagulopathy.[130] Edelson et al. recommend that the procedure be performed only if absolutely necessary in patients with a thrombocytopenia.[133] Platelets should be transfused prior to an LP in patients with platelet counts less than 20,000 or if platelet counts are dropping rapidly. The most skilled Emergency Physician should perform the LP using a 22 gauge (or smaller) needle.[133] Patients should be observed after the procedure for the development of neurological signs suggesting a hematoma. Such signs include paraplegia, lower extremity weakness, sensory deficits, or incontinence.

Another rare bleeding complication is an intracranial subdural hematoma.[134,135] This may result from the same mechanism causing a PDPH, namely the downward displacement of the brain from decreased CSF volume and persistent leakage after an LP. This may occasionally cause tearing of the bridging veins and lead to a unilateral or bilateral subdural hematoma. Suspect this diagnosis when a headache sounding like a PDPH lasts for more than a week, is no longer postural in nature, or returns after initially improving.[136]

MISCELLANEOUS COMPLICATIONS

Neuropathies involving cranial nerves III, IV, V, VI, VII, and VIII have been reported. They most likely result from traction on the nerves caused by low ICP after the LP. Typical complaints may include visual and auditory symptoms. Epidural fluid collections of CSF after an LP can be significant.[137] They usually resolve spontaneously with time but can compromise the thecal sac if large enough.

Mild low back pain is a common complaint that results from the local trauma of the needle tract. Transient dysesthesias are fairly common, resulting from spinal needle contact with the nerve roots. A spinal needle that passes beyond the subarachnoid space into the annulus fibrosis can cause disc herniation. This can also result in a discitis and vertebral collapse.[138]

Intraspinal epidermoid tumors are composed of well-differentiated stratified squamous epithelium surrounding a mass of caseous substance formed by the desquamation of epidermal tissue. They are often congenital but may result from the introduction of epidermal fragments into the spinal canal. This may occur if the stylet of the needle is not used. Spinal epidermoid tumors may present months to years after an LP.[139–142]

A dry tap is often the result of lateral displacement of the spinal needle. Maintain the spinal needle in the midline while it is being advanced. Not penetrating deep enough with the spinal needle can also result in a dry tap. This is especially true in obese patients that may require long, 7 to 10 in., spinal needles to gain access to the subarachnoid space. It has been suggested that the standard 3.5 in. spinal needle is adequate for 97% of patients.[143]

Prevent secondary injury by always inserting the stylet into the spinal needle before removing it.[61] Withdrawing the spinal needle without the stylet can result in the aspiration of a lumbar nerve root or arachnoid tissue into the epidural space. If this occurs, the patient may require a laminectomy to replace the nerve root or arachnoid tissue. The reinsertion of the stylet will also decrease the incidence of post-LP symptoms (e.g., dizziness, headache, nausea, and tinnitus).[61]

It is now common for adolescents and adults to have tattoos on their lower back. It is recommended to perform an LP in an area void of tattoo ink, at a higher or lower interspace, or nicking the skin with a needle or scalpel prior to inserting the spinal needle.[144,145] All these techniques avoid the spinal needle penetrating through the tattoo ink. The tattoo ink may contain substances that can be irritating or toxic if introduced into the spinal canal.

CSF INTERPRETATION

Proper interpretation of the CSF is an important skill for the Emergency Physician who performs the LP. **Tables 115-1** and **115-2** list the normal CSF values and the CSF values in a variety of different medical conditions.[146,147]

CSF PRESSURE

Normal CSF pressure ranges from 70 to 180 mmH_2O in adults and from 50 to 80 mmH_2O in infants and children. Note that many manometer kits use cmH_2O on the demarcations whereas results are commonly interpreted in mmH_2O. Elevated CSF pressure may be seen in bacterial meningitis, viral meningitis, brain abscesses, tuberculous meningitis, fungal meningitis, encephalitis, meningeal carcinomatosis, SAH, pseudotumor cerebri, and Guillain–Barré syndrome. It may be falsely elevated when the patient is tense or creating a lot of intraabdominal pressure by flexing their knees into the abdomen. The pressure will also be falsely elevated if the patient is in a sitting position. Although CSF pressure is not routinely recorded in infants and children (most likely because they are often crying, struggling, or difficult to hold), it should be recorded whenever possible. Low CSF pressure may be the result of a spinal root obstructing the flow of CSF into the needle or obstruction of flow from a spinal mass.

A novel device to measure pressure is the Compass LP (Mirador Biomed, Seattle, WA). This device is a single patient use and disposable unit that attaches to the spinal needle. It provides a digital readout of the CSF pressure. Further research is required before this device replaces the standard manometer.

CELL COUNTS AND DIFFERENTIAL

A variable amount of white blood cells (WBCs) may be normally present in the CSF depending upon the age of the patient.[148] Neonates may have up to 32 WBCs/mm^3 with 60% polymorphonuclear leukocytes (PMNs). Infants 4 to 8 weeks of age may

TABLE 115-1 Normal CSF Values

	Preterm infant	Term infant	Child	Adult
White blood cell count (WBC/mm^3)	9 (range 0–32) 57% PMNs	8 (range 0–22) 61% PMNs	0–7 0% PMNs	0–5 0% PMNs
Glucose (mg/dL)	24–63 (mean 50)	34–119 (mean 52)	40–80	50–80
CSF/blood glucose ratio				
Normal ratio	55%–105%	44%–128%	50%	60%–70%
Abnormal ratio	<0.5–0.6	<0.5–0.6	<0.4–0.5	<0.4–0.5
Protein (mg/dL)	65–150 (mean 115)	20–170 (mean 90)	5–40	15–45

TABLE 115-2 CSF Values in Various Neurological Conditions

Condition	Appearance	Pressure	Cell count (mm^3)	Glucose (mg/dL)	Protein (mg/dL)
Bacterial meningitis	Clear, cloudy, or purulent	Elevated	500–10,000 + cells with 90%–95% PMNs	0–40	>50
Partially treated bacterial meningitis	Possibly cloudy	Normal or elevated	1–500 cells, lymphs, or monos may predominate	Low or normal	>50 and <500
Brain abscess	Clear, cloudy, or purulent	Elevated	Possibly >100,000 cells if abscess ruptures. PMNs predominate	Normal	<200
Tuberculous meningitis	Clear, opalescent, or ground glass	Elevated	25–500 WBCs, PMNs early but usually lymphs predominate	10–40	50–500
Fungal meningitis	Clear or cloudy	Elevated	10–500 WBCs, lymphs predominate. PMNs early	<40	<600
Viral meningitis or encephalitis	Clear, may have faint opalescence	Normal or elevated	6–1000 cells, predominance of lymphs. PMNs early	Normal but may be low with herpes or mumps	<200
Acute syphilitic meningitis	Clear or turbid	Elevated	100–500 WBCs, usually lymphs	Normal or decreased	<200
Meningeal carcinomatosis	Clear or mucinous	Elevated	10–500 WBCs, lymphs predominate	<40	<500
Subarachnoid hemorrhage	Bloody, xanthochromia, clear	Elevated	1000–3.5 × 10^6 RBCs	Normal, but can be decreased in 10%–15% of cases	Increased
Multiple sclerosis	Clear	Normal	0–20 lymphocytes, >50 rare	Normal	45–75
Progressive multifocal leukoencephalopathy	Clear	Normal	<10 monos	Normal	Normal
Guillain–Barré syndrome	Clear or xanthochromic	Normal or elevated	Normal, but 10–200 WBCs, predominantly lymphs	Normal	May be as high as 1000
Pseudotumor cerebri	Clear	Elevated	Normal	Normal	Normal
Subacute sclerosing panencephalitis	Clear	Normal	Usually normal	Normal	Increased, check CSF measles titers and CSF gamma-globulin
Neuro-Behçet's syndrome	Clear	Normal or elevated	Up to 3000 WBCs, PMNs predominate	Normal	Increased

have up to 22 WBCs/mm^3. However, most sources consider anything greater than 8 to 10 WBCs/mm^3 to be abnormal.[149,150] Normal adult CSF should contain no more than 5 WBCs/mm^3 with a differential of mononuclear cells or lymphocytes. The presence of more than one PMN should be considered abnormal.

In cases of bacterial meningitis, cell counts are usually greater than 500 WBCs/mm^3 with a predominance of PMNs; though lymphocytosis can uncommonly occur.[151] The CSF will usually contain less than 1000 WBCs/mm^3 in patients with viral meningitis and have a differential of 100% lymphocytes. Early in the course of viral meningitis (the first 48 hours), 20% to 75% of patients will have a predominance of PMNs in the CSF, making it difficult to distinguish it from bacterial meningitis.[152,153] Within 8 to 12 hours, approximately 90% of patients will show a switch to a mononuclear pleocytosis on repeat LP.[154]

Normal cell counts and differentials do not always exclude meningitis. Approximately 95% of the population does not normally have any PMNs in their CSF. The presence of one PMN could represent an abnormality. One PMN may be seen in approximately 5% of normal children. Bonadio and colleagues reviewed 424 LPs of which 106 had PMNs but no pleocytosis.[155] All 106 patients had negative Gram's stains and cultures. The authors concluded that the older child without pleocytosis or abnormal CSF chemistries can be considered at very low risk for meningitis. If meningitis is suspected and the CSF is normal or has PMNs, close clinical observation and hospitalization for treatment and repeat LP should be considered until CSF culture results are negative.

A traumatic LP can often make the interpretation of the CSF difficult as peripheral WBCs can be introduced into the CSF. Clearing of the red hue of the CSF from the first to last tube suggests that the tap was traumatic. However, this is not always a reliable sign. Traditionally, the ratio of the RBCs to the WBCs in the blood is compared to the ratio in the CSF. This is based upon the assumption that when blood is introduced into the CSF, the ratio of RBCs to WBCs should stay the same. Some use a set RBC to WBC ratio of 750:1 or 500:1. This is not always accurate as a peripheral leukocytosis may often be present. By comparing the ratios, a predicted WBC count for the CSF can be obtained (predicted CSF WBC = CSF RBC × blood WBC ÷ blood RBC). The actual WBC count will then be the predicted WBC subtracted from the observed or measured WBC (actual CSF WBC = observed CSF WBC – predicted CSF WBC).

Most studies on patients with traumatic taps that did not have meningitis have shown that these formulae are often inaccurate.[156] Oftentimes, the observed CSF WBC count is less than the predicted CSF WBC count.[157] This raises concerns that in the presence of meningitis, the diagnosis could be missed. Mayefsky and Roghmann studied the use of the formula in patients that had meningitis and found that it led to many false-positive and false-negative results.[158] They investigated the value of an O:P ratio (observed CSF WBC/predicted CSF WBC) in predicting the presence of meningitis. They found that a ratio greater than 10 had a sensitivity of 88% and a specificity of 90% in predicting culture positive meningitis. They concluded, along with others, that pleocytosis in bacterial meningitis is rarely masked by a traumatic tap.[158,159] The O:P ratio of ≤0.01 can be used to identify patients with traumatic LPs that do not have meningitis.[160]

GLUCOSE

Normal values for CSF glucose are listed in **Table 115-1**. Compare the ratio of CSF glucose to a simultaneously determined blood glucose level to determine if low CSF glucose (hypoglycorrhachia) exists. The ratio is abnormal in preterm infants if it is lower than

0.5 to 0.6. A ratio of less than 0.4 to 0.5 in children and adults is abnormal. Approximately 58% of patients with bacterial meningitis will have a glucose of <40 mg/dL. The sensitivity for detecting bacterial meningitis increases to about 70% if a CSF-to-serum glucose ratio of <0.31 is used.[161] The normal steady state of 0.6 tends to decrease as serum glucose increases. Ratios of less than 0.3 should be considered abnormal in cases of severe hyperglycemia. The CSF-to-serum glucose ratio is less accurate when there are rapid changes in the serum glucose. **A low CSF-to-serum glucose ratio should always raise the concern of bacterial or fungal meningitis.** Other conditions such as tuberculous or syphilitic meningitis, meningeal carcinomatosis, or SAH can also be the etiology. Approximately 15% to 20% of patients with a SAH will have hypoglycorrhachia.[162,163] Normal CSF-to-serum glucose ratios are usually seen with aseptic meningitis, encephalitis, brain abscesses, and subdural empyemas.

PROTEIN

The normal CSF protein levels are listed in **Table 115-1**. Elevated CSF protein levels, often greater than 150 mg/dL, are seen in acute bacterial meningitis. Others causes of increased CSF protein include any type of meningitis, encephalitis, CNS tumors, SAH, demyelinating syndromes, and a traumatic LP.[164] Correct the CSF protein by subtracting 1 mg/dL of protein for each 1000 RBCs in traumatic LPs.

GRAM'S STAIN

The Gram's stain is a very reliable test when performed by properly trained individuals. In general, it is positive in identifying approximately 80% of bacterial CNS infections.[165] The probability of detecting bacteria on a Gram's stain depends upon the number of bacteria present in the CSF.[166] Approximately 25% of smears are positive with $\leq 10^3$ colony-forming units (CFU)/mL, 60% with 10^3 to 10^5 CFU/mL, and 97% with $>10^5$ CFU/mL. False negatives can result from partially treated meningitis where the sensitivity decreases to about 60%.[167] False positives can result from the use of contaminated LP trays or reagents, or the use of an unoccluded spinal needle.[168]

CSF CULTURES

CSF cultures should be obtained in all patients suspected of having meningitis. Positive cultures are assumed to be 100% specific but may only occur in 80% of patients thought to have bacterial meningitis.[169] Transport the CSF specimens to the laboratory promptly, as *H. influenza* and meningococcus will not survive storage or variations in temperature. In general, antibiotics given prior to LP can sterilize the CSF. However, depending upon the amount of bacteria in the CSF and the elapsed time from initiation of antibiotics, there is probably a window of about 2 to 3 hours where antibiotics do not affect the culture results. The percentage of positive CSF cultures decreases from 33% to 4% and Gram's stains from 41% to 7% when antibiotics are given prior to LP.[170] Blazer et al. studied the effect of full intravenous antibiotic treatment on CSF cultures by performing an initial LP and then a repeat LP in 44 to 66 hours.[171] All but one of the cultures became negative whereas the cytology and biochemistry were not affected. They concluded that partial treatment with antibiotics may alter the culture results but does not distort the other characteristics of a "bacterial" CSF.

SUBARACHNOID HEMORRHAGE

It is imperative to interpret the CSF results correctly when an LP is performed after a negative head CT to rule out the possibility of a SAH. Most sources agree that the presence of xanthochromia, which results from lysis of red blood cells, confirms the presence of intracranial bleeding.[172,173] Xanthochromia, when measured by spectrophotometry, has a sensitivity that approaches 100% when performed between 12 hours and 2 weeks from the initial SAH. Do not accept gross xanthochromia as a positive finding.[174–176] Gross xanthochromia can be a false positive. Always rely on a spectrophotometric determination of xanthochromia. Xanthochromia can develop in specimens within a few hours if the tap was traumatic.[177] One cannot rely on the finding of xanthochromia if the WBC count is >10,000 or if the analysis of CSF samples is delayed.[177]

So how should patients that present within 12 hours of their symptom onset be managed? Delaying a LP for 12 hours would require holding patients in the Emergency Department or admitting everyone who required an LP for evaluation. This presents a legitimate logistical problem. Edlow et al. suggest that patients that have a negative CT should undergo immediate LP.[178] If the CSF is persistently bloody without xanthochromia, and clinical suspicion is high, vascular imaging should be the next step.

SUMMARY

Most LPs will be performed in suspected cases of meningitis or SAH after a negative head CT. The risks of performing an LP need to be weighed against the potential benefits of diagnosing these two potentially life-threatening illnesses promptly. Knowledge of the proper indications, contraindications, technique, and interpretation of the CSF findings will undoubtedly help the Emergency Physician to minimize the complications that can be associated with the procedure. Although most complications are rare, awareness of their existence, presentation, and proper treatment is imperative.

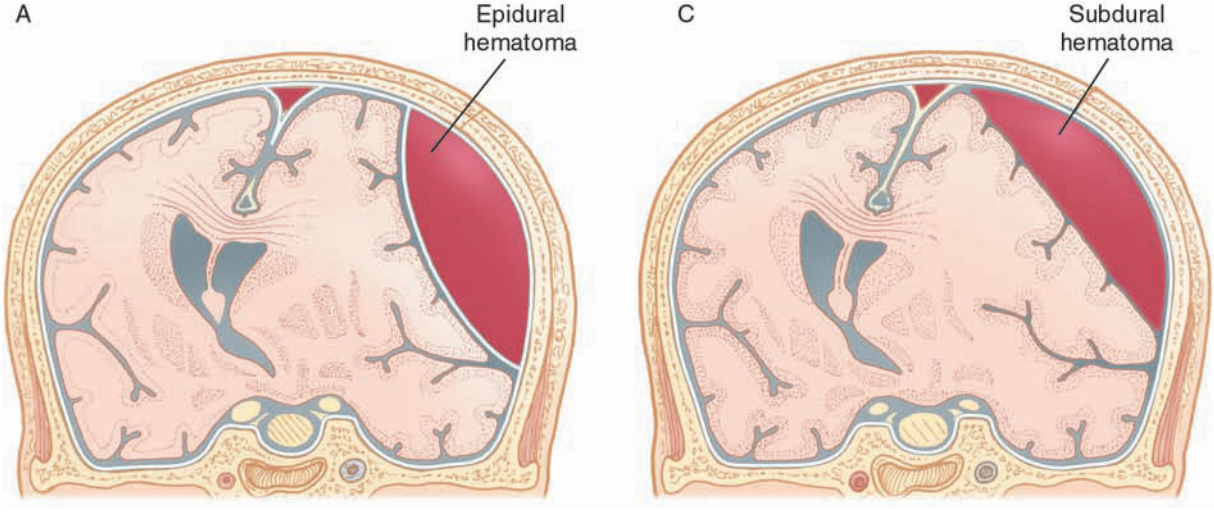
116 Burr Holes

Eric F. Reichman

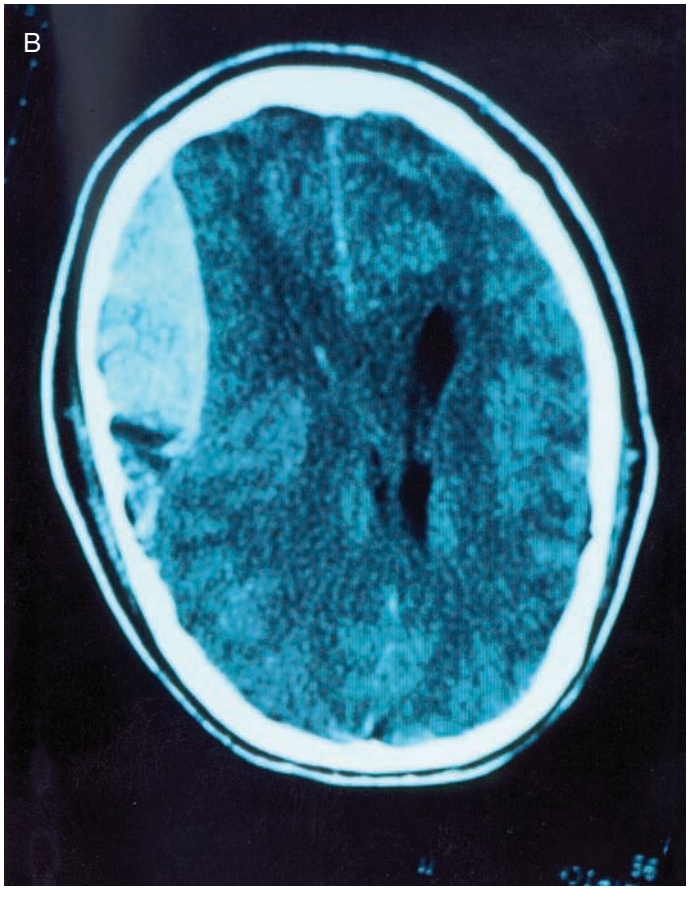
INTRODUCTION

Burr holes in the Emergency Department setting are uncommonly performed for diagnostic and therapeutic purposes. Diagnosis and treatment of increased intracranial pressure (ICP) in a timely fashion can be a lifesaving measure. Increased ICP can be the result of congenital anomalies, hemorrhage, infection, trauma, and tumors. There has been less need to make exploratory burr holes in head-injured patients since CT scanning has become widely available.

Burr holes can be lifesaving on rare occasions when the patient is worsening neurologically or has blown a pupil and CT scan is unavailable. Suspect a space-occupying lesion when there is clinical evidence of tentorial herniation or upper brain stem dysfunction. This includes pupillary dilation with a decreased or absent light reflex, progressive deterioration in the patient's level of consciousness, and/or hemiparesis including posturing (decerebrate/decorticate) or flaccidity. The placement of a temporal burr hole on the side of the mydriatic pupil to decompress an epidural or subdural hematoma can be lifesaving. Up to 70% of patients with evidence of brain stem dysfunction soon after head trauma have significant intracranial mass lesions, most of which are extra-axial blood collections.[1]



ANATOMY AND PATHOPHYSIOLOGY



A significant proportion of patients with fatal head injuries die before reaching the hospital. The cause of death is usually a result of an expanding intracranial hemorrhage, extensive basilar skull fractures with associated injury to the venous sinuses, intracranial

carotid artery lacerations, and/or major cortical blood vessel lacerations. Skull fractures are present in up to 90% of adults who develop a traumatic intracranial hematoma. Children are less likely to suffer a skull fracture after head trauma than adults.

The middle meningeal artery is a branch of the maxillary artery and enters the cranium via the foramen spinosum. It is usually located between the periosteal and meningeal layers of the dura mater. Shortly after entering the skull, it divides into anterior and posterior branches. The larger branches of the middle meningeal artery lie within the dura and are accompanied by veins. Their superficial location in the dura produces grooves on the interior of the cranium. This location makes them vulnerable to injury, especially from fractures of the temporal bone. The bony vault of the skull is fairly thick, approximately 5 mm in thickness, and shows considerable individual and regional variation. The temporal bone, in particular the squamous temporal bone, is much thinner than other areas of the skull. This makes it more vulnerable to a fracture with an associated injury to the underlying middle meningeal vessels.

Posttraumatic epidural hematomas usually develop in the temporal or temporoparietal location as a result of an injury to the middle meningeal vessels (**Figures 116-1A & B**). More than 50% of all epidural hematomas result from an injury to the middle meningeal

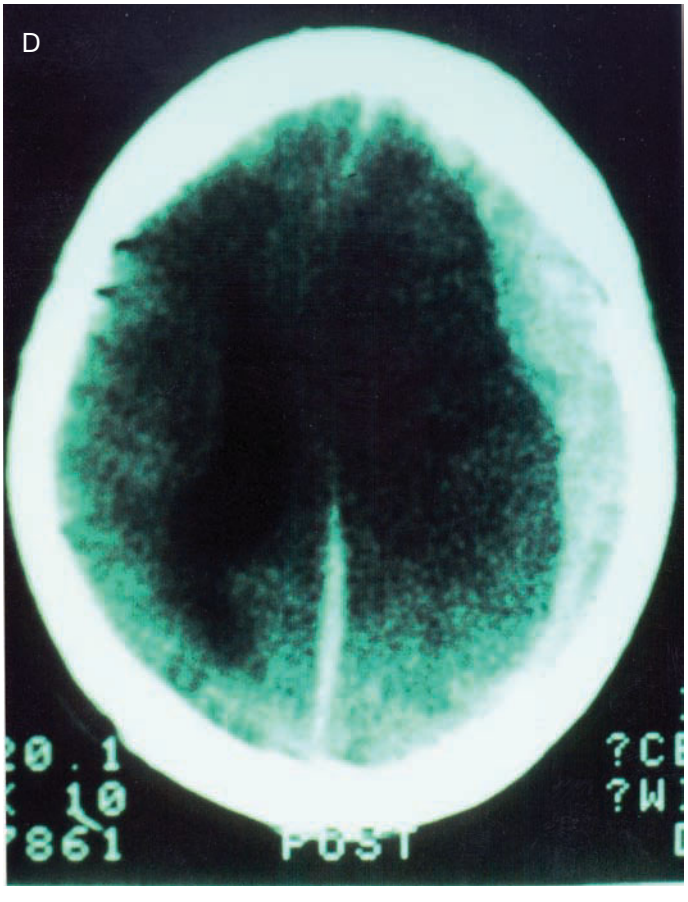


FIGURE 116-1. Hematomas requiring drainage through a burr hole. **A.** Illustration of an epidural hematoma. **B.** CT scan of an epidural hematoma. **C.** Illustration of a subdural hematoma. **D.** CT scan of a subdural hematoma.

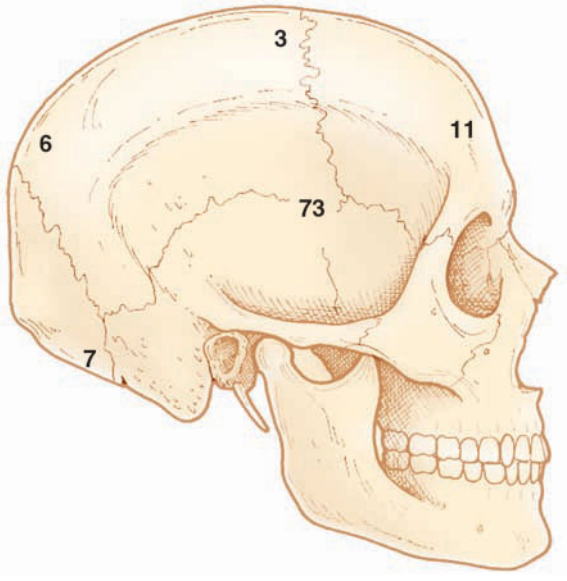

FIGURE 116-2. Percentages of epidural hematomas by anatomic location.

artery itself. Epidural hematomas occur laterally over the cerebral hemispheres with the epicenter at the pterion in approximately 70% of patients (**Figure 116-2**). The remaining epidural hematomas are distributed in the frontal area, occipitoparietal area, and the posterior fossa. Other sources of epidural hematomas include a torn venous sinus or an injury to the carotid artery before it enters the intracranial dural mater.

Subdural hematomas are collections of blood between the dura mater and the brain (**Figures 116-1C & D**). They usually are the result of blunt head trauma.[1] These result from the tearing of a bridging vein as the brain forcefully moves within the skull. The patient will present with an abnormal neurological examination minutes to hours after the acute injury.

Pupillary changes are not an early sign of an intracranial hematoma. However, when they do occur, they signify cerebral compression and transtentorial herniation. Other causes of acute pupillary changes need to be ruled out. Hematomas are usually found ipsilateral to the pupillary change in up to 85% of cases.

INDICATIONS

There are a few indications to emergently place a burr hole in the Emergency Department. These include monitoring of intracranial pressure, the emergent drainage of an intracranial hematoma, and the emergent cannulation of the ventricular system (Chapter 118). This procedure may be performed by trained Emergency Physicians if a Neurosurgeon has been consulted and is not immediately available.

CONTRAINDICATIONS

The only absolute contraindication is a patient who is coagulopathic. Otherwise, the available Emergency Physician with the most skill and experience in performing this technique should be the one to place the burr hole. Other contraindications include localized infections of the scalp and patients who are thrombocytopenic. This procedure should not be performed by those unfamiliar with the technique and its complications.

A coagulopathy or thrombocytopenia makes a burr hole dangerous to perform. The use of anticoagulants and antiplatelet agents by the patient increases their risk of hemorrhagic complications. Consider reversing these conditions by the administration of fresh frozen plasma and/or platelets prior to performing a burr hole. A mild elevation in the international normalized ratio (INR) up to 1.6 may be acceptable to place a burr hole.[3]

EQUIPMENT

- Sterile prep kit
- Sterile gloves and gown
- Face mask with an eye shield or goggles
- Cap
- Povidone iodine or chlorhexidine solution
- Sterile drapes
- 1% or 2% lidocaine containing epinephrine
- 22 gauge needles
- 5 mL syringe
- #10 scalpel blades
- #11 scalpel blades
- #3 scalpel handle
- Bipolar cautery, optional
- Self-retaining mastoid retractors
- Hudson brace drill
- Skull perforator bits
- Conical burr bits
- Small hook
- Bone wax
- Thrombin-soaked Gelfoam
- Periosteal elevator
- Suction catheter kit
- Head covers, masks, and sterile gowns
- Ventriculostomy catheter (optional)
- Bone rongeur
- Mayo scissors
- 4-0 nylon suture
- Potts scissors

The required equipment is all contained within a prepared sterile tray that can be obtained from the Operating Room or hospital central supply (**Figure 116-3**). A completely disposable, sterile, and single patient use instrument set is also available (Spectrum Surgical Instruments Corp., Stow, Ohio). The Hudson brace drill is a handheld device (**Figure 116-4**). It has a stabilizing handle in series with a handle that rotates in circles. The distal end has a snap lock chuck that slides to allow easy insertion and removal of the bits. The bits come in a variety of shapes and sizes (**Figure 116-5**). The perforator bits have a sharp point. The tip of the perforator bit is designed to penetrate the inner table of the skull and lock without allowing it to puncture the dura or the brain (**Figure 116-6**). **However, exercise extreme caution as the bit may occasionally not lock when it penetrates the inner table of the skull.** The burr bits are rounded. They are used to enlarge the hole in the skull made by the perforator bit (**Figure 116-6**).

PATIENT PREPARATION

The patient should be fully monitored with a noninvasive blood pressure cuff, pulse oximetry, cardiac monitor, and end-tidal carbon dioxide monitor (if available). Obtain a CT scan of the head

FIGURE 116-3. The contents of the hospital-prepared burr hole tray.

FIGURE 116-5. Examples of perforator bits (left) and burr bits (right).

to determine the presence of an acute subdural or epidural hematoma, the location and extent of the hematoma, to rule out the presence of a mass, and to determine if there is any herniation. Obtain a complete blood count (hemoglobin, hematocrit, and platelet count) and a coagulation profile (PT, PTT, and INR) to ensure that the patient is not thrombocytopenic or coagulopathic. These may require reversal with the administration of fresh frozen plasma and/or platelets.

Explain the risks, benefits, and complications of the procedure to the patient and/or their representative. Obtain an informed consent. However, in the patient who is deteriorating neurologically with tentorial herniation, consciousness is usually lost and time is of the essence.

Determine the site for the skin incision and the burr hole (**Figure 116-7**). A frontal or anterior burr hole is made just anterior to the coronal suture and 3 cm lateral to the midline, approximately along the midpupillary line (**Figure 116-7A**). The coronal suture is often palpable. If not, draw a perpendicular line midway between the lateral canthus of the orbit and the external auditory meatus. The frontal burr hole can be used to drain an intracranial hematoma or to perform a ventriculostomy. The temporal burr hole is made two

FIGURE 116-4. The Hudson brace drill.

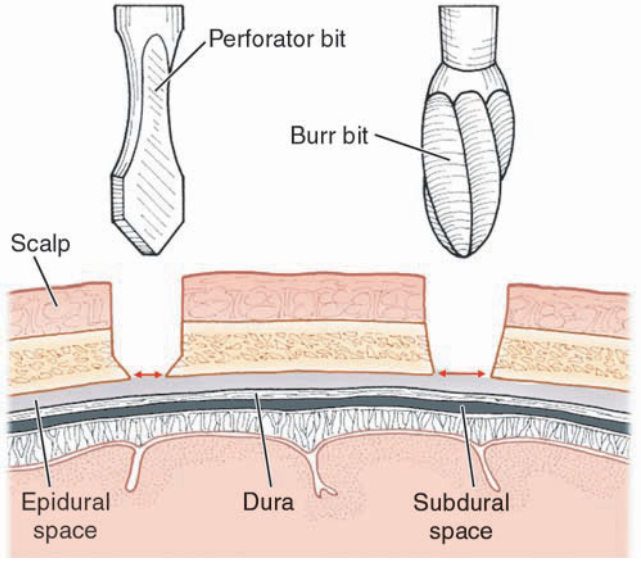

FIGURE 116-6. The perforator bit is used to make a hole through the skull and just penetrate the inner table of bone. The burr bit is used to enlarge the hole.

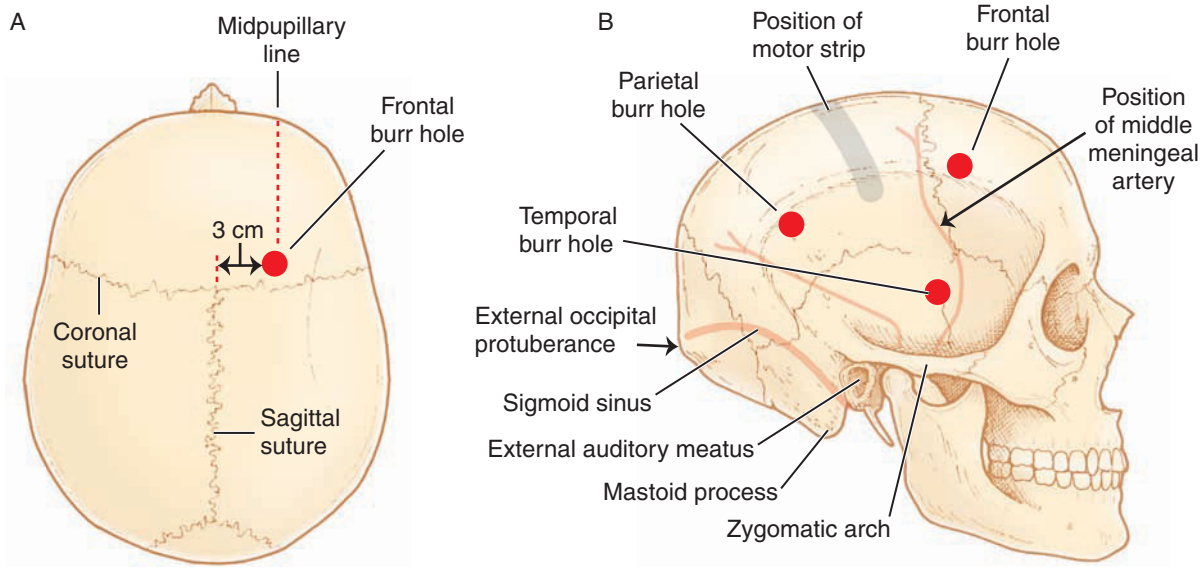

FIGURE 116-7. Typical locations for burr holes. **A.** Superior view of the skull. **B.** Lateral view of the skull.

finger breadths above the zygomatic arch and two finger breadths anterior to the external auditory meatus (**Figure 116-7B**). The parietal or posterior burr hole is made two finger breadths behind the external auditory meatus and three finger breadths above the mastoid process (**Figure 116-7B**).

Prepare the patient. Orotracheally intubate the patient to protect and secure the airway. Insert a nasogastric tube to decompress the stomach. Shave the scalp at least 5 cm in all directions from the proposed skin incision. **This procedure requires strict aseptic technique.** Clean the skin of any dirt or debris. Cleanse the skin first using 70% alcohol followed by povidone iodine or chlorhexidine solution. Allow the povidone iodine or chlorhexidine solution to dry. The Emergency Physician should don full sterile and personal protective equipment at this point. This should include sterile gloves, a sterile gown, a face mask with an eye shield or goggles, and a cap. Isolate the surgical field by using sterile drapes. Prophylactic intravenous antibiotic coverage is recommended if time permits. Administer a broad-spectrum antibiotic that covers gram-positive skin flora. Position the patient so that the proposed incision site is visible and easily accessible. Place the patient supine with a folded blanket or towel under the ipsilateral shoulder. Turn the head to the contralateral side if the cervical spine has been cleared. Instruct an assistant to hold and steady the patient's head.

TECHNIQUES

BURR HOLES

Identify the site to make the burr hole. Infiltrate 5 mL of lidocaine containing epinephrine along the proposed incision site and down to the level of the periosteum on the skull. This will result in analgesia and vasoconstriction that may aid in hemostasis. Make a 2 cm long skin incision centered about the site to make the burr hole. Carry the incision down to the bone of the skull. The incision must traverse all layers of the scalp including the skin, the subcutaneous tissue, the temporalis muscle (if present), and the periosteum. Remove the periosteum overlying the skull by scraping it away with a periosteal elevator. The periosteum will otherwise get caught in the perforator bit and make it difficult to turn. Insert a small self-retaining retractor into the wound (**Figure 116-8A**). Hemostasis can often be obtained with the use of the retractor. However, having cautery available can be helpful. Small bleeding vessels may be tied off with absorbable suture (**Figure 116-8A**).

Fit the Hudson brace drill with a perforator bit. Grasp the stabilizing handle of the Hudson brace with the nondominant hand. Grasp the rotating handle with the dominant hand. Place the tip of the perforator bit against the skull (**Figure 116-8B**). Turn the rotating handle clockwise with the dominant hand using a smooth and slow motion. **Always maintain the drill perpendicular to the skull. Maintain controlled pressure on the Hudson brace drill.** Watch as the perforator bit cuts through the skull. Frequently remove the perforator bit to examine the hole. Irrigate the area. Use suction to remove the bone fragments and the irrigation fluid. Gently probe the hole to determine if the inner table has been penetrated. Continue to drill until the inner table has been penetrated or the perforator bit locks (**Figure 116-8C**). **Do not apply too much downward pressure on the brace to prevent it from plunging into the brain. Exercise extreme caution as the bit does not always lock when the inner table is perforated.**

Remove the perforator bit from the Hudson brace drill. Place the burr bit on the Hudson brace drill. Place the burr bit into the hole in the skull. Hold the Hudson brace drill as described above. Rotate the handle clockwise to enlarge the hole in the skull (**Figure 116-8D**). Frequently remove the burr bit to examine the hole. Irrigate the area. Use suction to remove the bone fragments and the irrigation fluid. Continue to drill until the hole in the inner table is enlarged enough to accept the tip of the bone rongeur. **Do not apply too much downward pressure on the Hudson brace drill to prevent it from plunging into the brain.**

Control bleeding from the bone with bone wax and from the epidural space with Gelfoam. The clot of an epidural hematoma will be obvious as it separates the inner table of the skull from the dura. This clot will be gelatinous in consistency and drainage through a single burr hole can be difficult. Free the underlying dura from the bone edge with a Penfield elevator. **Gently insert the elevator between the inner table of the skull and the dura. Gently separate the dura from the skull.** Enlarge the burr hole in order to facilitate aspiration of the blood clot. Insert a bone

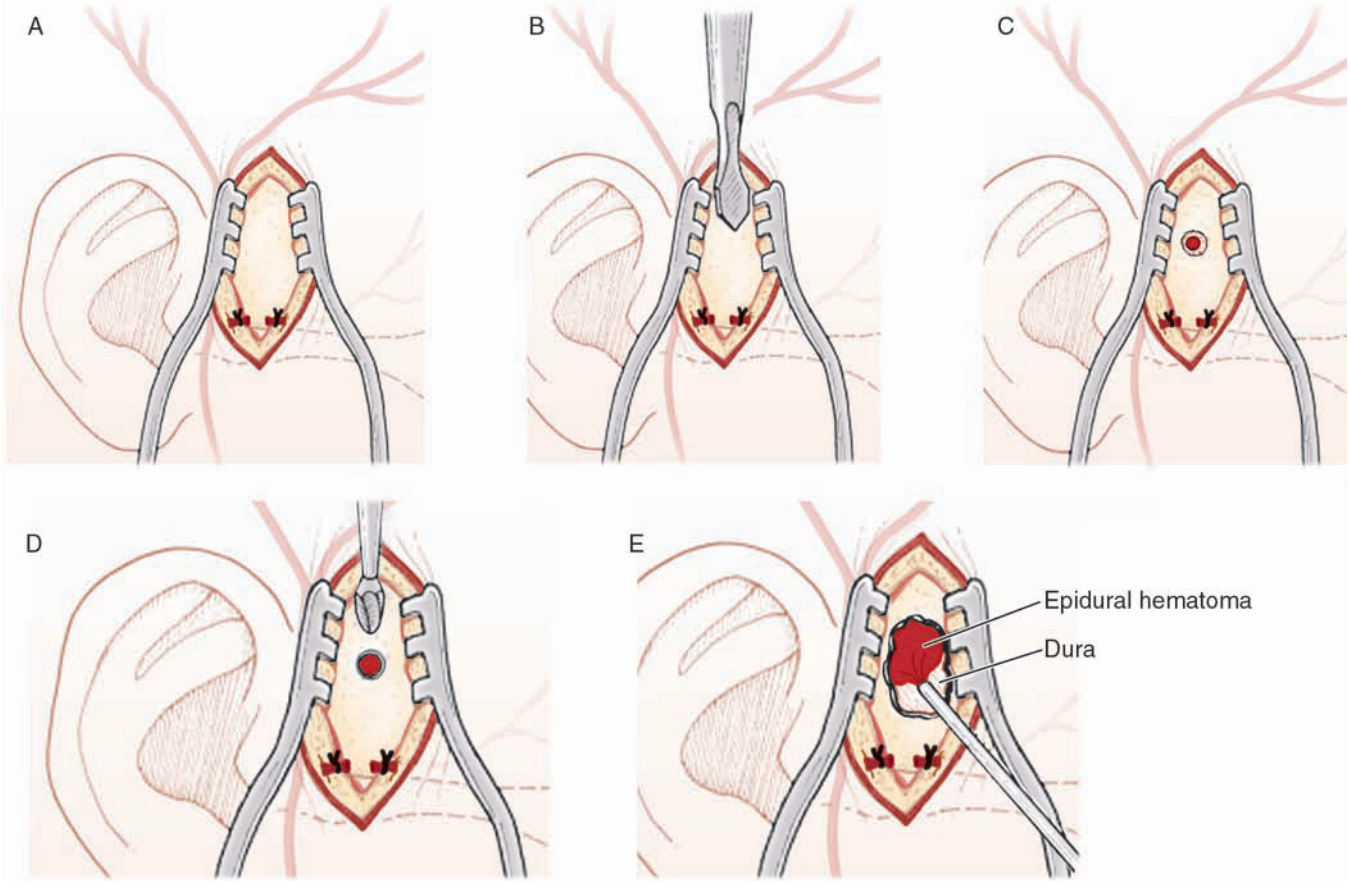

FIGURE 116-8. Drainage of an epidural hematoma. **A.** An incision is made through the skin, subcutaneous tissue, temporalis muscle, and galea aponeurotica. The incision is held open with a self-retaining retractor. **B.** A Hudson brace drill fitted with a perforator bit is used to penetrate the skull to the inner table. **C.** A hole has been made with the perforator bit. **D.** The hole is enlarged with a burr bit on the Hudson brace drill. **E.** The bone edges have been removed with a rongeur to expose the epidural hematoma. The hematoma is gently removed by suction.

rongeur into the hole. Take small bites of the skull to enlarge the hole (**Figure 116-8E**). Do not concern yourself with making the hole smooth or symmetric. The Neurosurgeon will later trim and repair the bony defect.

HEMATOMA DRAINAGE

An epidural hematoma is aspirated by gentle suction and irrigation with normal saline through an adequate bone opening (**Figure 116-8E**). **Pay close attention to the temperature of the irrigation solution. It should ideally be body temperature.** Use wall suction with a #9 or #11 French aspirator.

Epidural and subdural hemorrhages are usually clotted in the acute stages. In the event that an epidural hematoma is not identified after placement of the burr hole, inspect the underlying dura for a possible subdural hematoma. The presence of a subdural hematoma causes the dura to have a bluish hue or tinge (**Figure 116-9A**). Carefully place a traction suture in the middle of the exposed dura using 4-0 nylon (**Figure 116-9B**). Apply traction on the suture to elevate the dura. Incise the dura with a fine Mayo scissors or a #11 scalpel blade (**Figure 116-9B**). **Exercising extreme caution during the maneuver is mandatory to prevent lacerating the brain.** Open the dura in a cruciate fashion. Drain the subdural clot using suction and gentle irrigation. **At no time should any pressure be placed on the brain. Care should be taken not to irrigate with any force directly against the brain surface.**

VENTRICULOSTOMY

The burr hole can be made in order to place a ventriculostomy catheter. Make a nick in the dural with an 18 gauge needle or a #11 scalpel blade. Perform a ventriculostomy using an appropriate ventricular catheter. Anatomical landmarks suggestive for placement of the catheter within the ventricular system are to insert the catheter

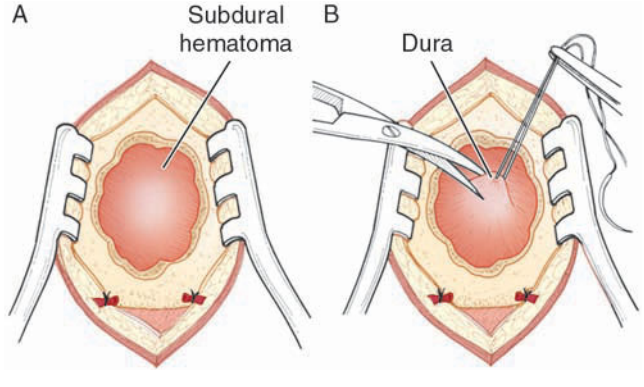

FIGURE 116-9. Drainage of a subdural hematoma. **A.** The dura is exposed and a hematoma is visible below it. **B.** Traction is placed on a suture that has been placed through the center of the exposed dura. The tented dura is carefully opened with a scissors or scalpel to expose the underlying hematoma.

perpendicular to the skull and directed toward the ipsilateral inner canthus.[2] Advance the catheter to a depth of approximately 5 to 6 cm. If unsuccessful after three attempts, place the parenchymal monitor or a subarachnoid bolt. Refer to Chapter 118 for the complete details of performing a ventriculostomy.

ASSESSMENT

Assessment and stabilization of the head injury victim prior to placement of the burr hole, during the procedure, and postprocedurally requires attention to securing the patient's airway, adequate and aggressive treatment of hemodynamic instability and shock, stabilization of the cervical and thoracolumbar spine, and concomitant treatment of any extracranial injuries. **Aggressive management of hypoxia and hypotension cannot be overemphasized. Hyperventilation in the first 24 hours after severe head injury should be avoided as it can reduce cerebral blood flow.** The assessment should include hemodynamic parameters, Glasgow Coma Score, and frequent neurological examinations. The neurological examination should include pupillary size and reaction, extraocular muscle function, and motor movements of the extremities. Intubation utilizing the rapid sequence technique often precedes burr hole placement in the patient with severe head injury. This precludes a detailed neurological examination as most patients will have received neuromuscular blockade.

Reduction in pupillary size can be appreciated postevacuation of the hematoma in patients who have had pupillary changes preceding the burr hole placement. Repeat the hemodynamic and neurological assessments often, every 5 minutes, and document these in the patient's record. Obtain a postprocedural CT scan of the head as early as possible to check the status of the hematoma. CT scanning also verifies catheter location and reduction in ventricular size in patients in which trephination has been completed for ventricular catheter placement.

AFTERCARE

Patients who have had burr hole placement because of neurological deterioration require further definitive management by a Neurosurgeon. A craniotomy is indicated for a more thorough evaluation, irrigation of the epidural or subdural space, and for hemostasis. Postprocedural CT scanning should not be performed if definitive management by a Neurosurgeon is available. It is an unnecessary waste of time and the patient should proceed directly to the Operating Room. Cranioplasty is often not completed initially after burr hole placement in order to minimize the infectious risk. Postprocedural treatment often requires airway protection with continued endotracheal intubation, adequate fluid resuscitation, management of hypoxia, management of hypotension, management of seizures, and management of any coagulopathy. Secondary injuries can evolve, even after adequate hematoma evacuation. They need to be anticipated, recognized, and treated aggressively.

A two-layer closure is recommended in the event a craniotomy is not to follow or will be delayed. The dura is usually not closed. Cover the dura with a small piece of thrombin-soaked Gelfoam. Close the galea with 3-0 absorbable suture. Close the scalp/skin with 3-0 nylon suture. Apply a dry dressing to the scalp wound. Alternatively, apply sterile saline-soaked gauze over the wound and cover this with a dry dressing.

COMPLICATIONS

Wound infections, abscesses, hemorrhage, and postoperative hematomas are major complications.[3] These can be avoided by using sterile precautions, antibiotic prophylaxis, and fine surgical technique. Other complications include plunging with the perforator bit or the burr bit resulting in a penetrating injury to the brain, cortical lacerations, cortical contusions, and seizures. Blunt or penetrating brain injuries can result in delayed stroke and hemorrhage. At times, this can be produced by a post-traumatic aneurysm or arteriovenous fistula. In the severely head-injured patient, a multitude of coagulopathic abnormalities can occur including hypercoagulable and fibrinolytic states as well as disseminated intravascular coagulation (DIC).

Significant bleeding complications can occur from this procedure.[3] Penetration of the sagittal sinus can result in significant hemorrhage and possible exsanguination. Prevent this by staying at least 2 cm from the midline and properly identifying the landmarks before drilling into the skull. Avoid lacerating the middle meningeal artery or its branches. Prevent injuries to these arteries by not drilling beyond the inner table and carefully separating the dura from the skull before using the bone rongeur. Another option is to obtain a lateral plain radiograph of the skull. Note the position of the grooves in relation to the external auditory meatus. Avoid these grooves, and thus the branches of the middle meningeal artery, when determining the exact site to place the burr hole.

SUMMARY

The prognosis for the severely head-injured patient with clinical evidence of tentorial herniation and brainstem compression is poor. Rapid evacuation of an intracranial hematoma may help to improve the outcome. Ideally, these patients are resuscitated and a CT scan of the head is completed in order to determine the presence of an intracranial hematoma. Patients may at times undergo rapid neurological deterioration prior to CT scanning or CT scanning may not be readily available. Diagnostic burr hole exploration and evacuation of an extra-axial hematoma can be a lifesaving measure. The author does not wish to suggest that exploratory surgery should replace CT scanning in the management of patients with a severe head injury. The CT scan is invaluable in assessing and identifying accurately the location of any mass lesion intracranially. Burr hole evacuation in a trauma setting should be considered only in the presence of rapid neurological deterioration with evidence of herniation and brainstem compression and the unavailability of a Neurosurgeon to perform the procedure.

117 Lateral Cervical Puncture

Eric F. Reichman

INTRODUCTION

The safest procedure to obtain cerebrospinal fluid (CSF) is lumbar puncture. However, there are situations where lumbar puncture is either contraindicated or technically not feasible. This includes infections in the lumbar area, obesity, previous spinal surgery, previous spinal fusion, a history of arachnoiditis, and the previous injection of chemotherapeutics. The usual and safe alternative method is a lateral cervical puncture under such circumstances. Cisternal puncture describes the suboccipital access to cisterna magna, a CSF containing space. It is a less frequently used procedure due to the high incidence of complications. As a result, cisternal puncture should be performed by a Neurosurgeon for patients whose CSF cannot be accessed by lumbar puncture or lateral cervical puncture.[1]

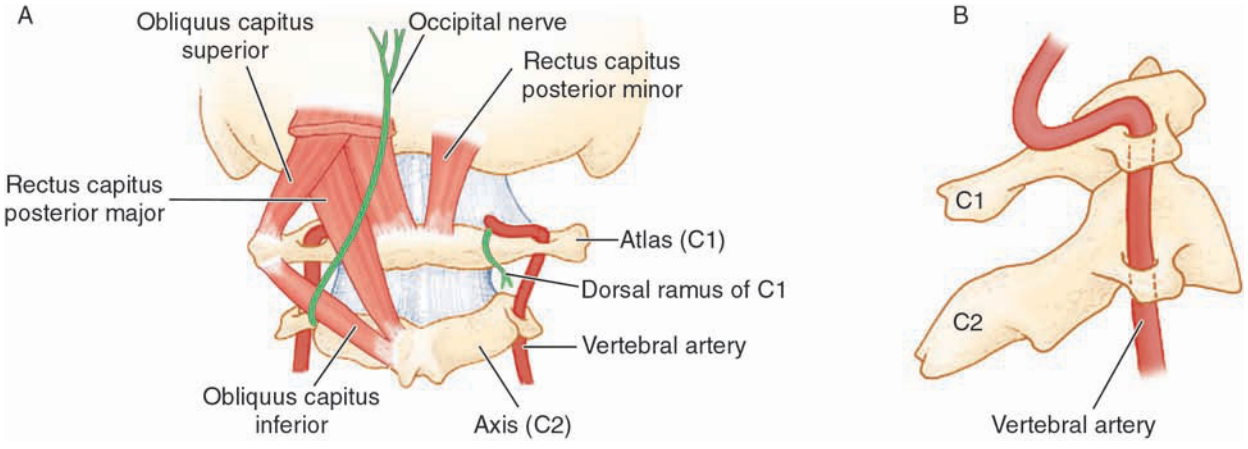

FIGURE 117-1. The course of the vertebral artery at the level of C1-C2. **A.** Posterior view. **B.** Lateral view.

Dr. Mullan introduced a method for performing a percutaneous cordotomy using a lateral cervical puncture in the early 1960s.[2] He introduced a strontium-90 needle through the C1-C2 interspace and into the subarachnoid space under fluoroscopic guidance. He then directed the needle anteriorly toward the anterior dura mater to interrupt the spinal thalamic fibers in an attempt to control intractable pain. The lateral cervical puncture is a direct derivative of this technique.

ANATOMY AND PATHOPHYSIOLOGY

Lateral cervical puncture involves the placement of a spinal needle into the C1-C2 interspace, posterior and inferior to the vertebral artery. The vertebral artery ascends through the foramina in the transverse processes of the cervical vertebrae beginning at the sixth cervical vertebra. It winds behind the lateral mass of the atlas (C1) to enter the skull through the foramen magnum (**Figure 117-1**). Inserting the needle 1 cm inferior to the tip of the mastoid process and 1 cm posterior from that point will avoid puncturing the vertebral artery (**Figure 117-2**).

The spinal canal is formed by sequential vertebral foramina and is triangular in shape. Its lateral width is greater than the anteroposterior width. The spinal canal is more spacious in the upper cervical spine allowing for safe placement of a needle into the C1-C2 interspace. The sagittal diameter of the spinal canal is approximately 23 mm at C1 and 20 mm at C2. The cross-sectional area of the cervical spinal canal is greatest at C2 and progressively decreases. It is smallest at the level of C7. The vertebral canal is narrower in women than in men. The spinal canal at the level of C1-C2 can be divided into three parts. The anterior third is occupied by the odontoid process. The middle third is occupied by the spinal cord itself. The posterior third is occupied by the subarachnoid space. The spinal cord is suspended and cushioned within the subarachnoid space by cerebral spinal fluid. The anterior boundary of the spinal canal is formed by the posterior aspect of the vertebral bodies and the intervertebral disks. The lateral wall of the spinal canal is formed by the pedicles and the intervertebral foramen. The posterior wall of the spinal canal is formed by the lamina, the ligamentum flavum, and the lateral masses or articular processes.

The morphology of the spinal cord demonstrates considerable individual variation in size and shape. The spinal cord changes in morphology throughout the entire spinal canal. It is cylindrical in shape and larger in transverse diameter than anteroposterior diameter. The spinal cord is largest from C3 to C6, obtaining approximately 13 to 14 mm in maximal transverse diameter. The average sagittal diameter of the cervical spinal cord is approximately 11 mm at C1 and 10 mm at C2.

The cervical nerve roots usually occupy the inferior one-third of the neural foramen. The first cervical spinal nerve root exits between the occiput and C1. The C2 through C7 spinal nerves exit above their corresponding numbered vertebra. Each nerve root innervates a specific dermatome and myotome, with considerable anatomical variation and overlap. The C1-C2 interspace is guarded laterally by the ligamentum flavum. The ligamentum flavum is composed of a yellow elastic tissue, the fibers of which are almost perpendicular in direction. It is attached to the lower part of the anterior surface of the lamina above and the posterior surface of the upper margin of the lamina below.

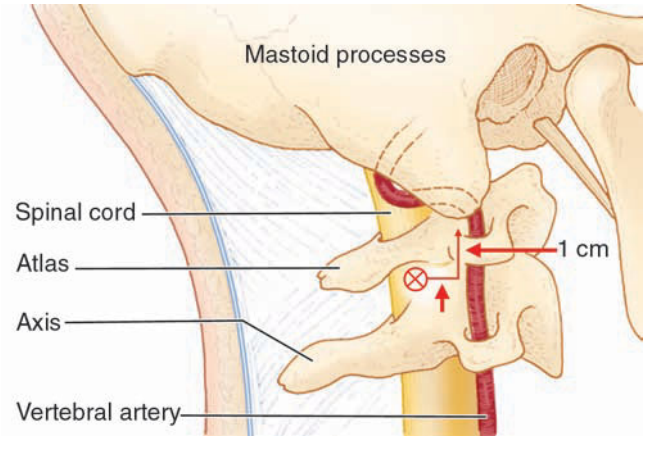

FIGURE 117-2. Anatomic landmarks for the lateral cervical puncture. The site for insertion of the needle is represented by an ⊗.

INDICATIONS

The lateral cervical puncture is an alternative method for obtaining CSF when lumbar puncture is not feasible or successful. Conditions that make lumbar puncture difficult are considered contraindications such as lumbar arachnoiditis, marked obesity, infections in the lumbar area, prior lumbar spine surgery, prior administration of lumbar intrathecal chemotherapeutics, and known congenital anomalies of the lumbar area (e.g., meningocele and myelomeningocele). The lateral cervical puncture is performed, like the lumbar

puncture, in order to obtain CSF for analysis. CSF analysis is indicated in patients suspected of having a central nervous system infection or a subarachnoid hemorrhage. Other indications for lateral cervical puncture include the installation of antineoplastic or antimicrobial agents. Lateral cervical puncture may also be necessary for the introduction of dye for radiographic studies.

CONTRAINDICATIONS

Contraindications for a lateral cervical puncture include brain abscesses, brain tumors, cervical spine anomalies and deformities, coagulopathy, increased intracranial pressure, inflammatory adhesions, local infections, posterior fossa abscesses, posterior fossa tumors, thrombocytopenia, and vertebral artery anomalies (course or location). Arnold-Chiari malformations and other congenital abnormalities in the region of the foramen magnum are also a relative contraindication. These include achondroplasia, basilar impression, Dandy-Walker malformation, Klippel–Feil syndrome, and syringomyelia.

EQUIPMENT

- Sterile gloves and gown
- Face mask with an eye shield or goggles
- Cap
- 20 gauge spinal needle with a stylet
- 23 gauge spinal needle with a stylet
- 3 mL syringe
- 20 gauge needles
- 22 gauge needles
- Three-way stopcock
- Manometer
- Extension tubing, optional
- Four specimen vials with caps
- Gauze pads
- Sterile towels
- Fenestrated sterile drape
- Lidocaine hydrochloride, 1%
- Sterile gloves
- Povidone iodine or chlorhexidine solution
- Fluoroscopy unit, optional

All of the basic equipment can be found in commercially available lumbar puncture kits. The kit needs to be supplemented with personal protective equipment and skin antiseptic.

PATIENT PREPARATION

The patient should be fully monitored with a noninvasive blood pressure cuff, pulse oximetry, cardiac monitor, and end-tidal carbon dioxide monitor (if available). Obtain a CT scan of the head if a complete neurological examination cannot be performed or if it is abnormal in any way, the patient has a history of malignancy, of the patient may have a potential mass occupying lesion (e.g., the HIV patient). Obtain a complete blood count (hemoglobin, hematocrit, and platelet count) and a coagulation profile (PT, PTT, and INR) to ensure that the patient is not thrombocytopenic or coagulopathic. Do not delay the administration of intravenous antibiotics pending these studies if meningitis is in the differential diagnosis and the reason for the lateral cervical puncture.

Explain the procedure, its risks, and benefits to the patient and/or their representative. Explain the postprocedural care. Obtain an informed consent for the procedure. Place the patient supine on the gurney, without a pillow, and the neck as straight as possible. Limit any head rotation from the true supine position. The landmark for needle insertion is 1 cm caudal and 1 cm posterior to the tip of the mastoid process (**Figure 117-2**).

This procedure requires strict aseptic technique. Clean the skin of any dirt and debris. Swab the area with alcohol pads. Shave the area so that the mastoid tip is contained within the sterile field. The Emergency Physician should don full sterile and personal protective equipment at this point. This should include sterile gloves, a sterile gown, a face mask with an eye shield or goggles, and a cap. Apply povidone iodine or chlorhexidine solution to the skin and allow it to dry. Apply sterile towels and drapes to delineate a sterile field. Inject local anesthetic solution subcutaneously at the above identified landmark. Consider the administration of intravenous diazepam or midazolam, if not contraindicated, to relax the patient. Some patients may require the administration of procedural sedation. The aid of an assistant to hold the patient's head straight and upright is recommended.

TECHNIQUE

Maintain the patient in the supine position with absolutely no head movement. An assistant should stabilize the patient's head. Introduce a 21 or 22 gauge spinal needle perfectly horizontal, parallel to the plane of the bed, and perpendicular to the neck (**Figure 117-3**). The needle will cross a number of tissue planes including the skin, subcutaneous tissue, trapezius muscle, suboccipital muscles, and the meninges. Advance the needle slowly and in 2 to 3 mm increments. Remove the stylette frequently to check for CSF. The subarachnoid space is approximately 6 cm from the skin surface in most adults. Puncture of the dura is often felt as a "pop" or loss of resistance. Frequent checks for CSF prevent excessive penetration of the needle

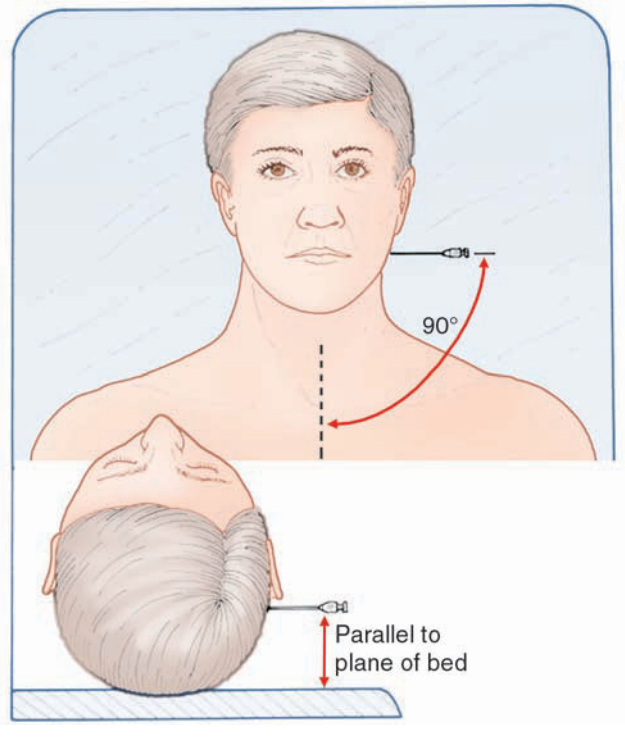

FIGURE 117-3. Proper needle trajectory for a lateral cervical puncture.

through subarachnoid space, overshooting the spinal canal, or inadvertent puncture of the spinal cord or vertebral artery. **Immediately remove the spinal needle if the patient develops any neurological symptoms.**

CSF flow through the needle signifies that the tip is within the subarachnoid space. If CSF is not draining after puncture of the dura and removal of the stylet, rotate the needle 30°. The use of a portable fluoroscopic unit can confirm the needle's trajectory and exact position. Carefully apply the three-way stopcock and manometer to the spinal needle to measure the pressure of the CSF. Carefully remove the stopcock and the manometer from the spinal needle. **Do not allow the spinal needle to move while applying and removing the stopcock and manometer. Keep in mind that the needle is not very well supported by the soft tissue as in the lumbar puncture. Hence, the needle must be supported more carefully.** Collect 1 to 2 mL of CSF in each specimen tube. Insert the stylet into the spinal needle. Remove the spinal needle and stylet as a unit. Apply a bandage to the skin puncture site.

Encountering arterial blood from the spinal needle usually indicates that it was pointing too far anteriorly and that the vertebral artery was penetrated. The venous plexus surrounding the vertebral artery may also be penetrated. Remove the spinal needle and apply manual pressure if the vertebral artery is inadvertently entered. Reattempt the procedure with the tip of the spinal needle directed slightly more posteriorly. Directing the spinal needle too far posteriorly causes it to enter the spinal musculature and miss the spinal canal. In the event that bone is encountered, meaning that either the lateral arch of C1 or C2 is encountered, redirect the spinal needle slightly rostrally or caudally and advance it into the subarachnoid space.

AFTERCARE

Maintain the patient in a supine position after the procedure. A small bandage is usually sufficient to control any soft tissue bleeding or continued CSF leakage. Postdural puncture headaches can be minimized by utilizing a small-gauged spinal needle inserted with the bevel parallel to the fibers of the dura. Resting in the supine position for 24 hours also reduces the incidence of postdural puncture headaches. Monitor the patient's neurological status. Any change in patient's baseline neurological examination requires a CT scan of the brain, posterior fossa, and occipital-cervical junction in order to rule out a herniation, epidural hematoma, or intradural hemorrhage.

Send the aspirated fluid for the appropriate laboratory analysis if an etiology other than an acute traumatic hemorrhage is suspected.[3] This can include a biochemistry analysis (glucose and protein level), cell count and differential, culture (bacterial, fungal, viral, etc.), cytology, and gram stain.

COMPLICATIONS

The complications associated with lumbar puncture are also possible during the lateral cervical puncture. Specific complications from lateral cervical puncture include penetration of the vertebral artery with subsequent hematoma formation and puncture of the spinal cord with resultant neurological deficits.[3–8] Minimize complications by utilizing a small gauge spinal needle. These complications should result in no serious consequences if unilateral and recognized.[3] Approximately 0.4% of the population has an anomalously positioned vertebral artery. There has been a single case report of a death from a subdural hematoma due to puncture of this vessel.[4] A nerve root may be irritated with passage of the needle resulting in local pain or possibly a headache. Other complications include infection, herniation syndromes, neck pain, and headache. The incidence of postdural puncture headache is less with the lateral cervical puncture than with a lumbar puncture. Refer to Chapter 115 for the complete details regarding the complications associated with a lumbar puncture.

SUMMARY

A lumbar puncture is still the preferred technique to obtain cerebrospinal fluid for analysis as well as for injection of contrast material. The lateral cervical puncture is a safe alternative method. One can avoid the complications of puncturing the vertebral artery or the spinal cord by observing maximum attention to detail. The lateral cervical puncture can be performed at the bedside. However, the availability of a portable fluoroscopy unit can facilitate the procedure.

118 Ventriculostomy

Eric F. Reichman

INTRODUCTION

Performing an emergent ventriculostomy may be lifesaving when faced with a patient who is deteriorating rapidly from a neurologic perspective and all other therapeutic options have been employed.[1] This chapter will discuss some of the situations when this procedure may be considered, other therapeutic options, and an explanation of how to perform an emergent ventriculostomy.

ANATOMY AND PATHOPHYSIOLOGY

The cranium is a fixed space after infancy that has little capacity for added volume or mass. Pathologic conditions such as tumors, intracranial hemorrhage, infection, massive cerebral infarctions, and edema can exert direct pressure on the brain or interrupt flow of the cerebrospinal fluid (CSF). These processes can all result in fluid accumulation and increased intracranial pressure (ICP).

The patient with increased ICP may display the classic clinical signs of headache, vomiting, and papilledema.[1] Vomiting is particularly associated with acute increases in ICP. Other signs include an abducens nerve palsy (cranial nerve VI) that causes diplopia, decreased consciousness, and an elevated blood pressure with bradycardia (Cushing's phenomenon). An increase in ICP may eventually progress to brain herniation.

Herniation occurs when there exists a force in part of the brain great enough to push other parts of the brain into different compartments. The cranial contents are divided into compartments by invaginations of the dura mater (**Figure 118-1**).[2] The supratentorial space is separated from the infratentorial space by the tentorium cerebelli. The right and left hemispheres are separated by the falx cerebri.

When a unilateral supratentorial mass exerts enough force, the ipsilateral cerebral hemisphere is pushed medially toward the opposite hemisphere (**Figure 118-2A**). The medial aspect of the temporal lobe is pushed down toward the brainstem and over the edge of the tentorium cerebelli (**Figure 118-2B**). This process is known as tentorial herniation. Symptoms of tentorial herniation include a worsening of any headache with vomiting, progressively decreasing consciousness, anisocoria, hemiparesis, and Parinaud's syndrome (an upward gaze paresis). Compression of the oculomotor nerve results in a sluggish and dilated pupil, usually on the same side as

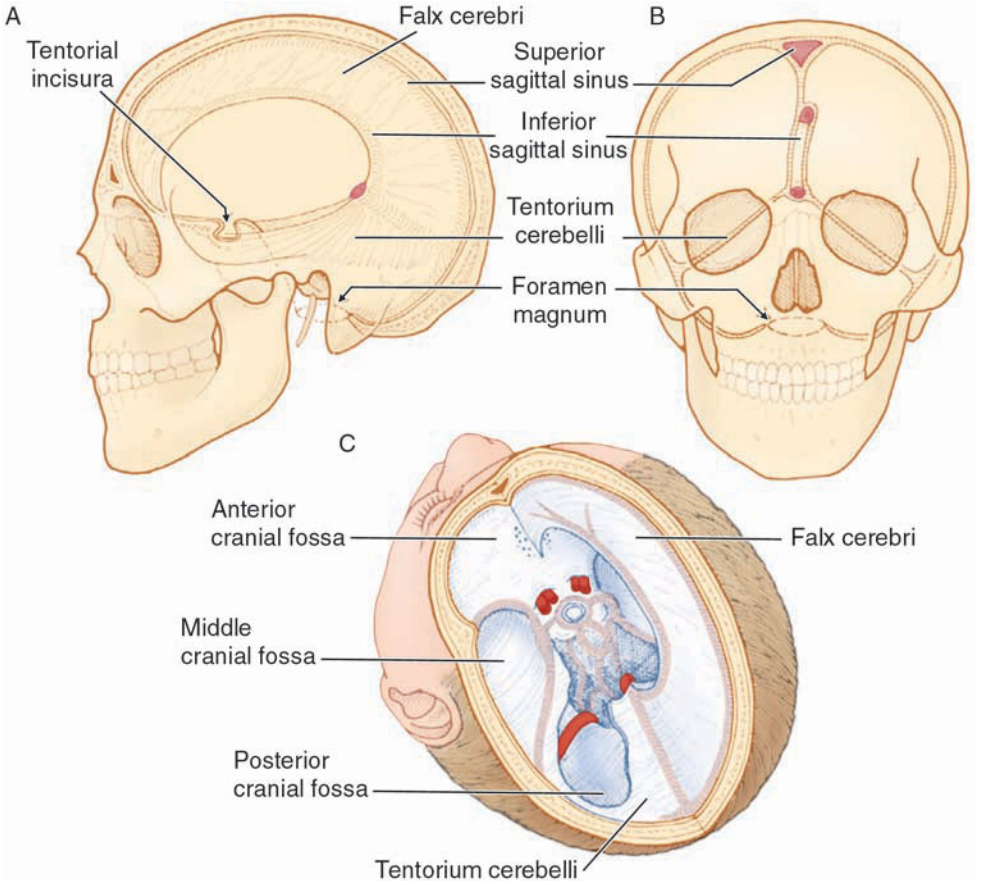

FIGURE 118-1. The falx cerebri and tentorium cerebelli divide the skull into compartments. **A.** Sagittal view. **B.** Coronal view. **C.** Top of the skull removed with a section of tentorium cerebelli also removed.

the mass lesion. A progression to a fixed and dilated pupil, with decerebrate rigidity (extensor posturing), is an ominous sign of increased ICP.

Mass effect in the infratentorial compartment of the skull may produce downward pressure of the cerebellum into the foramen magnum (**Figure 118-3A**) or upward pressure of the midbrain into the supratentorial compartment (**Figure 118-3B**), the former being more common. The downward pressure is known as tonsillar or cerebellar herniation (**Figure 118-3A**) and the terminal events surrounding this condition may occur more urgently and fatally than a supratentorial herniation. For example, an acute respiratory arrest may occur from compression of the medulla. Other important signs of tonsillar herniation include profuse vomiting, irregular respirations (ataxic breathing), neck pain, and neck stiffness. The patient may not necessarily lose consciousness or have pupillary changes prior to the terminal events of tonsillar herniation. Upward herniation forces the cerebellum and upper brainstem through the tentorial notch (**Figure 118-3B**). The patient is usually obtunded or comatose with small or anisocoric pupils that may, at first, be reactive. There may be an associated paresis of the extremities that progresses to decorticate posturing.

Any patient with these potentially life-threatening neurologic findings should be considered unstable and worked up accordingly. An emergent head CT scan, if available, is the diagnostic test

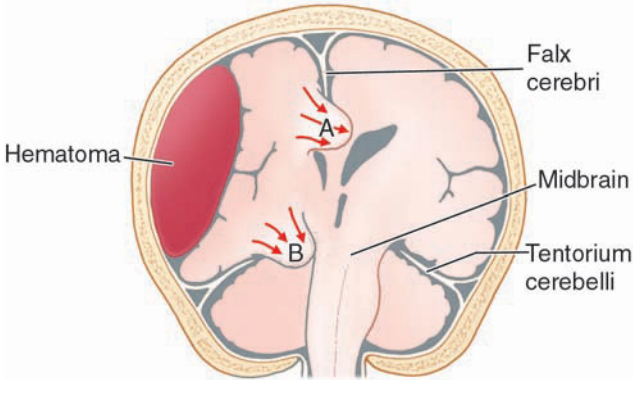

FIGURE 118-2. Supratentorial herniation of the brain. **A.** Tentorial herniation. **B.** Subfalcial herniation.

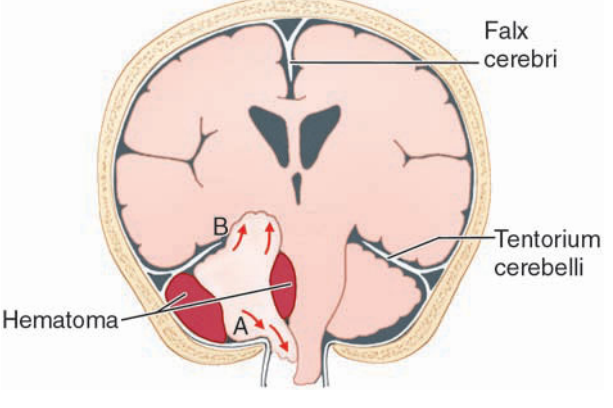

FIGURE 118-3. Infratentorial herniation of the brain. **A.** Downward tonsillar herniation through the foramen magnum. **B.** Upward herniation into the supratentorial compartment.

of choice after the patient's airway, breathing, and circulation have been stabilized. Signs of herniation on the head CT include an anterior midline shift with brain tissue from one side pushed under the falx and into the opposite side of the brain (subfalcial herniation; **Figure 118-2A**). Other signs include generalized cerebral edema with effacement of the sulci, the ventricles, the basilar cisterns, and the fourth ventricle.

There are several clinical interventions that should be implemented immediately once increased ICP, hydrocephalus, or herniation is suspected and the patient's condition is declining. The airway must be stabilized and rapid-sequence intubation is the procedure of choice. Pretreatment with lidocaine is useful in diminishing the elevation in ICP that occurs during direct laryngoscopy. Thiopental, etomidate, and propofol are the induction agents of choice as they decrease the ICP.

Neuromuscular blockade is accomplished with succinylcholine after administering a defasciculating dose of a nondepolarizing neuromuscular blocking agent. Paralytics may only be necessary for a brief period during intubation. **It is preferable to avoid paralysis for any length of time when the patient's neurologic status needs to be followed closely and any changes readily identified.** However, the need to follow the patient's neurologic course should be balanced by the need to reduce elevated ICP that may be accomplished, in part, with sedatives and paralytics. The potential for succinylcholine increasing ICP is most prevalent in patients with neoplasms of the central nervous system and may not be significant for acute trauma or bleeds.[3] Maintain the patient's oxygen saturation at 100%. Elevate the head of the bed to 30°. Place the patient in the reverse Trendelenburg position if a cervical spine injury is suspected.

It is desirable for the mean arterial pressure to be 90 mmHg or higher in order to maintain an adequate cerebral perfusion pressure and diminish the risk of cerebral ischemia. The commonly employed modalities of hyperventilation and osmotic diuresis are still used in the acutely deteriorating patient but their value is limited because of the ischemic and metabolic complications related to their use. Reducing the pCO_2 to 25 mmHg via hyperventilation can reduce the ICP in the acute resuscitation phase. The pCO_2 should not be maintained below 35 mmHg during the immediate postresuscitation period. The use of osmotic diuretics, such as mannitol, can also reduce ICP quickly. Unfortunately, any extended duration of use of osmotic diuretics places the patient at an increased risk for cerebral ischemia. Other methods to consider include the use of dexamethasone in patients with edema surrounding a neoplastic mass or abscess. Pentobarbital can be used to induce a coma and reduce the ICP, but it can also cause hypotension. An ICP monitoring device must be put into place since the ability to do sequential neurological checks is lost.

INDICATIONS

It is preferable to treat an identifiable pathologic process as soon as possible. This usually requires intervention by a Neurosurgeon. The Neurosurgeon may be able to take the patient to the Operating Room to place an indwelling ventricular shunt system in an expedited fashion. The ICP can be monitored and reduced by draining CSF via a ventriculostomy in the Emergency Department if the patient continues to deteriorate and a definitive procedure cannot be immediately arranged.

The primary indication for a ventriculostomy is cerebral herniation unresponsive to less invasive management methods. A ventriculostomy can also be performed to drain CSF to treat hydrocephalus, decrease ICP from any cause, measure ICP, introduce contrast for radiographic studies, or to collect CSF from the ventricular system.[4]

CONTRAINDICATIONS

Performing a ventriculostomy could precipitate or worsen herniation and hasten the patient's mortality if an infratentorial mass has been identified and it appears to be inducing upward pressure into the supratentorial compartment. A coagulopathy or thrombocytopenia makes a ventriculostomy dangerous to perform. The use of anticoagulants and antiplatelet agents by the patient increases their risk of hemorrhagic complications. Consider reversing these conditions by the administration of fresh frozen plasma and/or platelets prior to performing a ventriculostomy. A mild elevation in the international normalized ratio (INR) up to 1.6 may be acceptable to place a ventriculostomy.[5]

EQUIPMENT

- Skin razor
- Skin prep kit
- Sterile gloves and gown
- Face mask with an eye shield or goggles
- Cap
- Povidone iodine or chlorhexidine solution
- Skin marker
- Ventricular catheter with stylet
- Drainage tubing and collection system
- Measuring implement
- Scalpel handle
- #15 scalpel blade
- 10 mL syringe
- 25 gauge needle
- Lidocaine with epinephrine, 1%
- Self-retaining retractor
- Twist drill with a ¼ in. bit
- Sterile towels
- Bipolar cautery
- Needle driver
- 3-0 nylon suture
- Suction source
- Suction tubing
- Suction catheters
- Headlight, optional
- Curette, optional
- Three-way stopcock, optional

It is most useful to have either a commercially available ventriculostomy kit or assemble one to have available in the resuscitation area. Complete, disposable, and single-patient use kits are convenient and cost-effective (**Figure 118-4**).

PATIENT PREPARATION

The patient should be fully monitored with a noninvasive blood pressure cuff, pulse oximetry, cardiac monitor, and end-tidal carbon dioxide monitor (if available). Obtain a CT scan of the head to determine the presence of an acute subdural or epidural hematoma, the location and extent of the hematoma, to rule out the presence of a mass, and to determine if there is any herniation. Obtain a complete blood count (hemoglobin, hematocrit, and platelet count) and

FIGURE 118-4. An example of the contents of a commercially available ventriculostomy kit.

a coagulation profile (PT, PTT, and INR) to ensure that the patient is not thrombocytopenic or coagulopathic. These may require reversal with the administration of fresh frozen plasma and/or platelets.

This procedure is often performed emergently. Explain the procedure, its risks, and benefits to the patient and/or their representative. If it will not unduly delay the treatment, obtain an informed consent to perform the procedure.

This procedure requires strict aseptic technique. Place the patient supine on a gurney with the head elevated 30°. Identify the burr hole entry site. This is located 3 cm to the right of midline and 10 cm behind the glabella in the midpupillary line or 1 cm anterior to the coronal suture in the midpupillary line (**Figure 118-5**). Shave the right side of the head, the nondominant side in most people, for 4 to 5 cm surrounding the burr hole entry point. The hair from the entire frontal area back to the ear may be shaved, but it is probably unnecessary to do so. Clean the scalp of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry. The Emergency Physician should don full sterile and personal protective equipment at this point. This should include sterile gloves, a sterile gown, a face mask with an eye shield or goggles, and a cap. Denote the landmark on the skin with a sterile skin marker. Apply sterile drapes to the head so that the medial canthus of the right eye can be visualized. Note the premade markings on the ventricular catheter or mark 4, 5, and 7 cm on the catheter prior to its insertion.

Consider the administration of prophylactic intravenous broad spectrum antibiotics immediately prior to the procedure. The usual infecting organisms are *Staphylococcus epidermidis* and *Staphylococcus aureus.* Appropriate antibiotic coverage includes third-generation cephalosporins and penicillinase-resistant penicillins.

TECHNIQUE

Infiltrate the marked area with 3 to 5 mL of lidocaine with epinephrine. Make a 1 to 2 cm incision with a #15 scalpel blade. Carry the incision from the skin surface down to and through the periosteum of the skull. Tie off or cauterize any bleeding vessels. Insert the self-retaining retractor into the incision to provide adequate exposure.

Prepare the hand drill. Choose the appropriate drill bit and insert it into the drill. Adjust the safety stop on the drill bit to the estimated skull thickness. Secure the safety stop on the drill bit firmly with an Allen wrench. Carefully and slowly drill through the outer and inner tables of the skull. **Take care not to penetrate the dura. Do not apply too much force against the drill to prevent plunging the drill bit into the brain. Stop drilling when a loss of resistance is felt.** Flush the hole with warm sterile saline to remove any debris. Carefully make an opening in the dura with an 18 gauge needle or a #11 scalpel blade.

A simple ventricular catheter or a fiberoptic catheter with a screw-in mechanism should be available. Apply gentle pressure while inserting the catheter into the brain matter and aiming for the medial canthus of the ipsilateral eye (**Figure 118-5A**). A loss of resistance or a "give" will often be felt as the catheter enters the ventricle. There should be a return of CSF at a depth of 4 to 5 cm of catheter penetration. Withdraw the stylet and advance the catheter 1 cm farther. **Do not insert the catheter more than 7 cm deep.**

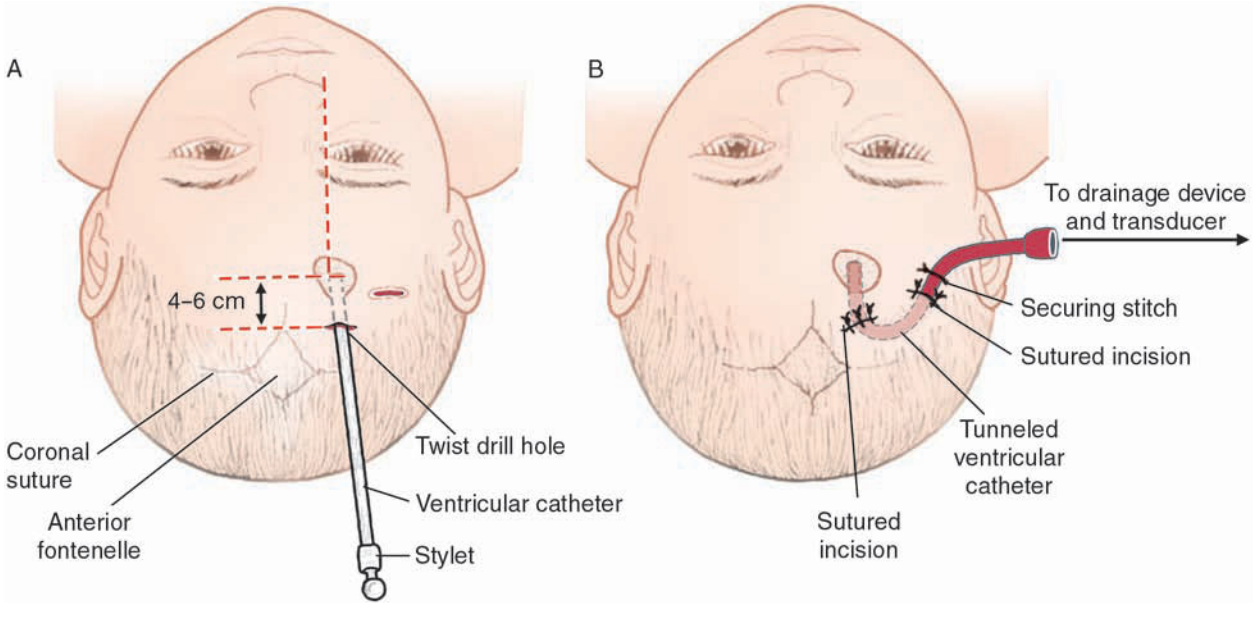

FIGURE 118-5. Placement of a ventriculostomy catheter. **A.** Insertion of the ventricular catheter. **B.** The catheter is tunneled and the skin closed.

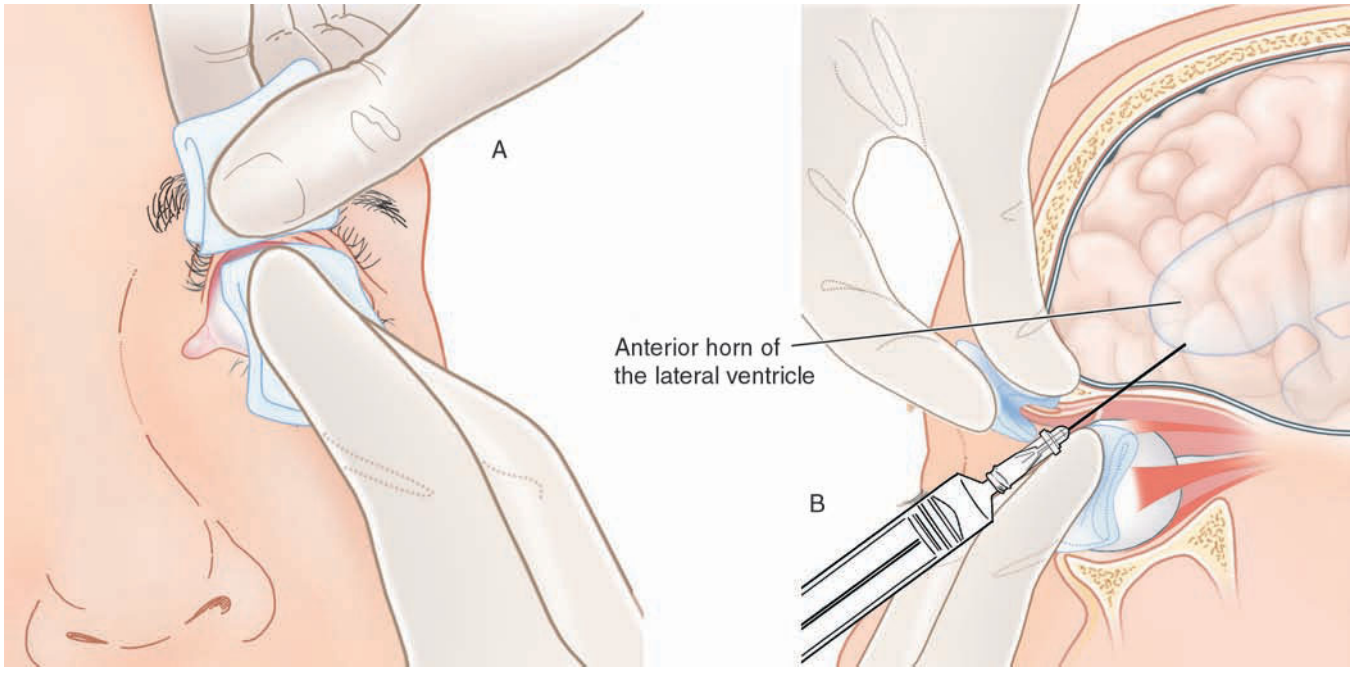

FIGURE 118-6. Transorbital ventricular decompression. **A.** The upper eyelid is retracted and the globe is displaced downward. **B.** Insertion of the needle.

If no CSF is obtained, withdraw the catheter and reinsert it while aiming slightly more medially and posteriorly, as the position of the ventricles may be distorted by the underlying pathologic process. Attach the pressure transducer to measure ICP.

ALTERNATIVE TECHNIQUE

The gathering of equipment, making the burr hole, and the insertion of the ventriculostomy catheter can take significant time and experience. The required equipment may not be readily available. An easier, quicker, and simpler technique is to perform a transorbital decompression.[9,10] This technique is adapted from the old frontal lobotomy of years ago. Clean and prep the skin of the eyelids and periorbital area. Moisten sterile gauze with sterile saline. Instruct an assistant to grasp the upper eyelid with a piece of saline-moistened gauze. Instruct the assistant to retract the upper eyelid outward then upward and maintain this position (**Figure 118-6A**). Grasp a piece of saline-moistened gauze in the nondominant hand. Apply this to the sclera at the 12 o'clock position and displace the globe downward (**Figures 118-6A & B**). **Be sure to not place the gauze on the cornea as this can cause a significant corneal abrasion.** Apply an 18 gauge, 1.5 to 2.5 in. angiocatheter or spinal needle on a syringe. Insert the needle through the orbital roof, 1 cm posterior to the superciliary arch (**Figure 118-6B**). Aim the needle toward the coronal suture at the midline or vertex of the skull. Advance the needle approximately 3 cm so that its tip enters the anterior horn of the lateral ventricle. Gently aspirate after the needle is inserted to a depth of 3 cm and CSF is aspirated. If using an angiocatheter, the soft plastic catheter can be secured to the orbital roof with a suture and the ICP monitored through the pressure transducer.

AFTERCARE

It is desirable to tunnel the drainage tubing subcutaneously for several centimeters to reduce the risk of infection (**Figure 118-5B**).[1,6] Suture the ventricular catheter and tubing to the skin so that it remains in place (**Figure 118-5B**). Close the skin around the ventricular catheter. If a pressure transducer is being utilized, obtain a measurement prior to allowing any quantity of CSF to drain. Attach the sterile fluid collection system. If a simple drainage bag is being used, ensure that it is kept at the level of the ventricle to avoid overdrainage. **Frequently recheck and document the patient's neurologic status.** It is useful to send a baseline sample of CSF for culture, cell count, chemistry, and cytology (if applicable) after ventriculostomy placement.

PEDIATRIC CONSIDERATIONS

Young children have an open anterior fontanelle. This large area devoid of bone is ideal for the introduction of a needle to drain CSF from the ventricular system. This procedure may be required in cases of acute patient decompensation due to an acute nonobstructing hydrocephalus (e.g., meningitis), an acute obstructing hydrocephalus (e.g., brain abscess, brain tumor, epidural hematoma, intracranial hemorrhage, or subdural hematoma), or the acute decompensation of a chronic hydrocephalus (e.g., aqueductal stenosis, posterior fossa tumors, or other congenital malformations).[4]

The ventriculostomy procedure in a young child is similar to that in an older child, adolescent, and adult with a few exceptions. A burr hole is not required as the anterior fontanelle allows an easy access point. Use an 18 or 20 gauge, 1.5 in. long angiocatheter instead of the spinal needle. The procedure is similar to inserting an intravenous catheter. Insert the angiocatheter perpendicular to the skin and at the most lateral aspect of the anterior fontanelle or the coronal suture to avoid the midline sagittal sinus. Stop advancing the angiocatheter when CSF flows from the hub of the needle. Slightly advance the plastic catheter while withdrawing the needle. Apply the pressure transducer to the hub of the catheter to measure ICP. Remove enough CSF to decrease the ICP to an appropriate level or until the signs and symptoms of herniation are reversed.[6,7] Remove the catheter or secure it to the scalp with suture. The secured catheter can be capped or left attached to transducer to continue to monitor ICP.

COMPLICATIONS

The most common complication of placement of an emergent ventriculostomy is a CSF infection. The risk of infection increases the longer the drain is left in place. Fortunately, infections are rare for those in place for fewer than 4 days. Tunneling the drainage tubing, adhering to strict aseptic technique, and administering prophylactic antibiotics can reduce the incidence of infection.

Ventricular puncture can result in an acute bleed in the subdural, intraparenchymal, or ventricular spaces. This can occur from direct trauma to the vascular system or excessive CSF drainage that shrinks the brain and tears the bridging vessels to the subdural space. It is estimated that the risk of hemorrhage associated with a ventriculostomy is 5.7%, with 1% of ventriculostomy patients having a clinical significant hemorrhage.[8] **An emergent head CT is indicated if the patient's condition deteriorates further after ventriculostomy placement. Patients should always be tested for normal blood clotting function prior to performing a ventriculostomy.**

The most feared complication of this procedure is plunging with the drill bit uncontrollably into the brain substance. This procedure should not be performed by those unfamiliar and untrained in the technique. Apply the minimal amount of pressure to the drill so that the bit penetrates the bone. **Never use a hand twist drill without the safety stop.**

SUMMARY

The traumatically head-injured patient or the patient with chronic hydrocephalus who presents with a rapidly deteriorating neurologic status may have increased ICP or be in the process of brain herniation. There are several tools, in addition to emergent ventriculostomy placement, that can temporarily stabilize the patient's changing neurological status. This includes intubation, hyperventilation, osmotic diuresis, maintenance of cerebral perfusion pressure, dexamethasone administration, and barbiturate coma. While the ultimate goal is to treat the primary pathologic condition, this chapter was designed to describe the use of CSF drainage via a ventriculostomy and its use in the context of the other methods commonly used to reverse the life-threatening complications of an acutely increasing ICP.

119 Ventricular Shunt Evaluation and Aspiration

Eric F. Reichman

INTRODUCTION

Pediatric and adult patients with ventricular shunts frequently seek medical attention in acute care settings with complaints that may or may not be caused by a malfunction and/or infection of these indwelling devices. The challenge for the Emergency Physician is to determine if the shunt system is functioning properly and if it is a direct cause of the patient's acute problem. This chapter will discuss the complications of ventricular shunt malfunction including infection.

Complications in children with ventricular shunts are common whereas those in adults occur less frequently. Approximately 30% to 40% of infants will experience shunt complications during their first year following shunt placement.[1,2] Children who had shunts placed as infants will require two shunt revisions secondary to obstruction within their first 10 years.[1] The overall shunt infection rate is 10% to 20%.[1,3,4] Approximately 90% of these infections will present within 3 months of the shunt placement.[1] These statistics apply to the population with conventionally treated hydrocephalus using indwelling ventricular shunt devices. It is significant to note that with the wide application and development of neuroendoscopic techniques, many of the complications discussed in this chapter may be significantly reduced or possibly eliminated.

Complications resulting from ventricular shunts take many forms.[5] These include proximal obstruction (most common), distal obstruction, disconnection, wound and cerebrospinal fluid (CSF) infections, seizures, epidural hygromas, subdural hematomas, low (overdrainage) and high pressure (slit ventricle) syndromes, and cranial deformities. There are other unique complications experienced by the smaller number of patients who have ventriculoatrial (V-A) and ventriculopleural shunt systems and these will be discussed separately. Unless stated otherwise, the reader should assume that reference is being made to the more common ventriculoperitoneal (V-P) shunt device.

Patients with shunts may present with clinical entities as benign as a viral upper respiratory infection or with a life threat like hydrocephalus. The wide range of possibilities is a challenge to the Emergency Physician's diligence and clinical acumen. Common presenting symptoms include headache, fever, vomiting, decreased alertness, neck stiffness, visual changes, malaise, abdominal pain, abdominal distension, and surgical site problems.

ANATOMY AND PATHOPHYSIOLOGY

Hydrocephalus, a condition defined by an excessive quantity of CSF, is the condition most frequently associated with the initial need for a ventricular shunt or a shunt revision if it malfunctions. Most abnormal accumulations of CSF are identified in the ventricles, although it may also occur in the subarachnoid or subdural spaces.

Several types of hydrocephalus are cited in the literature. Communicating hydrocephalus occurs when there is unobstructed flow of CSF between the ventricular system of the brain and the spinal cord. It frequently occurs in patients who have had a hemorrhage or infectious process whereby particulate matter interferes with the normal circulation and absorption of CSF. A congenital problem such as aqueductal stenosis or a mass lesion in the posterior fossa may obstruct the flow of CSF between the brain and spinal cord causing obstructive hydrocephalus or noncommunicating hydrocephalus. Normal pressure hydrocephalus is usually a diagnosis made in older people who present with the clinical triad of dementia, ataxic gait, and urinary incontinence. The CSF is found to flow within a normal pressure range, but the patient accumulates excess CSF due to decreased absorption. Hydrocephalus ex vacuo is the result of excessive CSF and ventricular enlargement due to brain atrophy. It presents a challenge to the acute care practitioner who may need to decide if a patient with large ventricles on head CT has a pathologic condition or has so much brain atrophy that the fluid-filled spaces appear excessively large.[6]

The clinical presentation of hydrocephalus will vary depending upon its acuity and the age of the patient. The individual who experiences shunt failure may present in the same way as one who is presenting with hydrocephalus initially. Infants may have an enlarged head circumference, a bulging anterior fontanel, separation of the cranial sutures, bilateral or unilateral palsy of the abducens nerve (medial eye deviation), or Parinaud's syndrome.[7] Parinaud's syndrome is a paralysis of upward gaze (also known as "sunset eyes" or the setting sun sign), unequal pupils, and the loss of convergence.[7]

Within hours of an acute cause of hydrocephalus, the patient (past infancy) will commonly experience a headache with nausea

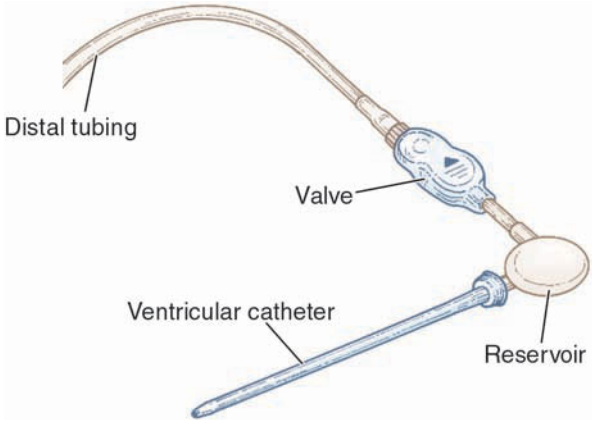

FIGURE 119-1. The components of a ventricular shunt.

and vomiting secondary to the quick increase in intracranial pressure (ICP). The patient may less commonly have a focal neurological deficit due to the pressure exerted by the brainstem from a dilated third ventricle. There may also be visual changes that include Parinaud's syndrome. A change in mental status may occur as the increase in ICP persists. Finally, the signs of herniation signify a terminal event. It will be observed with, for example, decorticate or decerebrate posturing, a third cranial nerve palsy, and the Cushing reflex (elevated blood pressure accompanied by bradycardia). The process of herniation is nearly completely reversible with immediate ventricular drainage through emergent revision of a malfunctioning shunt or the de novo placement of a ventricular drain.

Chronic hydrocephalus can present with a variety of signs and symptoms. The patient may complain of an isolated bifrontal headache, a generalized headache, vomiting, a change in behavior, a change in mentation, or a change in cognition. Ocular findings include papilledema, unilateral or bilateral abducens nerve palsy, Parinaud's syndrome, or even a bitemporal hemianopsia. The extremities may be involved with spasticity in the legs that is more pronounced than that found in the arms.

Once the diagnosis of hydrocephalus is made, the Neurosurgeon will be responsible for treating the primary causes (e.g., tumor, bleed, congenital abnormality) along with placement of an indwelling ventricular shunt. The components of a standard shunt system include a ventricular catheter, a one-way valve, and distal tubing that enters the cavity into which the fluid is being shunted (**Figure 119-1**). It is standard practice to enter the right lateral ventricle and tunnel the valve system and distal tubing subcutaneously along the right temporoparietal region of the skull, the lateral neck, the anterolateral chest wall, and finally into the peritoneal space just superior or lateral (right side) to the umbilicus (**Figure 119-2**). The shunt system may occasionally be found on the left side in some patients.

Much of the shunt pathway is palpable on physical examination (**Figure 119-2**). The entire system may be visualized on plain radiographs. The system is impregnated with radiopaque material either entirely or with intermittent markings.

The ventricular catheter is inserted through a burr hole and into the lateral ventricle. The distal end of the ventricular catheter is connected to one of many different types of valves currently available. Functionally, there are two main types. The differential pressure valve allows the Neurosurgeon to select a low, medium, or high pressure system whereby the CSF will flow out of the ventricle through a one-way system when the CSF pressure or CSF flow rate builds to

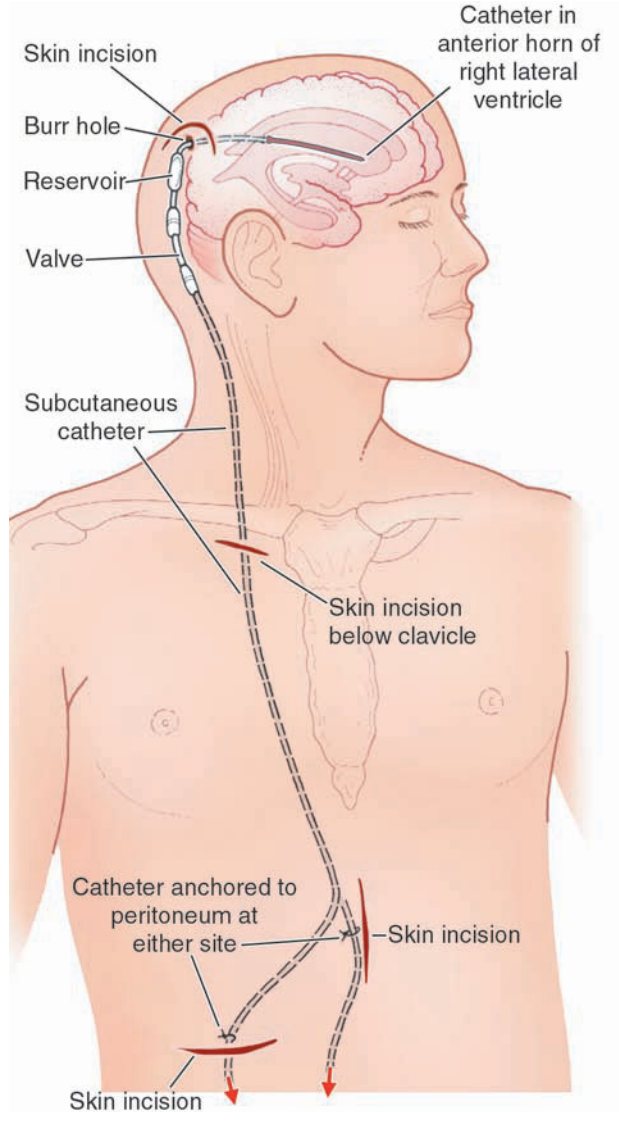

FIGURE 119-2. The anatomical pathway of a ventriculoperitoneal shunt.

a specified level. A variable resistance constant flow valve keeps CSF rates constant and, therefore, provides a more physiologic system by varying the resistance in the valve as the individual changes position. Some of these valves, although palpable on physical examination, do not allow access to the CSF for aspiration nor do they allow for any noninvasive assessment of CSF flow. A bubble-like reservoir (may be single or two bubbles in tandem) for the draining of CSF is a common addition to the standard three-part shunt system. While they can be inserted anywhere in the system, they are most frequently located adjacent to the valve mechanism on the lateral aspect of the skull (**Figure 119-2**).

The distal tubing is made of a flexible and soft synthetic rubber material that is attached to the reservoir or valve system and tunneled subcutaneously through the lateral neck, chest, and abdominal wall. A small incision is made in the skin and the peritoneum where the tubing is brought from the subcutaneous tissue into the peritoneal cavity. After securing the tubing to the peritoneum, a generous portion of tubing is left free floating inside the peritoneal cavity. This allows for the distal end to lengthen as the patient grows and lends further stability to its place within the abdominal cavity.

The distal tubing in ventriculoatrial and ventriculopleural shunt systems will terminate in the right atria and right pleural cavity,

respectively. However, these configurations are not used frequently. One may also come across a patient with a lumboperitoneal shunt that avoids any invasive procedures to the brain directly. This system is inserted into the lumbar subarachnoid space with the valve/reservoir system located above the iliac crest and the distal tubing tunneled subcutaneously in the abdominal wall and into the abdominal cavity.

The patient is subject to a host of complications due to mechanical malfunctioning that can occur anywhere along the path of the system. There is the risk of infection, as is the case with any indwelling medical device. The remainder of this chapter will guide the Emergency Physician through the process of identifying the various types of shunt problems.

INDICATIONS

The Emergency Physician is obliged to assess the patency, placement, and integrity of the shunt system when a patient presents with any symptoms even remotely related to hydrocephalus. The presence of systemic signs (e.g., fever, tachycardia, or hypotension) or local signs of infection (e.g., warmth, tenderness, bogginess, or redness along the shunt tract) is a reason to consider aspirating CSF from the system. This is not to say that every child with an upper respiratory infection requires that the shunt be tapped. It is not uncommon to have overlapping findings in that an infection may obstruct the system and therefore require both mechanical and infectious complications to be addressed. **The withdrawal of CSF from the shunt can be lifesaving and sustain the patient who is herniating, in extremis, or deteriorating neurologically until a Neurosurgeon can repair the shunt.**

CONTRAINDICATIONS

There are no contraindications to performing a thorough physical examination of the shunt system, obtaining a head CT, and obtaining plain radiographs to assess its integrity. There is some controversy, however, that surrounds the tapping of a shunt by personnel other than a Neurosurgeon.[8–10] It is possible to disrupt the pressure and valve mechanism by the manipulation of the needle that is required to perform the tap. The reservoir may develop a leak if the correct technique is not employed or if the shunt is tapped too frequently. There is the risk that bacteria will be introduced into the system. Many patients have had multiple complications related to both a primary disease and the shunt, with some already having undergone a number of shunt revisions. **It is prudent to assume a conservative approach with each of these patients and consult a Neurosurgeon prior to tapping the shunt.**

SHUNT ASSESSMENT

The technique of shunt evaluation begins with taking a complete history and performing a thorough physical examination. Palpate the entire system starting with the cranium. Examine the surrounding scalp carefully for any bogginess (indicating that CSF may have extravasated from the system), redness, tenderness, or warmth. The suture line should be examined as well if the shunt has been placed recently. Examine the scalp on the right side for a burr hole. This is where you may palpate a shunt reservoir that is placed subcutaneously. The reservoir feels like a firm fluid-filled bubble. Compress the bubble gently to assess if there is brisk refilling of the CSF. Quick filling of the reservoir is an indication that the proximal portion of the system may be patent, but this is by no means a perfect test. Resistance to compression indicates a distal malfunction. **Avoid pumping the reservoir repeatedly.**

A double bubble (reservoir system) may be occasionally palpated. Compress the proximal reservoir to empty it and fill the distal reservoir. While still compressing the proximal reservoir, compress the distal reservoir. Any resistance to compression indicates a distal malfunction. With both reservoirs compressed, release the proximal reservoir. It should refill very quickly. Any delay in filling of the proximal reservoir indicates a proximal malfunction.

Move down and palpate the temporal region of the scalp and the neck. Note any gaps in the system that could indicate a disconnection. The individual components of the shunt system are commonly joined by small connectors that may come apart. Continue to palpate the tubing along the neck and chest until you reach the abdomen. Perform a thorough abdominal examination, specifically noting the presence of any tenderness, masses, distension, or erythema of the abdominal wall.

The distal end of the shunt may not function for several reasons. The tip may have withdrawn out of the peritoneal cavity and into the preperitoneal fat or subcutaneous tissue of the abdominal wall where the CSF cannot be resorbed. This may have occurred simply because the patient had grown and used up the extra length of catheter that was originally left in the peritoneal cavity just for this reason. Intraperitoneal infections, particularly those caused by anaerobic organisms, may cause loculations around the catheter tip forming a pseudocyst. It is important to note that these patients may not have any signs of a systemic infection. Additional causes of distal catheter obstruction include kinking of the intraabdominal tubing, debris collection around the tube openings, and compression secondary to pregnancy or other processes that increase the intraabdominal pressure.

After completing the history and physical examination, including an assessment of the shunt system, the differential diagnoses will help initiate an appropriate work-up. One or more of the following studies may be indicated: plain radiograph shunt series, computerized tomography (CT) of the head, shunt aspiration of CSF, or a radioisotope shunt scan. **Stabilize the patient and arrange for an emergent head CT if any life-threatening signs of neurologic dysfunction appear.**

There are several important points to note. Findings consistent with hydrocephalus include enlargement or effacement of the ventricles, particularly looking for fullness of the temporal horns of the lateral ventricles (**Figure 119-3**). It can be difficult to determine if there is a change in the ventricular system because congenital or chronic abnormalities can give the CT scan an abnormal appearance. The best way to approach this situation is to compare the current scan to a previous one, preferably by comparing the two scans side by side. Brain atrophy causes the ventricles to appear abnormally full when, in fact, they appear large because of the relative loss of brain tissue.

Impending herniation may be a concern if the brain appears to be under increased pressure with a loss of the sulcal markings, loss of the differentiation between the gray and white matter, or an inability to visualize the fourth ventricle. The ventricles can appear unusually small which may be an indication of a shunt system that is draining CSF too vigorously. Overdrainage may be the problem if the patient complains of a positional headache that is worse in the upright position and less severe when supine. **If this is the case, it is important to carefully examine the CT scan for any subdural hematomas that can result from the brain shrinking away from the dura and tearing a bridging vein secondary to overdrainage of CSF.**

The patient's scan may reveal small ventricles accompanied by signs of increased ICP in the slit ventricle syndrome.[11,12] While the slit ventricle syndrome is poorly understood, it is theorized that ventricles with poor compliance (common in those with chronic hydrocephalus) will respond to small increases in CSF pressure with

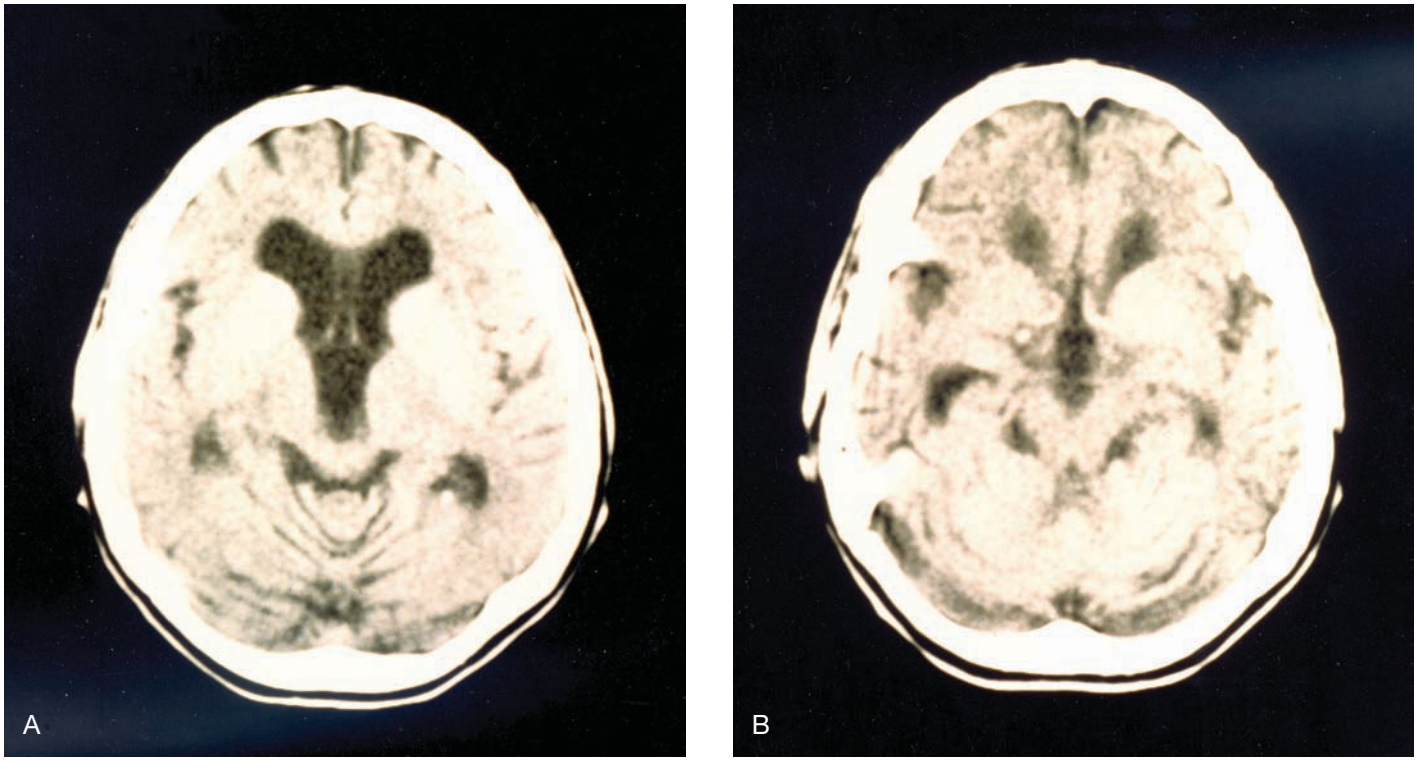

FIGURE 119-3. Head CT of a patient with hydrocephalus. **A.** The ventricles are enlarged with effacement. **B.** Pronounced temporal horns.

large increases in ICP. The management of the slit ventricle system can be medical, replacement of the valve with one of a higher resistance to flow, or the placement of a new shunt.[12,13]

Obtain a plain radiograph shunt series if there is the slightest suspicion of a shunt malfunction or infection. This study consists of anteroposterior and lateral plain radiographs of the skull, neck, chest, and abdomen. These films are useful for assessing placement and integrity of the connections within the shunt system.[14] Shunt materials are impregnated with a radiopaque substance either completely or in regularly placed markings so that the entire device can be visualized on plain radiographs. **It is important to obtain and review the lateral abdominal film as this view is frequently overlooked.** It is impossible to determine if the shunt tubing lies within the peritoneal cavity or not if the lateral abdominal film is excluded. The entire path of the shunt system should be visualized. Particular findings to note on this study include placement of the ventricular catheter inside of the ventricle, the integrity of the connections around the valve and/or reservoir, and the identification of the distal catheter within the peritoneal cavity. Examine the chest radiographs closely for a pleural effusion or a pneumothorax in a patient with a ventriculopleural shunt.[15]

SHUNT ASPIRATION

Tapping the ventricular shunt should be considered whenever there are signs of localized infection, systemic infection, or in some cases of suspected obstruction without an identifiable cause. It should also be performed if the patient is in extremis, deteriorating neurologically, or has signs of herniation on the CT scan. This can temporarily restore cerebral perfusion and sustain the patient until a Neurosurgeon can repair the shunt. **It is recommended that a Neurosurgeon be consulted and given the first option to perform the procedure.** The Neurosurgeon may have already manipulated the hardware multiple times and will ultimately be responsible for any shunt revisions and follow-up. Patients with ventriculoatrial shunts are a particular concern when there are any signs of an infection. The distal catheter sits at the intersection of the right atrium and the superior vena cava. This puts the patient at risk for life threats such as endocarditis and septic emboli. It may be possible to evaluate the majority of shunt malfunctions without tapping the device.[8]

Tapping a ventricular shunt is a quick and simple procedure. Palpate the lateral aspect of the skull (usually the right side of the patient) for the reservoir. Plain radiographs may be helpful if it is difficult to identify upon palpation. Prepare for the procedure by having the following equipment available: four sterile fluid specimen tubes with tight fitting tops (those supplied in the standard lumbar puncture kit are ideal), a 23 to 25 gauge butterfly needle, a 5 to 10 mL syringe, a shave-prep set, an antibacterial cleansing preparation (povidone iodine or chlorhexidine solution), a fenestrated drape, and personal protective equipment.

Local anesthetic is not required for this procedure. Place the patient in whatever position is mutually comfortable. Shave a small patch of hair overlying the reservoir. Clean the skin of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry. **This procedure requires strict aseptic technique.** The Emergency Physician should don full sterile and personal protective equipment at this point. This should include sterile gloves, a sterile gown, a face mask with an eye shield or goggles, and a cap. Place the drape over the patient's head so that the fenestration overlies the reservoir and prepped skin. Set up a bedside table with a sterile drape and all the supplies. A lumbar puncture tray supplemented with a butterfly needle is all that is required.

Insert the needle at approximately 45° from the vertex of the reservoir bubble with the tip pointed toward the center of the reservoir (**Figure 119-4**). This is where the greatest amount of CSF is located. **Avoid inserting the needle into any of the connections or internal pressure mechanisms that may be at either end of the reservoir.**

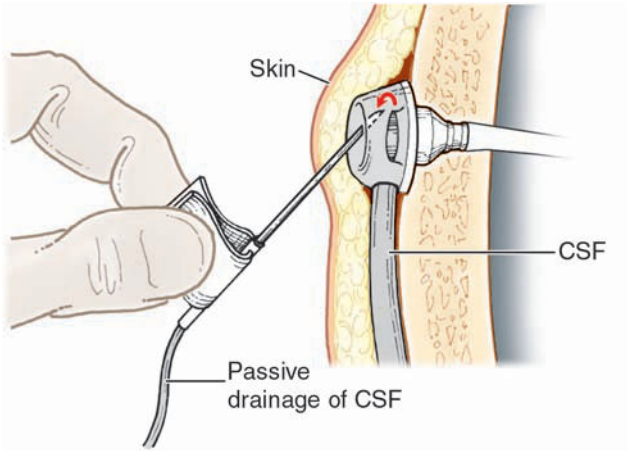

FIGURE 119-4. Tapping the shunt reservoir.

Allow the CSF to passively drain from the butterfly tubing into sterile tubes. It may be necessary to very gently aspirate 4 to 5 mL of CSF with a sterile syringe. The ventricular end of the shunt is usually obstructed if CSF cannot be aspirated.[10] Withdraw the needle from the shunt reservoir.

Label the tubes of CSF and have them transported to the laboratory for a cell count and differential, Gram's stain, culture (bacterial, viral and fungal), and chemistry (protein and glucose). Obtain a sample of the patient's serum glucose at the same time so as to more accurately determine what level of glucose in the CSF to call abnormal. A normal level of CSF glucose should not be any lower than 50% to 66% of the serum level.

It is possible to attach the end of the butterfly tubing to a manometer so that an opening pressure can be measured. This must be done, however, with the patient in the lateral decubitus position, reservoir side up, and the head level with the heart.

Obtain a nuclear medicine scan ("shunt-o-gram") if CSF cannot be aspirated to determine proximal patency of the system. A radioactive isotope (e.g., technetium) is injected into the reservoir after manually occluding the distal shunt tubing. The flow, or lack thereof, of the radioactive isotope is then imaged.[4] The addition of a nuclear medicine scan to the CT scan can increase the sensitivity of diagnosing a shunt malfunction.[16]

A lumbar puncture should never be performed in lieu of tapping the shunt. Obstruction of the shunt system can result in obstructive hydrocephalus. Lumbar puncture in a patient with obstructive hydrocephalus can cause a significant pressure differential and precipitate brain herniation.

CSF ASSESSMENT

The CSF obtained from the shunt is interpreted in the same way as CSF from a lumbar puncture. A high white cell count with a large number of polymorphonuclear leukocytes, low glucose, and a high protein level indicates a high likelihood of bacterial infection. However, the positive Gram stain and culture make the definitive diagnosis. Unfortunately, there is no standard for the number of white cells that definitively indicates an infection. Some patients with indwelling shunts may have a chronically elevated CSF white blood cell count, albeit with more lymphocytes or eosinophils than polymorphonuclear leukocytes.[3] Refer to Chapter 115 for a more detailed discussion regarding the evaluation of CSF. Antibiotic coverage should be initiated if a shunt is being tapped. *Staphylococcus epidermidis* causes the vast majority of infections with *Staphylococcus aureus* and gram-negative bacilli following in frequency.[17,18] The current management of shunt-related infections has been reviewed by Stenehjem and Armstring.[19] Empiric therapy includes vancomycin with either cefotaxime or ceftriaxone for children and vancomycin with rifampin for adults.[20] Consider additional coverage for methicillin-resistant *Staphylococcus aureus* if indicated.

FUTURE CONSIDERATIONS

The ShuntCheckT (NeuroDx Development, Bensalem, PA) is a new device that allows the noninvasive detection of CSF flow through a shunt.[21] The procedure requires placing an ice cube over the shunt. A single patient use and disposable sensor is placed on the skin of the neck overlying the shunt tubing. The sensor is attached to the ShuntCheckT device with a cable. The ShuntCheckT analyzes the temperature readings from the sensor and determines if CSF flow is present or not.

COMPLICATIONS

There are a few complications associated with the aspiration of a ventricular shunt. The introduction of bacteria into the reservoir can result in meningitis, peritonitis, brain abscesses, shunt occlusion, or infection anywhere along the course of the shunt tubing. It is of the utmost importance to maintain strict aseptic technique. The needle can damage the reservoir and result in a permanent hole necessitating its removal and replacement. A misplaced needle can damage the connections or valves of the shunt system.

SUMMARY

Patients with indwelling ventricular shunt devices are subject to many complications throughout their lives. This most commonly includes obstruction, infection, and malfunction secondary to loss of placement or connection. Emergency Physicians will see patients of all ages with shunts and who present with headache, fever, nausea, vomiting, seizures, irritability, or a change in mental status. The challenge, frequently a formidable one, will be to determine whether or not the patient's complaint is related to the shunt. This chapter discussed some of the common shunt complications and an approach to their diagnosis. The head CT, the plain film shunt series, and the shunt tap will prove most useful. Of course, a careful history and a skilled physical examination will set the Emergency Physician on a path toward a good outcome for the patient. A Neurosurgeon should be consulted if available. A conservative approach to diagnosis, management, and patient disposition is strongly recommended due to the life-threatening nature of shunt complications.

120 Subdural Hematoma Aspiration in the Infant

Eric F. Reichman

INTRODUCTION

Extra-axial fluid collections in children are classified as symptomatic and asymptomatic. Symptomatic, chronic extra-axial fluid collections have been variously classified as hematomas, effusions, or hygromas with differing definitions associated with each. It has been proposed that they all be classified together as extra-axial fluid collections because their appearance on CT scan and the treatment is identical.[1] Symptomatic, chronic extra-axial fluid collections usually show ventricular compression and flattening or obliteration of the

cerebral sulci on CT scans. Benign subdural fluid collections usually appear as a hypodensity over the frontal lobes with dilatation of the interhemispheric fissure, cortical sulci, and Sylvian fissure. The ventricles are usually normal or slightly enlarged with no evidence of transependymal flow.

Seizures, a large head, vomiting, irritability, depressed level of consciousness, and lethargy are common presenting symptoms of a symptomatic extra-axial fluid collection. The physical examination reveals a full fontanel, macrocephaly, fever, lethargy, hemiparesis, retinal hemorrhages, generalized increased tone, or gaze paresis. Markwalder has done an excellent review of the pathophysiology and experimental studies of chronic subdural hematomas.[2]

The majority of extra-axial fluid collections result from head trauma. Other causes include bacterial meningitis (postinfectious) and the placement of a ventriculoperitoneal shunt. The etiology of intracranial hemorrhage and extra-axial fluid collections are quite varied (**Table 120-1**). Acute and chronic subdural fluid collections are common problems during infancy. Males are affected more commonly than females. **A clear history of injury or trauma should be sought in the presence of an acute or chronic subdural hematoma. Consider the possible etiology of child abuse if a history of injury is not forthcoming or if the history does not make sense. It is incumbent upon the medical team to rule out abuse.** This may require a period of inpatient observation, social services consultation, a radiographic skeletal survey, a bone scan, and possibly an ophthalmological assessment. **The presence of retinal hemorrhages in association with a subdural fluid collection is highly suspicious for child abuse.** Admission to the hospital for further observation is warranted if child abuse cannot be ruled out. The presence of congenital anomalies may predispose the child to subdural hematoma formation.

Percutaneous removal of the subdural fluid is useful in diagnosing an active infection and rapidly lowering the intracranial pressure in the symptomatic patient. Repeated removal of the fluid by percutaneous aspirations has been advocated by some Neurosurgeons for definitive treatment of chronic extra-axial fluid collections.[3,4] Subdural fluid collections in infants have a tendency to increase in size, are often bilateral, can be difficult to diagnose, and are most often seen in children under the age of 2 years. The combination of CT and MRI is usually diagnostic.

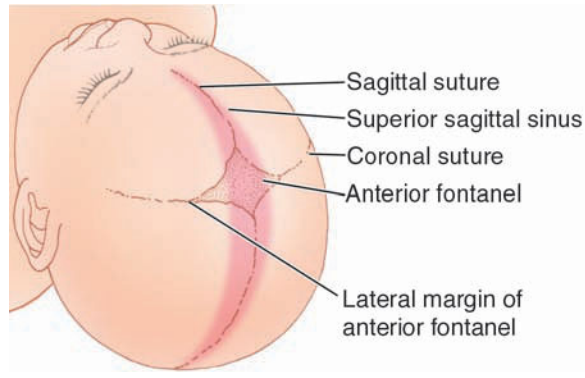

FIGURE 120-1. Surface anatomy of the infant skull. The shaded area represents the underlying superior sagittal sinus.

ANATOMY AND PATHOPHYSIOLOGY

A subdural aspiration (or tap) is usually performed by puncturing the anterior fontanel. However, it can also be approached through the coronal suture as well as through the soft cranium. The diamond-shaped anterior fontanel is formed by the junction of the sagittal, coronal, and frontal sutures (**Figure 120-1**). It measures approximately 4 cm in the anteroposterior plane and 2.5 cm in the transverse plane. The bones of the infant calvarium are separated by connective tissue bands referred to as sutures. The fontanels are readily palpable at the junctions of the sutures. Six of the fontanels are located at the corners of the two parietal bones. Two of these, the anterior and posterior fontanels, are in the midline.

The anterior fontanel, the largest of the neonatal fontanels, is utilized for percutaneous subdural aspiration. The diamond-shaped anterior fontanel is formed by the junction of the sagittal, coronal, and frontal sutures (**Figure 120-1**). It measures approximately 4 cm in the anteroposterior plane and 2.5 cm in the transverse plane. The posterior fontanel is at the junction of the lamboidal and sagittal sutures. In general, the anterior fontanel has usually closed by 18 months of age but can be patent up to the age of 2 years. The posterior fontanel usually closes earlier in life and is usually complete by 6 weeks of age.

The anterior fontanel is composed of connective tissue and easily perforated with a spinal needle. Continued advancement of the needle would then perforate the underlying dura, allowing the tip of the needle to rest within the subdural space. Traversing the dura is usually associated with a definite change in resistance as the subdural space is entered. Successful entry of the tip of the needle into the subdural fluid collection can be confirmed by removal of the stylet and observing spontaneous drainage from the needle hub. The anterior fontanel is readily palpable and bulging in cases of symptomatic chronic extra-axial fluid collections. The lateral extent of the anterior fontanel is continuous with the coronal suture (**Figure 120-1**).

INDICATIONS

A subdural aspiration is performed for diagnostic purposes as well as for rapid decompression of subdural fluid collections, whether acute or chronic. Perform a subdural aspiration in the young child with a subdural fluid collection and radiographic signs of elevated intracranial pressure, a depressed level of consciousness, and/or a changing level of consciousness.[5] Other indications to perform a subdural aspiration include the clinical signs and symptoms associated with elevated intracranial pressure: bulging fontanelles, coma, cranial nerve palsies, hemiparesis, hypotonia, irritability, lethargy,

posturing, seizures, somnolence, and vomiting (repeated or intractable). Aspiration of extra-axial fluid collections can reduce intracranial pressure dramatically. Subdural aspiration of fluid allows for culture and sensitivity, identification of microorganisms, and aids in the selection of bacterial specific antimicrobial agents if an infectious etiology is considered to be the cause of the extra-axial fluid collection.

CONTRAINDICATIONS

The main contraindications to performing a subdural aspiration include localized infections of the scalp, patients who are coagulopathic or thrombocytopenic, children over the age of two, children who have an absence of the anterior fontanel as a result of premature closure, a solid clot that is not liquefied, and children with congenital anomalies of the skull or brain. This procedure should not be performed by those unfamiliar with the technique and its complications. Consult a Neurosurgeon, if available, prior to performing this procedure. Repeated aspirations are rarely indicated as blood or fluid reaccumulation often requires the placement of a drain or a surgical procedure by a Neurosurgeon.

EQUIPMENT

- Sterile skin prep kit
- Povidone iodine or chlorhexidine solution
- Sterile gloves and gown
- Face mask with an eye shield or goggles
- Sterile drapes
- 1% or 2% lidocaine, with or without epinephrine
- 18 to 22 gauge, 1.5 in. spinal needle or angiocatheter
- Tincture of benzoin
- Cotton swab
- Bandage
- Bundling blanket
- Commercially available immobilization device
- Syringe for aspirating fluid
- Sterile specimen containers
- Culture bottles or swabs
- IV extension tubing, optional

All of the basic equipment can be found in commercially available pediatric lumbar puncture kits. The kit needs to be supplemented with personal protective equipment and skin antiseptic.

PATIENT PREPARATION

The patient should be fully monitored with a noninvasive blood pressure cuff, pulse oximetry, cardiac monitor, and end-tidal carbon dioxide monitor (if available). Obtain a CT scan of the head to determine the presence of an extra-axial fluid collection, the location and extent of the fluid collection, the type of fluid (e.g., blood, pus, etc.), and to rule out the presence of a mass. Obtain a complete blood count (hemoglobin, hematocrit, and platelet count) and a coagulation profile (PT, PTT, and INR) to ensure that the patient is not thrombocytopenic or coagulopathic.

Explain the procedure to the parents and/or guardian of the child if time permits. Obtain an informed consent to perform the procedure. Place the patient supine on a stretcher. The child may need to be restrained to prevent movement during the procedure. Bundling an infant in a blanket and placing their head close to the edge of the bed facilitate aspiration. An alternative is to use a commercially available immobilization device (e.g., Papoose board). The aid of an assistant to hold the child's body with the head straight and upright is recommended if the child is restless. Some children may require the administration of parenteral sedatives or procedural sedation.

This procedure requires strict aseptic technique. Shave the frontal and parietal regions of the child's head. Clean any dirt and debris from the scalp. Identify by palpation the anterior fontanel, the coronal suture, and the lateral margin of the coronal suture. The Emergency Physician should don full sterile and personal protective equipment at this point. This should include sterile gloves, a sterile gown, a face mask with an eye shield or goggles, and a cap. Apply povidone iodine or chlorhexidine solution to the skin over the entire scalp and allow it to dry. Ensure that the solution is not allowed to drain onto the baby's face or eyes. Apply sterile drapes leaving the frontal and parietal regions of the skull exposed. A local anesthetic agent is usually not required but may be used at the Emergency Physician's discretion. If used, place a skin wheal using 0.25 to 0.50 mL of 1% or 2% lidocaine at the site the needle will enter the scalp.

TECHNIQUE

Form a Z-tract by gently sliding the scalp skin laterally (**Figure 120-2**). Insert a 22 gauge spinal needle into the lateral margin of the anterior fontanel, about 2.5 to 3 cm off the midline (**Figure 120-2**). Advance the spinal needle beneath the frontal bone until the subdural space is penetrated. This is usually within 5 to 8 mm from the skin surface. A loss of resistance is usually appreciated as the dura is penetrated and the subdural space is entered. **Do not advance the needle any further. Securely hold the spinal needle so that it does not move (Figure 120-3).** An alternative is to insert the needle at a 45° angle to the skin surface, tunnelling it under the scalp and into the subdural space (**Figure 120-4**). Remove the stylet. Spontaneous drainage is often appreciated. This fluid may appear hemorrhagic. However, it is not uncommon, especially in patients who require multiple aspirations, to drain xanthochromic fluid.

The initial subdural aspiration usually results in spontaneous drainage through the spinal needle. The spontaneous cessation of flow through the needle suggests that the extracranial and intracranial pressures are equalized, not that the fluid has been completely evacuated. If the fluid does not spontaneously drain, carefully and gently apply a syringe to the spinal needle and gently aspirate the fluid. **Use minimal negative pressure to just aspirate**

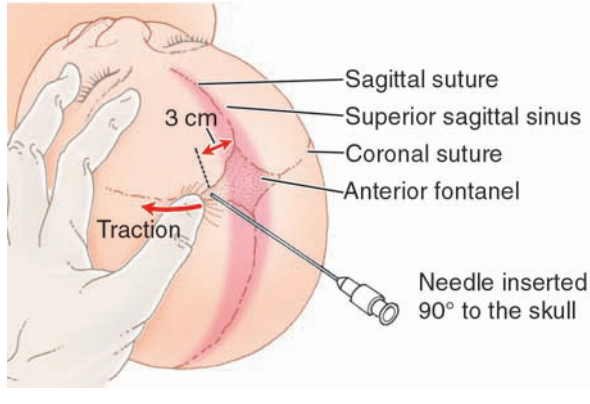

FIGURE 120-2. Subdural fluid aspiration. The needle is inserted at the lateral border of the coronal suture and at 90° to the skull.

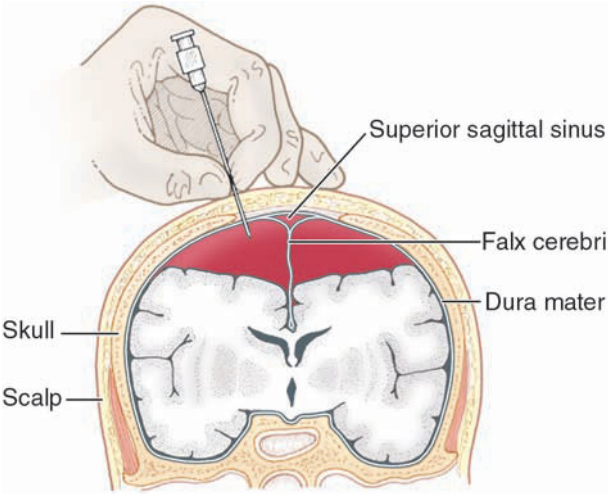

FIGURE 120-3. Coronal section through the skull at the level of the coronal suture. The needle is visible along its trajectory.

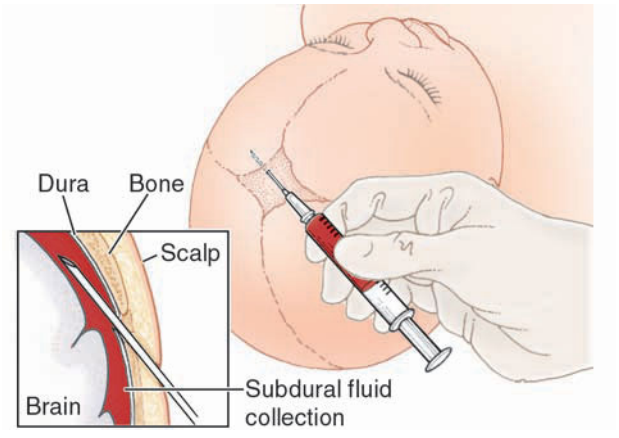

FIGURE 120-4. An alternative method for subdural fluid aspiration. The inset shows the oblique trajectory of the needle into the subdural space.

the fluid collection and prevent pulling the brain or any bridging veins into the needle. Alternatively, apply digital pressure to the anterior fontanelle to increase the flow through the spinal needle. Some Physicians may choose to apply intravenous extension tubing to the spinal needle to allow the subdural fluid to drain away from the patient and directly into the specimen tubes. This is left to the Emergency Physician's preference. Observe the gradual flattening of the anterior fontanel to determine the endpoint for the procedure.[6] Generally, on any one occasion, no more than 25 to 30 mL of subdural fluid should be aspirated. Larger volumes, up to 80 mL, have been safely aspirated.[7] Remove the spinal needle and apply a bandage.

ALTERNATIVE TECHNIQUES

Consult a Neurosurgeon to evaluate and manage the patient. There are numerous alternatives to the aspiration of the fluid collection. These include observation, burr hole drainage, drainage through an external collecting system, placement of a subdural-to-peritoneal shunt, and a craniotomy. A craniotomy should be performed in patients with a symptomatic nonliquefied clot or extensive membrane development precluding aspiration.

Some Physicians prefer to use an intravenous catheter rather than the spinal needle. Removal of the metal needle leaves a soft Teflon catheter in place that minimizes the risk of injury to the brain or intracranial vascular structures. The use of an intravenous catheter set rather than a spinal needle is left to the discretion of the Emergency Physician.

ASSESSMENT

Monitor the child for a change in their level of functioning after subdural aspiration. Comparison to the child's baseline neurological examination is essential. It is mandatory to document timed serial neurological examinations in the patient's chart. The clinical examination is age-related. It is often prudent to observe the infant in the arms of a parent or healthcare worker while monitoring their level of alertness, facial expression, extraocular movement, pupillary response, and limb movement. Obtain daily head circumference measurements and plot them on a head circumference chart. Note the size and feel of the anterior fontanel. Infection can be prevented with careful attention to aseptic technique. A simple bandage placed over the puncture site is usually sufficient and can be removed 48 to 72 hours after the procedure. Continued spontaneous drainage through the puncture site should be monitored carefully as it poses an infectious risk.

AFTERCARE

Perform an ultrasound or CT scan of the head to determine if the fluid collection has been adequately drained. Bedside ultrasonography is an effective tool in neonates and young children. Any change in the child's neurological examination requires an emergent head CT scan or ultrasonography to determine if the subdural fluid collection has reaccumulated. Send the aspirated fluid for the appropriate laboratory analysis if an etiology other than an acute traumatic hemorrhage is suspected. This can include a biochemistry analysis (glucose and protein level), cell count and differential, culture (bacterial, fungal, viral, etc.), cytology, and gram stain. Admit the child to the Intensive Care Unit where they can be appropriately monitored and observed.

COMPLICATIONS

Injury to the superior sagittal sinus or draining veins is best avoided by inserting the spinal needle 2.5 to 3 cm lateral to the midline. **At no time should the trajectory of the needle be in the midline or parasagittal in location.** Overpenetration of the spinal needle can result in intracerebral hemorrhage. Have an assistant immobilize the child to prevent them from moving and the needle lacerating the brain or a blood vessel. Persistent leakage of subdural fluid from the puncture site can be the result of insufficient fluid aspiration or failure to use a Z-tract. This complication can also be prevented by tunneling the needle under the scalp prior to penetrating the lateral margin of the anterior fontanel (**Figure 120-4**). This leakage can usually be controlled with local pressure, head elevation, and rarely by using cotton soaked with tincture of benzoin. Placement of a single suture at the puncture site will usually control continued leakage if less invasive methods fail. Introducing infection into the subdural space has also been reported following a subdural aspiration.[8] This is best avoided by maintaining strict aseptic technique.

SUMMARY

Acute and chronic subdural fluid collections are common problems during infancy. They are regarded as posttraumatic lesions in the great majority of cases. Birth trauma is sometimes implicated

but uncommon. It appears that minor injuries during infancy or even more violent injuries such as infant shaking and/or cranial impact are the inciting events. It is incumbent upon the Emergency Physician to rule out any possibility of child abuse! Report actual or suspected abuse to the appropriate state agency as required by law. Aspiration of extra-axial fluid collections in the symptomatic child can be completed safely with very little risk to the child. Admission and continued observation are mandatory.

121 Skeletal Traction (Gardner-Wells Tongs) for Cervical Spine Dislocations and Fractures

Eric F. Reichman

INTRODUCTION

Traumatic injuries to the cervical spine result from forces acting on the head and neck. The incidence of spinal cord injury in the United States is approximately 5 per 100,000 population.[1] Approximately 60% to 80% of spinal cord injuries involve the cervical spine. Motor vehicle collisions are the most common cause and account for almost half of the cervical spine injuries.[2] The remaining cervical spine injuries result from falls, sports injuries, violence, penetrating wounds, and miscellaneous causes.

The primary aims of therapy in the treatment of the patient with an acute spinal cord injury are to minimize secondary injury to the spinal cord, to realign the spine, to improve neurological recovery, to maintain spinal stability, and to obtain an early functional recovery. This is achieved by decompression of the spinal cord by restoring the normal sagittal diameter of the spinal canal or by removing a compressive lesion surgically. This is particularly important in patients who have sustained an incomplete spinal cord lesion and are found to have a progressing neurological deficit. Restoring the normal anatomic position also provides for pain relief.

Early operative intervention can be performed for the treatment of acute cervical fractures to achieve decompression and restore normal alignment. The use of skeletal traction in the acute spinal cord injury patient remains a very safe and straightforward method of reducing fractures and maintaining the spinal canal in anatomical alignment.

Fabricius Hildanus utilized forceps in treating fractures or dislocations of the cervical spine as early as 1646. Crutchfield developed a pair of self-tightening tongs in 1933 that allowed him to apply traction to the cranium in a patient with a cervical spine fracture.[3] These tongs were subsequently modified and have essentially been replaced by the Gardner-Wells tongs.[4]

ANATOMY AND PATHOPHYSIOLOGY

Cervical spinal cord injuries can be divided into upper (occiput to C3) and lower (C3 to C7) injuries. Numerous classification systems exist. These are based upon the morphology and the mechanism of injury.[5] No classification is ideal. However, critical to all cervical classifications is the determination of stability of a fracture or dislocation. Stability of the vertebral column is dependent upon the integrity of the vertebra, the intervertebral disk, the facet joints, and most importantly the ligamentous structures.

Clinical stability of the cervical spine is determined by the ability of the spine under physiological loads to maintain its normal anatomical relationship so that there is no damage to the spinal cord or nerve roots. It has been proposed that spinal instability be separated into mechanical, neurologic, and combined types. Mechanical instability implies that the injured spine could collapse or distort under normal physiological stresses. Neurological instability implies a risk of neural injury (spinal cord and/or nerve root) subsequent to the initial injury.

It is exigent that a thorough clinical and radiological evaluation be completed to determine if the patient has suffered an unstable cervical spine injury. This begins with a thorough history and physical examination, including a complete neurological examination with particular attention to spinal cord function. Cervical spine radiography (including possibly CT, MRI, and myelography) is indicated to evaluate fracture patterns, disk disruption, vertebral subluxation, vertebral dislocation, vertebral angulation, and ligamentous injury. Ligamentous injury evaluation should look for disruption of each of the major spinal ligaments including the anterior longitudinal ligament, the posterior longitudinal ligament, the apophyseal ligamentous complex, and the posterior ligamentous complex. Radiological findings that indicate instability include vertebral displacement, interspinous process widening, diastasis of the apophyseal joints, widening of the spinal canal, and disruption of the posterior vertebral body line.

White and Panjabi proposed a checklist point value system (**Table 121-1**).[6] A point value is assigned to each of the injuries appreciated on the cervical spine radiographs. A specific point value is allotted to the location of injuries, sagittal plane translation or rotation, spinal cord injury, nerve root injury, and the presence of intervertebral widening, rotation, or angulation. The total point values are then summated. A score of five or more is suggestive of clinical instability. A discussion of the indications for the application of the Gardner-Wells tongs includes evidence of cervical spine instability.

Crutchfield is credited for introducing skeletal tongs in the management of cervical spinal injuries.[3] Gardner-Wells tongs were introduced in the early 1970s and utilize the principle of a spring-loaded point for cervical traction.[4] The spring-loaded pin design and tilting of the pins in the direction of pull ensure a firm and prolonged grasp of the skull. These tongs have the capacity to tolerate at least 65 pounds or more of traction. The amount of weight necessary to accomplish reduction varies considerably. As a rule, 5 pounds of weight should be applied for each vertebral level above the level of the fracture or the dislocation. Most authors have recommended the use of up to 50 to 60 pounds of weight.[7] Others have, on occasion, applied weights in excess of 100 pounds to reduce a cervical subluxation.[8]

TABLE 121-1 Checklist for the Diagnosis of Clinical Instability in the Lower Cervical Spine[6]

Element	Point value*
Anterior element destroyed or unable to function	2
Posterior element destroyed or unable to function	2
Relative sagittal plane translation > 3.5 mm	2
Relative sagittal plane rotation > 11°	2
Positive stretch test	2
Spinal cord damage	2
Root damage	1
Abnormal disk narrowing	1
Dangerous loading anticipated	1
Developmentally narrow spinal canal	1

*Summate the points. A total of five or more points is considered clinically unstable.

The concern for using an excessive amount of traction weight is overdistraction that can result in a traction type of spinal cord injury. Begin by applying 5 to 10 pounds of weights.[2] Add additional weight in 3 to 5 pound increments if the initial application of weights fails to achieve spinal alignment. Obtain lateral cervical spine radiographs 10 to 15 minutes after each addition of weight until the cervical spine is realigned. This time is needed after the application of weight to allow the soft tissues to accommodate. **It is of paramount importance to monitor the patient's neurological status during the entire procedure to prevent iatrogenic injury from overdistraction of an unstable motion segment.**

INDICATIONS

Definitive management of the cervical spine injury would include skeletal traction with Gardner-Wells tongs if clinical instability is demonstrated or suspected. Other indications for the application of Gardner-Wells tongs in a neurosurgical setting are cervical spondylosis, anterior cervical diskectomy with graft fusion, and certain cervical infections or neoplasms. Gardner-Wells tongs should only be applied if the patient requires temporary longitudinal traction.[9] Their use requires the patient to remain bedridden, as compared to halo vest traction.

CONTRAINDICATIONS

Cervical traction is contraindicated in someone who has sustained posttraumatic disc herniation with spinal cord compression. Hence, a good neurological evaluation and an MRI scan should be performed prior to applying cervical traction. Fractures of the skull and infections overlying the potential pin sites are contraindications to the use of skeletal traction. Other contraindications are diseased bone, children less than 3 years of age, atlantooccipital dislocations, and C1-C2 dislocations. Applying Gardner-Wells tongs to someone who survives an atlantooccipital type injury could worsen the patient's condition and/or neurological deficit.

EQUIPMENT

- Prep kit
- Povidone iodine or chlorhexidine solution
- 1% or 2% lidocaine with epinephrine
- 5 mL syringe
- 18 gauge needles
- 22 gauge needles
- Gardner-Wells traction tongs
- Pulley traction system
- Traction weights, 3 to 5 pound increments

Gardner-Wells tongs are a simple device (**Figure 121-1**). It consists of a contoured and rigid stainless steel rod that follows the coronal contour of the calvarium. Gardner-Wells tongs are also available in versions composed of graphite or titanium alloy. These versions are compatible with and facilitate subsequent CT and MRI scans without producing artifacts. It has a threaded hole on each end that accommodates the pins. The spring-loaded pins are threaded screws with sharp cone-shaped points. One of the pins is the calibration pin (**Figure 121-2**). It contains an indicator pin that extends and retracts as the tip penetrates the skull. The pins screw into the rigid rod so that the points are tilted in the direction of the pull. This results in the pins pressing into the skull when traction is applied and ensuring that they do not pull out. A squeezing pressure of 30 pounds is applied to the skull when the pins are properly positioned.[3] An

FIGURE 121-1. The Gardner-Wells tongs.

S-shaped hook is permanently attached to the top of the Gardner-Wells tongs. The string and traction weights are attached to this hook. Permanently attached to the S-hook is a metal plate that is engraved with the instructions (**Figure 121-3**). **The instruction plate faces upward and is readable when the Gardner-Wells tongs are properly applied (Figure 121-4).**

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain an informed consent to apply the Gardner-Wells tongs. Signed consent may be omitted in cases where the patient is immobilized or has an altered mental status. Document the reason for the lack of a signed consent in the medical record. Intravenous sedation may be required in certain cases, at the discretion of the treating Emergency Physician.

Consider the use of some form of deep venous thrombosis prophylaxis since the application of Gardner-Wells tongs requires the patient to remain bedridden. The use of sequential compressive devices (SCDs) is simple, easily applied in the Emergency Department, and will not cause complications. Consult a Spine Surgeon or Neurosurgeon before prescribing intravenous, oral, or subcutaneous anticoagulants.

Identify the anatomic landmarks required to place the Gardner-Wells tongs. The pins are introduced in the temporal region, 2 to 3 finger-breadths (3 to 4 cm) above the pinna of the ear (**Figure 121-5**). Place them directly above the external auditory meatus for neutral distraction, 2 to 3 cm posterior to the external auditory meatus for flexion distraction, and 2 to 3 cm anterior to the external auditory meatus for extension distraction. A helpful landmark is the squamosal line where the temporalis muscle inserts into the skull. Tong placement should be below this line to allow

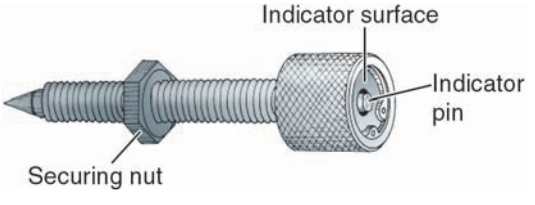

FIGURE 121-2. The calibration pin of the Gardner-Wells tongs.

FIGURE 121-3. Instructions for the use of the Gardner-Wells tongs.

FIGURE 121-4. Application of the Gardner-Wells tongs to a human skull.

adequate traction. Another useful landmark is to observe for the widest biparietal diameter of the patient's skull. This usually corresponds to the landmark just inferior to the squamosal line.

The use of Gardner-Wells tongs does not require shaving the patient's hair at the proposed pin sites. Clean the skin and hair of any dirt and debris. Apply povidone iodine or chlorhexidine solution to the skin and hair at the proposed pin sites and allow it to dry. Infiltrate 1 mL of lidocaine with epinephrine into each of the two proposed pin sites. Infiltrate subcutaneously and down to the level of the periosteum of the skull.

TECHNIQUE

The Gardner-Wells tongs are fast and easy to apply by one person. The patient should already be supine on the gurney. Stand above the patient's head. Assemble the Gardner-Wells tongs by inserting the pins into the threaded holes. Place the pins of the Gardner-Wells tongs over the proposed pin insertion sites. **The instructions on the S-hook must be facing upward and readable. If not, the tongs are upside down.** Apply the Gardner-Wells tongs so the pins are symmetrically located on each side of the head. Screw in the pins equally and symmetrically on both sides of the tongs (**Figure 121-5B**). Note that a small spring-loaded indicator pin is observed on one side of the tongs when adequate tension is applied (**Figures 121-2 & 6**). Recommendations by the manufacturer suggest that the pins should be tightened simultaneously until there is a 1 mm protrusion of the indicator pin beyond the flat surface (**Figure 121-6**). Tighten the securing nuts to prevent the tongs from loosening.

The points of the pins will not pull out when properly applied. The depth of penetration of the pins is self-limited by a gradual lessening of the spring tension and an increase in the surface area of contact between the tips of the pins and the skull. The pressure exerted by each pin is exactly the same, regardless if one pin has been advanced farther than the other. The curve of the rigid rod allows the traction loop to find its proper position.

ASSESSMENT

Gently rock the Gardner-Wells tongs to assure that the pins are properly seated within the outer table of the skull (**Figure 121-7**). Place the patient in the reverse Trendelenburg position (**Figure 121-8**). Tie a rope to the S-shaped hook. Feed the other end of the rope through a pulley at the head of the bed and apply weights. Proper attention to the head position and the axis of distraction are important elements in achieving closed reduction. Initially apply

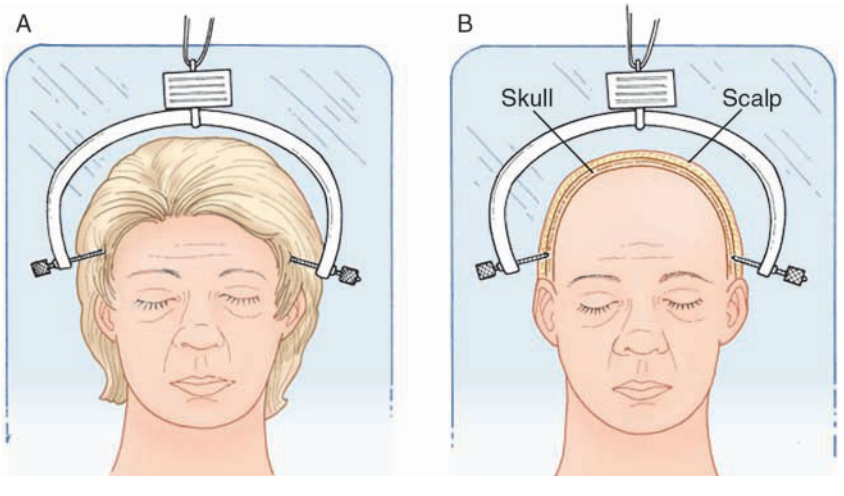

FIGURE 121-5. Application of the Gardner-Wells tongs. **A.** It can be positioned and applied without shaving the patient's entire head. **B.** Schematic demonstrating the pin position into the skull.

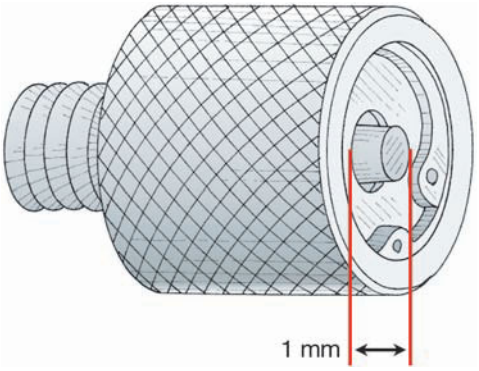

FIGURE 121-6. The calibration pin indicator is at 1 mm when the pins are properly seated in the skull.

a 10-pound weight for the head.[6] Obtain a lateral cervical spine radiograph 10 to 15 minutes after the application of the weight. Add 5 pound weights, one at a time, for each vertebral segment above the level of the injury. Obtain a lateral cervical spine radiograph 10 to 15 minutes after each 5 pound weight is added. Continue to increase the traction weight in 3 to 5 pound increments. Obtain repeat lateral cervical spine radiographs 10 to 15 minutes after each additional weight is added. Stop adding weights when the radiographs demonstrate appropriate alignment of the cervical spine. **Careful assessment and documentation of the patient's neurological function is mandatory throughout the application of weights and skeletal traction.**

AFTERCARE

Clean the pin sites every shift with povidone iodine or hydrogen peroxide solution followed by iodine ointment. Obtain daily cervical spine radiographs to follow the spinal alignment. Reduce the weight by 50% to maintain the alignment if spinal realignment is obtained with traction.

The points of the pins tend to penetrate the outer table of the skull due to the continuous pressure exerted by the springs on a very small area. Readjust the pins in 24 hours, again setting the indicator pin so that it protrudes approximately 1 mm from the flat surface. Further adjustment of the Gardner-Wells tongs is not necessary and is not recommended as it can result in erosion of the pin point through the skull.

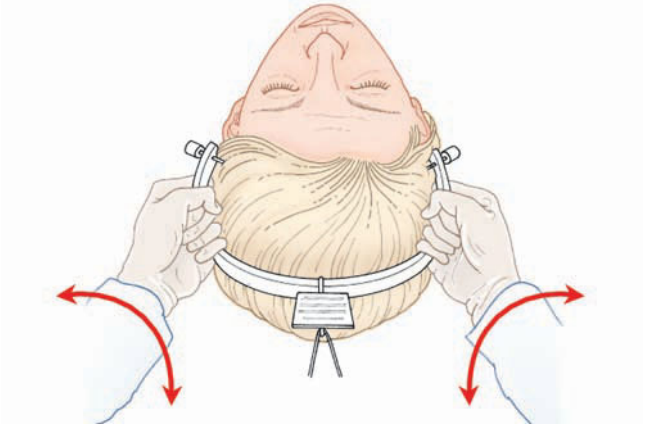

FIGURE 121-7. The Gardner-Wells tongs have been applied. The arms are grasped and gently twisted to confirm proper seating of the pins.

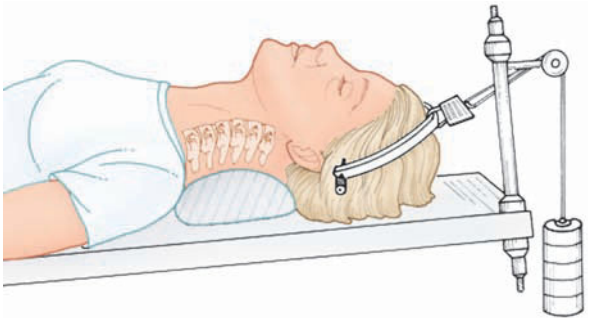

FIGURE 121-8. The patient is placed in reverse Trendelenburg and traction is applied.

COMPLICATIONS

Skull penetration from placing the pins too low in the temporal region where the skull is thinnest can lead to dural tears, epidural hematomas, and possibly intracranial injury. Pins located in the temporal fossa pierce the temporalis muscle and can cause painful mastication. Overdistraction can lead to iatrogenic injury. This is best prevented by the initial use of a minimal amount of weight necessary to distract or reduce the cervical spine injury. Pin site infections are prevented by close attention to surgical technique and daily hygiene. Other complications reported include intracranial aneurysms, CSF leaks, and osteomyelitis of the skull.

SUMMARY

The application of skeletal traction in the form of Gardner-Wells tongs is a safe, simple, and quick procedure when there is evidence of clinical or radiological cervical spine instability. It requires only local anesthesia and antiseptic preparation of the skin. Careful attention to the application technique utilizing the suggested anatomical landmarks will reduce the chances of complications. Monitoring realignment and/or reduction procedures with frequent cervical spine radiographs is prudent. Gardner-Wells tongs are not recommended as a long-term immobilization technique. Definitive management of cervical spine instability requires surgical stabilization and/or halo bracing.

122 Edrophonium (Tensilon) Testing

Eric F. Reichman

INTRODUCTION

Myasthenia gravis is an autoimmune disorder that occurs when polyclonal antibodies bind to a significant number of postsynaptic acetylcholine receptors at the neuromuscular junction leading to inadequate neuromuscular transmission.[1–3] It most commonly affects 10- to 30-year-old females and 70- to 90-year-old males. Multiple tests are available to diagnose myasthenia gravis.[3–7] These include the use of muscle biopsies, curare, edrophonium chloride (Tensilon), electromyography, ice packs, neostigmine, nerve stimulation, and serologic testing. The edrophonium test is the most commonly used diagnostic test for myasthenia gravis.[8–10] Many of these techniques are seldom used and not feasible

to perform in the Emergency Department. For these reasons, only the edrophonium test and the ice pack test will be described in this chapter.

ANATOMY AND PATHOPHYSIOLOGY

Acetylcholine is a neurotransmitter of the neuromuscular junction that is released by the presynaptic nerve terminals when stimulated.[4,11] An electrical potential is produced at the myoneural end plate when sufficient numbers of the postsynaptic receptors at the neuromuscular junction are bound by the released acetylcholine. This electric potential then propagates and ultimately leads to muscle contraction. Simultaneously, acetylcholinesterase rapidly terminates the neurotransmission by metabolizing the acetylcholine in the synaptic cleft of the neuromuscular junction.

Myasthenia gravis is an autoimmune disorder that occurs when polyclonal antibodies bind to postsynaptic acetylcholine receptors at the neuromuscular junction.[2–4,11] This leads to inactivation of the receptors and inadequate neuromuscular transmission. Myasthenia gravis is characterized clinically by muscle weakness that develops after repetitive muscle contraction.

Patients are divided into two clinical groups. The first includes patients who present with ocular complaints. Patients most commonly present with some degree of ocular muscle involvement. Diplopia is the most common patient complaint. Ptosis is the most visible sign noted on the physical examination. Diplopia with disconjugate gaze can be elicited by having the patient maintain a vertical gaze for approximately 3 minutes. Ptosis can also be made to worsen by having the patient maintain an upward gaze for the same duration of time. These patients may or may not have associated weakness of the pharyngeal and facial muscles that present with the complaints of dysarthria and dysphagia. These symptoms can often be elicited by having the patient count backward from 100.

The second group includes patients with proximal muscle weakness. Weakness of the limbs usually involves the proximal muscles and may be asymmetric. Weakness of the muscles can be elicited by having the patient perform repetitive exercises involving the muscle groups in question. **Involvement of respiratory and pharyngeal muscles should be taken very seriously as it may lead to respiratory failure or aspiration.**[2,3,12–15]

Edrophonium chloride is a short-acting acetylcholinesterase inhibitor (anticholinesterase) used in the diagnosis of myasthenia gravis.[3,11] Its onset of action is rapid (within 1 to 2 minutes) and the duration of action is brief (2 to 5 minutes). These characteristics make it ideal to use in the Emergency Department. Edrophonium given intravenously to patients with myasthenia gravis briefly inhibits the actions of the acetylcholinesterase, thus prolonging the interaction between the acetylcholine and the postsynaptic receptors. This results in a temporary but noticeable improvement in muscle contraction.[1,14] Edrophonium can rapidly, and temporarily, reverse the signs and symptoms of myasthenia gravis.

INDICATIONS

Testing is indicated when the patient's condition is suggestive of myasthenia gravis.[4,5] Edrophonium chloride can be used for patients presenting with diplopia, facial muscle weakness, appendicular muscle weakness, or ptosis suggestive of myasthenia gravis. The ice pack test is reserved to evaluate patients presenting with ptosis.[16–18]

CONTRAINDICATIONS

There is the possibility of worsening the patient's symptoms, causing respiratory distress or arrest, and cardiac dysrhythmias. Do not administer edrophonium if resuscitative equipment, Advanced Cardiac Life Support medications, and additional support personnel are not immediately available. Edrophonium should not be administered if the Physician is not properly trained in airway management and rescue techniques. Use caution when administering edrophonium if the patient's medications can cause atrioventricular node blocking or slowing of transmission (e.g., beta-blockers, calcium channel blockers, and digoxin). These can make the edrophonium associated dysrhythmias more pronounced.

Edrophonium testing is relatively contraindicated in patients with known myasthenia gravis that are taking oral pyridostigmine (Mestinon) and present with increasing weakness. The weakness may be due to insufficient drug treatment (myasthenic crisis) or too much drug treatment (cholinergic crisis).[3] The terminology regarding these types of crises is controversial and beyond the scope of this chapter.[19,20] The patient will improve with edrophonium testing if the etiology of the weakness is a myasthenic crisis. The symptoms will worsen with edrophonium testing if the etiology of the weakness is a cholinergic crisis. Consult a Neurologist, for these reasons, prior to performing an edrophonium test on a patient with myasthenia gravis who is already taking oral anticholinergic medications.

A patient with known myasthenia gravis complaining of respiratory distress should be assessed and managed similar to any other patient with respiratory compromise. An edrophonium test is contraindicated if it is being used to improve a patient's respiratory distress. A cholinergic crisis treated with edrophonium can further compromise the patient's respiratory status, possible leading to a respiratory arrest.

The use of edrophonium is contraindicated in pregnancy. It may induce the patient into preterm labor. A neostigmine test is safer if testing is required. Testing should be performed only after consultation with an Obstetrician and a Neurologist.

Edrophonium testing is relatively contraindicated in patients with asthma, bronchospastic disease, cardiac dysrhythmias, or if a group of muscles that are weak are not easily observable. Edrophonium testing should be deferred in favor of neurological consultation and consideration of other testing methods.

EQUIPMENT

- 10 mg edrophonium chloride (Tensilon)
- Tuberculin syringe
- 10 mL syringe containing 9 mL of sterile normal saline
- Intravenous access with normal saline solution attached to the IV catheter
- Cardiac monitor
- Pulse oximeter
- Noninvasive blood pressure monitor
- Supplemental nasal oxygen
- Resuscitative equipment and medications
- Digital camera
- Ice pack, ice cubes, or instant cold packs

PATIENT PREPARATION

Explain the risks, benefits, and potential complications to the patient and/or their representative. Obtain a signed consent for the procedure. Place the patient sitting upright or supine in a bed. Obtain intravenous access. Apply supplemental oxygen, pulse oximetry, cardiac monitoring, and noninvasive blood pressure monitoring. **Resuscitative equipment and medication must be immediately available if required.**

Identify a group of muscles that can easily be observed and monitored for improvement of function. If possible, the muscle group to be tested should be fatigued. For example, have the patient look upward for 3 minutes to accentuate ptosis. Muscle groups of the extremities can be exercised for several minutes until the patient experiences fatigue. Take a picture, if a camera is available, of the muscle group to be observed after it has been fatigued. This is the "before" photograph.

Prepare the edrophonium chloride. **It is essential that the edrophonium concentration be accurate regardless of who (i.e., Emergency Physician, Nurse, or Pharmacist) prepares the solution.** It is supplied in a concentration of 10 mg/mL. Using sterile technique, transfer 10 mg (1 mL of 10 mg/mL) of edrophonium into a syringe containing 9 mL of sterile normal saline. The resulting solution will contain 1 mg of edrophonium chloride per mL of fluid. **Verify the concentration of the edrophonium solution prior to use, especially if it was made by someone else.**

TECHNIQUE

Administer the edrophonium soon after the weakened muscle is identified, carefully noted, and fatigued. Ideally, one person should administer the medication while another person observes the patient for the effects of the edrophonium chloride. **It may be administered in increasing doses up to a total of 10 mg.** Inject 1 mg (1 mL) of edrophonium chloride intravenously followed by a saline flush. Physical improvement in the observed muscle group should be seen within 30 seconds to 2 minutes if the edrophonium is effective. Muscle improvements will revert to their original state after 2 to 3 minutes. **The test is concluded if there is a positive response to the edrophonium in the observed muscle group.** Inject 3 mg (3 mL) of edrophonium chloride intravenously followed by a saline flush if there is no improvement after the first dose. **The test is concluded if improvement is seen in the muscle group**. Inject the remaining 6 mg (6 mL) of the edrophonium chloride intravenously followed by a saline flush if there is no response within 2 to 3 minutes after the second dose. **The test is considered negative and concluded if there is no response to the third dose of edrophonium (total of 10 mg). A negative test argues against myasthenia gravis, but does not completely exclude the diagnosis.**[13,15]

Some Neurologists prefer to give the entire 10 mg (10 mL) dose of edrophonium chloride as a single intravenous bolus and observe the muscle group for improvement. **This has the potential to cause significant bradycardia and is not recommended.**

The total dose of edrophonium to administer to children is 0.15 mg/kg, not to exceed 10 mg of edrophonium.[5] An initial dose of 1 mg is appropriate for children. Administer subsequent doses of 1 to 2 mg to a maximum of 0.15 mg/kg or 10 mg of edrophonium.

ALTERNATIVE TECHNIQUE

ICE PACK TEST FOR OCULAR MYASTHENIA GRAVIS

The ice pack test can be used to diagnose patients with ocular signs of myasthenia gravis.[16–18] This test is reserved for the patient presenting with ptosis and/or diplopia suggestive of myasthenia gravis. The basis of this test is the finding that patients with myasthenia gravis have symptoms that worsen in warm weather and that improve in cold weather. Based on this clinical observation, studies have shown that placement of a bag of ice directly over the eyes of myasthenia patients with ptosis actually relieved the symptoms and signs of ocular myasthenia gravis.[16,17] This test is quick, simple, inexpensive, and easy to perform in the Emergency Department. It has none of the potential complications associated with the intravenous administration of edrophonium chloride. There are no contraindications to performing in this test.

Place a bag of ice directly over the eye with ptosis and/or diplopia for 2 minutes or until the patient is no longer able to tolerate the cold. An alternative to an ice pack is ice cubes placed in a glove or instant cold packs that are activated by compression. Remove the ice pack from the eye and observe the patient for any improvement in the ptosis or diplopia. **A clear improvement of the ptosis indicates a positive test.** This test may be limited by the patient's intolerance to the ice pack.

ASSESSMENT

These tests can be positive and confirm the diagnosis of myasthenia gravis. **Objective findings of improved muscle function must be observed to identify the test as positive.** It is very common to observe fasciculations of the facial muscles or tongue after the intravenous administration of edrophonium chloride. **Muscle fasciculations are not considered a positive test.** The patient having the subjective feeling of "feeling better" without objective evidence of improved muscle function is also not considered a positive test. Document improvement by taking a photograph. This is the "after" photograph. Place both the "before" and "after" photographs in the patient's medical record.

AFTERCARE

The patient may be safely discharged if they are ambulatory and without respiratory distress. All patients with suspected or proven myasthenia gravis should be referred to their Primary Care Physician and a Neurologist for further evaluation and management.

COMPLICATIONS

Muscarinic side effects can be seen due to the prolonged cholinergic stimulation in patients hypersensitive to edrophonium chloride. These effects include increased salivation, increased lacrimation, and miosis. Some patients may experience bradycardia, junctional rhythms, and ventricular dysrhythmias due to the increased vagal effects of the prolonged acetylcholine stimulation of the heart.[11] Older patients may experience a resultant postural syncope. **These effects are usually transient and self-limited. Intravenous atropine in low doses (0.5 mg) is effective to counteract any of the above symptomatology**.

There are no complications associated with the proper use of the ice pack test. Leaving the ice pack on the eyelids too long can result in a frostbite injury.

SUMMARY

Myasthenia gravis is an autoimmune disease that results in muscle weakness. The edrophonium test allows for a rapid, simple, and safe way to diagnose myasthenia gravis in the Emergency Department. The ice pack test for ocular myasthenia gravis offers a simple alternative to diagnose myasthenia gravis. Obtain prompt Neurological consultation for all patients presenting with signs and symptoms suggestive of myasthenia gravis.

SECTION 9

Anesthesia and Analgesia

123 Local Anesthesia

Michael A. Schindlbeck

INTRODUCTION

Modern medicine can trace the use of local anesthetics back to the year 1884, when the Austrian Physician Karl Koller first used topical cocaine to assist with an ophthalmological operation.[1] The following year, the premier Surgeon William Halstead first used injected cocaine to generate the intentional blockade of nerve transmission.[2] Unfortunately for Halsted, his experiments with cocaine soon led to a concurrent dependency.[3] The emerging illicit market for this compound soon prompted the search for a less toxic agent.[3] Procaine, more commonly known by its trade name Novocain, was the first synthetic local anesthetic. It is a benzoic acid ester derivative developed by the German chemist Alfred Einhorn in 1904. Although it had less drawbacks than its cocaine predecessor, it was far from the ideal agent. Lidocaine was the first amide local anesthetic agent and was first produced in 1945. The market for more effective agents continued to blossom. Over the following decades, no less than 20 additional agents were developed for use as a local anesthetic agent, each possessing unique pharmacokinetic properties to tailor its utility to specific clinical applications. They are all synthetic derivatives of cocaine.

Parallel to this proliferation in pharmacologic development, the clinical utilization of these agents has become widespread throughout all medical specialties. The daily practice of Emergency Medicine presents multiple scenarios that necessitate their use. The Emergency Physician must maintain a familiarity with the local anesthetic agents available and their unique characteristics, have an expertise in their delivery, be knowledgeable of the potential side effects, and know how to avoid and treat adverse reactions to ensure the safest and most optimal pain relief.

PHARMACOLOGY AND PATHOPHYSIOLOGY

At a cellular level, nerve cell function and signal conduction are dependent upon a resting negative intracellular electrical potential (approximately −70 mV) as compared to the surrounding extracellular environment. This polarity results from the abundance of sodium (Na^+) cations found within the extracellular space. Membrane-based sodium–potassium (Na^+/K^+) pumps establish this sodium gradient. Adjacent voltage-gated sodium channels maintain the gradient by inhibiting the concentration mediated and electrically driven sodium influx that would invariably result. Upon the stimulation of an idle neuron, a small intracellular sodium influx ensues. This sodium influx results in a slight depolarization of the resting membrane potential. When a critical threshold of sodium influx is met, the voltage-gated sodium channels reflexively open. This results in a massive sodium ion influx and widespread membrane depolarization.[4–6] Impulse transmission proceeds as this membrane depolarization is propagated down the entire length of the nerve fiber.[7]

Local anesthetic agents function by reversibly binding to membrane-based sodium channels, thereby inhibiting the initial sodium influx that results upon the stimulation of an idle neuron.[4–9] If a significant number of these channels are blocked, the critical threshold of sodium influx required for the voltage-gated sodium channel opening cannot be met, widespread membrane depolarization cannot occur and nerve impulses will not be transmitted. Careful examination of neuronal cells reveals that the actual binding sites for local anesthetic agents are located on the internal surfaces of their cellular membranes. Therefore, in order to function, the local anesthetic agent must first diffuse across the bi-lipid cellular membrane as an uncharged lipophilic compound. Once intracellular, the local anesthetic agent is converted to its active cationic state, terminating signal transduction and subsequently producing tissue anesthesia.[13]

All local anesthetic agents generally share the same molecular framework. They contain a lipophilic aromatic group linked to an ionizable group, usually a tertiary amine, via an intermediate linkage.[4,7] This intermediate linkage comes in two types, namely an amino-amide or an amino-ester bond. This property is used to classify the local anesthetics as either "amides" or "esters." Beyond this basic dichotomy, further variations on this generalized structure generate the altered pharmacokinetics that impart the unique qualities to the individual local anesthetic agents.[7]

The potency of a given local anesthetic agent is directly proportional to its lipid solubility.[9,10] More lipophilic agents tend to be more potent, as the more soluble agent will readily diffuse across the cellular membrane despite a lower concentration of the extraneuronal anesthetic. Therefore, a lower quantity of local anesthetic is needed to elicit the same endpoint response.[11] However, variable potencies are rarely of significance to the Emergency Physician. The available preparations utilize concentrations of the local anesthetic specifically formulated to correct for this variable potency.

The primary determinant of a local anesthetic's onset of action is its pKa.[12] The pKa is the pH at which a given drug exists in equal proportions as ionized and unionized molecules. The unionized molecules more readily cross the nerve cell membrane. A portion of the molecule becomes charged once inside the neuron. It is this ionized portion that binds most completely to receptor proteins within the sodium channels.[4,10] Commercially available local anesthetic agents are weak bases with pKa's of 7.6 to 8.9.[4] Agents with a lower pKa at physiologic pH (7.4) will have relatively more uncharged molecules free to cross the nerve cell membrane (i.e., faster onset) than agents with a higher pKa.[6,10] Low tissue pH, such as seen in abscess cavities, results in so little local anesthetic in the uncharged form that the agent is ineffective.[6] This phenomenon explains why local anesthetics function poorly in acidic environments (e.g., abscess cavities) as a greater percentage of the agent is secondarily converted to its ionized state within the extracellular environment. It also explains why the addition of a buffering agent such as sodium bicarbonate increases the pH of the injected local anesthetic solution, increasing the ratio of nonionized local anesthetic agent present, and enhancing the rapidity of anesthesia onset. Increasing the total quantity of local anesthetic injected, whether by manipulating its concentration or increasing the overall

volume, will hasten the onset of activity by augmenting the diffusion gradient and more aggressively driving the local anesthetic agent intracellularly.[7,8] Conversely, once successfully intracellular, local anesthetic agents with higher intrinsic pKa's generate more effective sodium channel blockade via their tendency to persist in an ionized and functionally active state.[8,13] The rate at which a local anesthetic agent diffuses through surrounding non-neuronal tissues also appears to be an important variable.[5,8]

A local anesthetic agent's duration of activity is typically proportional to the overall degree of protein binding.[6–8,10] Those that possess a higher affinity for the target receptor are less likely to be dislodged and thus exhibit a longer duration of action.[7,10] All of the available local anesthetic agents produce a degree of localized vasodilation. This serves to increase regional blood flow, promote systemic absorption of extracellular fluid, and thusly decrease the total duration of activity.[5,7,10] Therefore, counteracting this phenomenon by compounding a vasoconstrictor with the local anesthetic agent represents another practical way to increase the duration of action of a particular agent.[4,14] This is accomplished clinically via the addition of small doses of epinephrine.

The two classes of local anesthetic agents undergo metabolism via different mechanisms.[5,7,15–17] Esters are metabolized rapidly by plasma pseudocholinesterase to the major metabolite *para*-aminobenzoic acid or PABA.[5,7,15] PABA is allergenic and likely responsible for the infrequent allergic reactions to ester agents.[5,7,16] Patients with atypical pseudocholinesterase are at increased risk for systemic toxicity from ester anesthetic agents.[16,17] Amide anesthetic agents are metabolized more slowly by the liver to a variety of metabolites that are unrelated to PABA. Patients with impaired liver function are at increased risk for systemic toxicity from amide anesthetic agents.[16,17]

INDICATIONS

Local anesthetic agents are used in the Emergency Department for local infiltration, regional nerve blockade (Chapter 126), peripheral nerve blockade, and topical application (Chapter 124). General principles concerning their use and local infiltration will be discussed in this chapter. A complete review of specific techniques and procedures are available elsewhere in this text.

Localized injected anesthesia, or infiltrative anesthesia, represents the most common use of local anesthetic agents within the Emergency Department. It is generally a safe procedure that is technically easy to perform and well tolerated by the patient. It can be readily used for the majority of surgical procedures that are routinely performed by the Emergency Physician. This includes wound repair, foreign body removal, cutaneous abscess drainage, intravascular catheter placement, and hematoma blocks to name a few.

CONTRAINDICATIONS

The primary and most important contraindication to the use of a local anesthetic agent is a history of an allergic reaction. Less than 1% of all adverse reactions from local anesthetic agents are due to true IgE-mediated allergic phenomena.[18] Ester agents are responsible for the majority of such cases, whereas allergic reactions to amide anesthetics are exceptionally rare.[7,15,19–21] The physiology behind this finding is rooted in the divergent metabolism of the two classes of local anesthetic agents.

The ester-type local anesthetic agents are rapidly metabolized within the bloodstream by serum pseudocholinesterase, explaining their very short plasma half-lives. The secondary metabolites are derivatives of the organic compound PABA. They exhibit allergenic properties and are the agents responsible for the allergic response. This property makes ester-type local anesthetic agents (e.g., cocaine, procaine, and tetracaine) a less commonly used option in daily practice. Amide-type local anesthetic agents, however, are metabolized in the liver into nonallergenic byproducts via cytochrome P-450 mediated pathways. Allergic reactions to the amide-type local anesthetic agents are very rare but do occur. Methylparaben is a close analog of PABA and a preservative commonly used in multidose preparations of amide agents. It may account for the rare occurrence of an apparent allergic reaction to the amide class of local anesthetic agents.[7,15,16,21–24]

An agent from the opposite class may be chosen if a history of a prior allergic reaction to a particular agent is obtained from a patient requiring local anesthesia. There is no true cross reactivity between the esters and the amides.[7] A preservative-free preparation should be chosen, however, to avoid possible reaction from this source.[22] Solutions intended for single use or intravenous use tend to be free of preservatives. Intravenous formulations of lidocaine can be found in any standard Emergency Department "crash cart."

The size of the anesthetic field required for a given procedure can further dictate the utility of infiltrative anesthesia. Larger fields, by default, will require the injection of larger quantities of local anesthetic solution. Do not exceed the maximum safe dose of a local anesthetic agent (**Table 123-1**). Consider an alternative anesthetic technique (e.g., regional nerve blockade, procedural sedation) if infiltrative anesthesia requires potentially toxic local anesthetic doses. An alternative is to dilute the local anesthetic solution in half using sterile normal saline. This diluted local anesthetic solution may not provide adequate anesthesia.

Certain procedures necessitate meticulous tissue reapproximation (e.g., facial lacerations). The injection of local anesthetic solution, especially in higher volumes, can distort the surrounding tissue and diminish the probability for an optimal outcome. Consider an alternative anesthetic technique in these situations.

TABLE 123-1 Properties and Dosages for Injectable Local Anesthetic Agents

Local anesthetic class	Anesthetic agent	Relative potency	Relative onset of action	Duration of action (min)*	Maximum dose with epinephrine		Maximum dose without epinephrine	
					(mg/kg)	(mg)	(mg/kg)	(mg)
Ester	Procaine (Novocaine)	1	Slow	60–90	9.0	500	7.0	600
Ester	Chloroprocaine (Nesacaine)	3	Rapid	15–90	11.0	800	14.0	1000
Ester	Tetracaine (Pontocaine)	8	Slow	120–480	1.5	100	2.5	200
Amide	Lidocaine (Xylocaine)	2	Rapid	90–200	7.0	300	4.5	500
Amide	Mepivacaine (Carbocaine)	2	Rapid	120–240	8.0	300	7.0	500
Amide	Bupivacaine (Marcaine)	8	Moderate	180–600	3.0	175	2.0	225
Amide	Etidocaine (Duranest)	8	Fast	120–240	0.4	300	8.0	400

*Longer times represent the addition of epinephrine to the local anesthetic solution.

Topical anesthetic agents are contraindicated on mucous membranes, the eye, denuded skin, or burned skin as they are rapidly absorbed through these tissues. Such absorption can produce severe systemic toxicity and death. Eye contact can produce corneal injury. Topical agents containing cocaine and epinephrine are contraindicated in regions of end artery flow because they can result in intense vasoconstriction.[25]

Infiltration of a wound with 1% diphenhydramine is clinically effective as an alternative agent in the rare circumstance that a patient has a true IgE-mediated allergy to the local anesthetic agents.[26] Diphenhydramine is more painful to inject than the local anesthetic agents. It was less effective at attaining adequate anesthesia when compared to local anesthetic agents. **Reserve the use of diphenhydramine for the rare instance of a patient with an actual local anesthetic allergy.[26]** Dilute the 5% parenteral formulation of diphenhydramine to 1% (add 1 mL of diphenhydramine to 4 mL of normal saline) to make a solution for local infiltration.

EQUIPMENT

- Syringes, 1 mL to 20 mL sizes
- Needles, various sizes and lengths
- Local anesthetic solution, with and without epinephrine
- Alcohol swabs, povidone iodine, or chlorhexidine
- Gauze squares
- 8.4% sodium bicarbonate solution (1 meq/mL)
- Gloves
- Face mask with an eye shield or goggles
- 5% parenteral diphenhydramine solution

Universal precautions are of utmost importance in performing any procedure using a local anesthetic agent. It is vital to wear gloves when administering topical anesthetic agents to protect the fingers, to prevent absorption of the local anesthetic agent through the fingers of the healthcare worker, and to prevent introduction of bacteria into the wound. Wear a mask with a face shield or goggles to prevent accidental mucous membrane exposure if the injectable local anesthetic solution shoots out of the wound margins.

One of the most important determinants of pain response during administration of a local anesthetic agent is needle size. Use a 25 or 27 gauge needle for infiltration to minimize pain. A long needle allows for the infiltration of a larger region with a single needle pass and decreases the number of times tissues must be punctured. A 2.0 inch, 27 gauge needle is typically an optimal choice. The needle should not be inserted more than two-thirds of its length to prevent inadvertent breakage within the tissues.[12] Another important factor is the rate of infiltration. A slow steady method minimizes the pain response.

Many Emergency Departments have a small local anesthesia tray or basket containing the necessary equipment for providing local anesthesia. Such a kit may include the following items. Needles in sizes from 18 to 30 gauge, 1 to 2 cm long and 4 cm long. Syringes ranging from 1 mL (tuberculin) through 10 mL. Cotton-tipped applicators for the application of topical agents. Local anesthetic agents such as 1% and 2% lidocaine, 0.25% and 0.5% mepivacaine and bupivacaine, and the same agents combined with 1:200,000 epinephrine. Sodium bicarbonate may be used for buffering the local anesthetic agent. Alcohol swabs, povidone iodine swabs or solution, or chlorhexidine are required for cleansing the skin. Nonsterile and sterile examination gloves are required for the infiltration of the local anesthetic agent and performing the procedure.

PATIENT PREPARATION

Discuss the procedure with the patient and/or their representative. The most common adverse reaction to a local anesthetic agent is a vasovagal reaction.[12] This complication is more likely when patients are anesthetized while sitting in an upright position (e.g., dental procedures). The Emergency Physician must take precautions to alleviate secondary injury to the patient. Whenever possible, place the patient lying in a bed with side rails up to prevent injury no matter how minor the procedure. Friends and family members have been reported to syncopize upon witnessing injections. Therefore, they should either be asked to leave the room prior to starting or kept in a sitting position throughout the duration of the procedure. Sedation can minimize the response to treatment while maintaining stable vital signs and spontaneous respirations when the patient exhibits considerable anxiety. Refer to Chapter 129 regarding the details of procedural sedation.

Prepare the area prior to injecting local anesthetic solution. Clean the skin of any dirt and debris. Apply an alcohol swab, povidone iodine, or chlorhexidine to the skin over the injection site and the surrounding area and allow it to dry. Apply sterile drapes, if applicable, to delineate a sterile field.

LOCAL INFILTRATION AND PERIPHERAL NERVE BLOCKADE

LOCAL ANESTHETIC DOSING

Infiltration anesthesia refers to the injection of a local anesthetic solution directly into the subcutaneous tissues about to be manipulated. The first step to be considered is the selection of the proper anesthetic. Barring a history of an allergic reaction to a given class of local anesthetic agents, the amide anesthetics lidocaine (Xylocaine) and bupivacaine (Marcaine) are the most common agents employed within the Emergency Department. The choice between these agents should be tailored to the individual patient and situation. Lidocaine exhibits a quicker onset of activity, whereas bupivacaine exhibits a longer duration of action (**Table 123-1**). Lidocaine possesses a wider margin of safety, with larger doses required to illicit a toxic response. In amide allergic patients, the ester agent procaine (Novocain) is a reasonable alternative.

It is important to keep in mind the maximal recommended doses for the chosen local anesthetic agent to avoid systemic toxicity (Table 123-1). The disadvantage of local infiltration is that a large amount of local anesthetic must be used for a small area. Extensive wounds may require toxic doses of local anesthetic agents. A lower concentration or the addition of epinephrine will allow a larger volume of local anesthetic to be used. Local infiltration may distort the wound edges and complicate the repair.

The maximal recommended dose of a local anesthetic agent is the same for local infiltration or regional nerve blockade. **It is important to properly calculate the amount of local anesthetic agent administered to a patient.** Local anesthetic solutions are supplied with the concentration denoted as a percentage (e.g., 1% lidocaine, 0.25% bupivacaine, 4% cocaine). This percentage must be converted to mg/mL. A 1% local anesthetic solution is prepared by dissolving 1 g of the local anesthetic agent in 100 mL of diluent. This results in a concentration of 10 mg/mL (1 g/100 mL = 1000 mg/100 mL = 10 mg/mL). **A simple method to calculate the strength of a local anesthetic solution is to move the decimal point one place to the right to convert from a percentage to a concentration in mg/mL (e.g., 0.25% = 2.5 mg/mL, 2% = 20 mg/mL, 4% = 40 mg/mL). This value must be multiplied by the volume to be administered**

to determine the total amount (in mg) of local anesthetic agent administered. This value must be compared to the maximal allowable dose (Table 123-1) to ensure it is not a toxic dose.

EPINEPHRINE CONTAINING AGENTS

Epinephrine can be added to a local anesthetic solution to prolong its duration of action, to assist with hemostasis by local vasoconstriction, and to slow the absorption of the local anesthetic agent. This allows for larger quantities of local anesthetic solution to be injected without the concern for systemic toxicity. Local anesthetic agents are generally compounded with epinephrine in a 1:100,000 or 1:200,000 solution and usually come packaged as such by the manufacturer.

If a compounded solution is not available, one can be readily formulated. Begin by obtaining 1:1000 epinephrine that is usually administered to patients for severe allergic reactions or bronchospasm. This solution of 1:1000 contains 1 g of epinephrine per 1000 mL or 1 mg/mL of epinephrine. Diluting this solution by a factor of 100 will result in the desired 1:100,000 concentration. Place 0.1 mL of 1:1000 epinephrine into 10 mL of local anesthetic solution to make a dilution of 1:100,000 (or 0.010 mg/mL). Place 0.1 mL of 1:1000 epinephrine into 20 mL (or 0.05 mL in 10 mL) of local anesthetic solution to make a dilution of 1:200,000 (or 0.005 mg/mL).

REDUCING THE PAIN OF INFILTRATION

Local anesthetic agents are weak bases. They are packaged, however, as hydrochloride salts with a pH of 4 to 6 to increase their solubility and shelf life. This acid pH causes much of the pain associated with the injection of local anesthetic agents.[4,6] Because epinephrine is unstable at a physiologic pH, commercial solutions containing epinephrine are generally formulated with similarly acidic pH values. **Buffering lidocaine, mepivacaine, or bupivacaine with sodium bicarbonate has been shown to reduce the pain of injection significantly.**[25,27,28] Raising the pH of the local anesthetic agent increases the percentage of local anesthetic molecules in the nonionized diffusible state.[27] This may allow nearly instantaneous penetration of the nerve cell membrane by the anesthetic molecules and block or reduce the pain of infiltration.[27,29,30] Raising the pH also contributes to decreasing the pain of the injection. Buffering local anesthetic agents does not appear to affect the duration or degree of anesthesia. There does not appear to be an increase in the degree of anesthesia, the serum levels of the local anesthetic agent, or in toxicity of buffered anesthetic agents.

Caution must be exercised when buffering highly lipophilic and less soluble anesthetic agents, like bupivacaine, because precipitation can occur.[4] To buffer a local anesthetic agent, use the prepackaged 50 mL ampules of 8.4% (1 meq/mL) sodium bicarbonate found in any "crash cart." Add 1 mL of 8.4% (1 meq/mL) sodium bicarbonate to 10 mL of 1% lidocaine or 1% mepivacaine, with or without epinephrine, to achieve buffering.[27] Add 0.05 to 0.10 mL of 8.4% (1 meq/mL) sodium bicarbonate to each 10 mL of 0.5% bupivacaine.[28]

The use of warm lidocaine [37°C (98.6°F) to 42°C (107.6°F)] decreases the pain of infiltration.[31,32] The exact etiology of this is unknown. It is hypothesized that warm lidocaine does not stimulate cold receptors and it diffuses into tissues faster. Warm the local anesthetic agent by placing it in a blanket warmer or a water bath. The combination of both warming and buffering a compound results in an even less painful procedure.[32,33]

Other simple measures can help to limit the pain of the local anesthetic injection. Limit the infiltration of a local anesthetic solution to the subdermal space. This practice helps to limit the overall pain of injection, minimize the degree of tissue distortion, and protect the patient from the inadvertent injection into an intravascular space. When anesthetizing an open wound, make every attempt to infiltrate through the exposed wound edges rather than puncturing through the adjacent intact skin (**Figure 123-1**).[34] This will provide a much less painful experience for the patient. Infiltrate grossly contaminated wounds percutaneously through clean and intact skin to decrease the risk of spreading the contamination and to decrease the risk of an infection related to the infiltration. Also limit the number of needle punctures through uninjured skin in contaminated wounds. The application of gentle pressure to the injection site prior to the injection, such as pressing a sterile cotton-tipped applicator against the skin, limits the pain associated with childhood vaccinations.[35] Dentists have been using similar techniques for many years to perform dental blocks. The use of this technique in the Emergency Department is limited by the fact that infiltrations into previously inflamed tissue, and thus any kind of additional stimulation, may simply expose the patient to unwarranted additional pain. A slower rate of local anesthetic solution injection is associated with less pain.

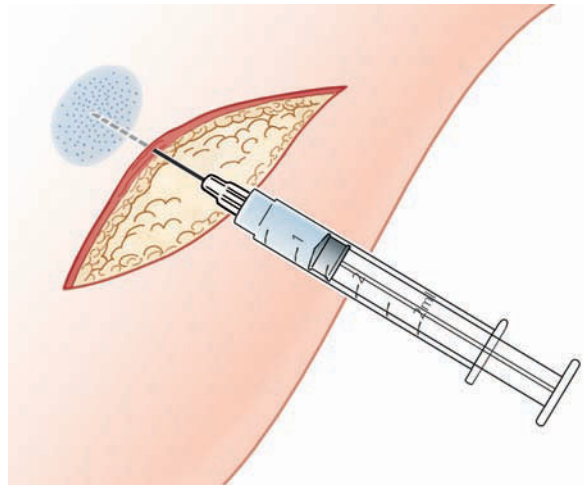

FIGURE 123-1. The needle is inserted through the wound edge to inject local anesthetic solution.

Insert the needle into an open wound at its apex (**Figure 123-2**). Tunnel the needle its entire length down the wound margin. Inject the local anesthetic solution while slowly withdrawing the needle.

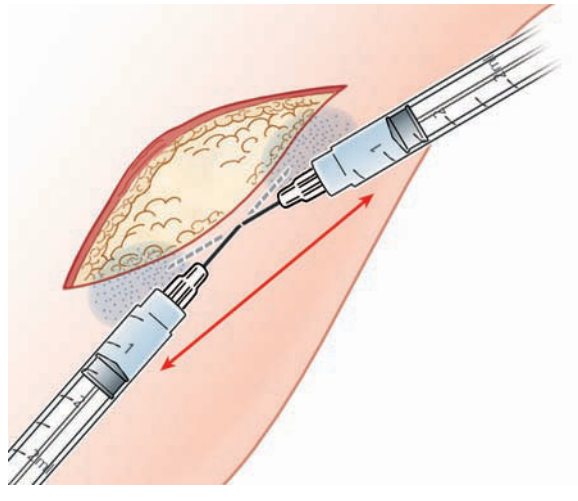

FIGURE 123-2. The needle is inserted through the intact skin below the wound to inject local anesthetic solution.

Do not completely withdraw the needle from the skin. Redirect it along the opposing wound margin and repeat the technique. This can be performed down the entire length of the wound as necessary. Minimizing the number of skin punctures will help to minimize pain.

The pain upon injection of local anesthetic agents can be reduced by following a few simple suggestions. Warm and/or buffer the local anesthetic agent as discussed previously. Inject the local anesthetic agent slowly. Inject open wounds through the wound edges and not through intact skin. An exception to this is grossly contaminated wounds. Infiltrate subdermally to minimize pain and tissue distention. Insert and advance the needle to create a tract and inject as the needle is withdrawn to minimize tissue distention. Do not totally withdraw the needle after infiltration. Leave the tip of the needle within the skin and redirect the needle to prevent excessive skin punctures.

COMBINING LOCAL ANESTHETIC AGENTS

Physicians have for some time combined various local anesthetic agents in an attempt to exploit the unique properties of each individual local anesthetic agent and achieve both a rapid onset of action and a prolonged duration of action.[36,37] Lidocaine, with its rapid onset, can be safely mixed in a 1:1 ratio with longer acting bupivacaine or mepivacaine. Employing this mixture may be no more dangerous than sequentially administering equal doses of either parent compound. **The value of such an approach is questionable.** Enough concern still persists regarding the potential toxicity of this mixture to often preclude its use within the Emergency Department. The combined benefits might not be as relevant within the Emergency Department, as the majority of the studies referenced come from the anesthesia and surgical literature.

It is important to realize that the toxic effects in an overdose situation are additive, even if an amide and ester are combined.[38,39] Mixing two local anesthetic agents can complicate the overall dosage calculations and enhance the potential for a toxic injection. **It is also difficult to determine the maximum dose if two local anesthetic agents are mixed together.** If the patient develops an allergic reaction, it will be impossible to determine which local anesthetic agent is the causative agent. The combination of local anesthetic agents can therefore not be currently recommended. **Use lidocaine containing epinephrine to prolong the anesthetic effect rather than combining it with a second local anesthetic agent.**

ALTERNATIVE TECHNIQUES

It has been known since the 1940s that injected antihistamines exhibit anesthetic properties. A 1956 study comparing the infiltration of diphenhydramine to procaine demonstrated equal anesthetic properties. Subsequent Emergency Medicine based studies have shown equal anesthetic results when comparing the injection of 1% solutions of either lidocaine or diphenhydramine, although the latter was associated with a more painful infiltration. A further study comparing 0.5% diphenhydramine to 1% lidocaine demonstrated a resolution in the disparity regarding the pain of injection, although at the expense of a decreased anesthetic effect.[40] The overall duration of anesthesia produced by infiltrated diphenhydramine is shorter than that of lidocaine. A concern has arisen regarding the possible destruction of local tissue and subsequent skin necrosis associated with diphenhydramine infiltration. Multiple early experiences had reported this complication. However, an appropriate dilution prior to injection should eliminate this potential complication. Dilute 1 mL of standard parenteral 5% diphenhydramine solution with 4 mL of sterile normal saline to achieve a 1% solution that is suitable for injection.[41,42] Diphenhydramine should be considered a viable alternative to the more commonly used local anesthetic agents when they are contraindicated.

ASSESSMENT

It is important to wait long enough after the local anesthetic agent is administered to allow the onset of adequate anesthesia before the planned procedure is started. A period of 5 to 10 minutes is adequate for subcutaneous local infiltration. A period of 15 to 30 minutes may be required for peripheral nerve blocks. A simple examination of the area being anesthetized with fine touch and pinprick is important to insure adequate anesthesia prior to the procedure. It may be necessary to inject additional local anesthetic solution in areas of continued sensitivity, keeping in mind the total dose injected to avoid toxicity.

AFTERCARE

The Emergency Physician should observe the patient for a minimum of 15 minutes following the use of local anesthesia to insure no evidence of an adverse reaction. The length of time analgesia is maintained depends upon the agent used for the procedure (**Table 123-1**). The patient need not wait in the Emergency Department for normal sensation to return prior to discharge. They should be instructed to return to the Emergency Department if normal sensation has not returned within 12 to 24 hours.

COMPLICATIONS

Toxic reactions to local anesthetics agents are far more common than allergic sequelae.[12,17,43] The propensity for toxicity is directly proportional to the potency of the drug.[7,9,10] **Table 123-1** lists the recommended maximal doses for commonly used local anesthetic agents. **These are only estimates and in certain circumstances the toxic dose might be considerably less.[7,20] Infiltration into highly vascular areas, inadvertent intravascular injection, or application to mucous membranes may cause toxicity at accepted standard doses.**[7]

It is unlikely that toxic serum concentrations of local anesthetic agents will be reached in most clinical situations in the Emergency Department. For example, the maximum dose of 1% lidocaine without epinephrine in a 70 kg patient would be approximately 31.5 mL, a volume more than adequate for most wounds. **It is important to be vigilant of the total dose administered, especially in patients with large or multiple lacerations in whom higher doses of local anesthetics may be required.** A less concentrated form of the local anesthetic agent (e.g., 0.5% lidocaine as opposed to 1%) may be used when the maximum dose could be exceeded. General anesthesia in the Operating Room may be required to repair larger wounds.

The major manifestations of local anesthetic toxicity occur in the central nervous system (CNS) and the cardiovascular system.[6,9,12,15] Initial signs and symptoms are of CNS excitation. This occurs as a result of the suppression of inhibitory cortical neurons that permits unopposed functioning of facilitatory pathways. Signs and symptoms include lightheadedness, dizziness, nystagmus, sensory disturbances (e.g., visual difficulties, tinnitus, perioral tingling, metallic taste in the mouth), restlessness, disorientation, and psychosis. Slurred speech, muscle twitching, and/or tremors may immediately precede seizures. There may also be augmentation of medullary and sympathetic activity with resultant tachypnea, hyperpnea, hypertension, and tachycardia. Generalized depression of the entire CNS can occur and is manifested as drowsiness, coma, and respiratory arrest.[9,15]

Management of CNS toxicity should begin with an assessment of the patient's airway, breathing, and circulation. Treatment is primarily supportive. Hypoxia and acidosis enhance CNS and myocardial absorption of local anesthetic agents and must be addressed aggressively. Hypocapnia raises the seizure threshold (to prevent convulsions) by inducing cerebral vasoconstriction and by decreasing the delivery of the local anesthetic agent to the CNS.[7,44] An alert and cooperative patient may be instructed to hyperventilate if early signs of toxicity are present.[6,20,45] Manage seizures with intravenous benzodiazepines as they raise the CNS threshold to local anesthesia-induced convulsions. The metabolism of local anesthetics is short enough that loading patients with long-acting antiseizure agents, such as phenytoin, is generally not required. The effect of phenytoin upon sodium channel conduction can potentiate the arrhythmogenic property of local anesthetics. Administer short-acting neuromuscular blocking agents, such as succinylcholine or vecuronium, until serum levels of the local anesthetic agent decline if the seizures fail to respond to benzodiazepines.[7] Succinylcholine, however, is metabolized by pseudocholinesterase. This is the same plasma enzyme that metabolizes ester anesthetic agents. Therefore, avoid succinylcholine in ester-induced seizures.[7,6,20]

The cardiovascular system is relatively resistant to local anesthetic toxicity in comparison with the CNS.[17,24] The cardiovascular system does not exhibit toxicity until much higher blood levels are reached.[17,24] Cardiovascular toxicity results from the direct effects upon cardiac and vascular smooth muscle and the indirect effects upon autonomic tone. Complications are the result of negative inotropism, peripheral vasodilatation, and slowing of the myocardial conduction system.[9,15] Arterial dilation combined with decreased cardiac contractility leads to progressive hypotension and eventual cardiovascular collapse. Additionally, the sodium and calcium channel blockade exhibited at more toxic doses of local anesthetic agents predisposes the patient to fatal arrhythmias. The end results are hypotension, bradycardia, prolonged electrocardiographic intervals, and cardiac arrest.[9,10,15] Treatment is supportive with intravenous fluids, vasopressors, and inotropes as the mainstays of therapy. Avoid class IB antidysrhythmics due to their potential to accentuate cardiac sodium channel blockade. Vasopressors with positive inotropic effects, such as dopamine, will treat profound cardiovascular depression.[7]

Bupivacaine is more cardiotoxic than other local anesthetic agents. Treatment of bupivacaine cardiotoxicity has shown a potential benefit with the use of high dose intravenous insulin (2 IU/kg) in concert with supplemental intravenous glucose and intravenous potassium boluses.[46] The infusion of a lipid emulsion (i.e., Intralipid) has been proposed for use in bupivacaine-associated cardiac arrests. Several recent case reports have substantiated the use of Intralipid. The actual mechanism of action is unclear, but proposals include the extraction of lipophilic anesthetics from their target tissues via the fatty emulsion and/or the direct antagonization of anesthetic mediated suppression of cardiac fatty acid metabolism.[47]

There is no accepted standard protocol for the administration of Intralipid. A proposed dosing regimen is described here. Of note, these rescue interventions should be attempted only in patients failing to respond to standard ongoing ACLS protocols. Administer an initial bolus of 1.5 mL/kg of a 20% Intralipid solution. This is the standard used for adult total parenteral nutrition (TPN). Repeat this dose up to two additional times over a 5 minute period for patients in refractive asystole. If the return of spontaneous circulation ensues, initiate a maintenance intravenous infusion of 0.25 mL/kg/min for 30 to 60 minutes. This allows the toxic effects of the local anesthetic agent to dissipate. The Intralipid infusion can be easily titrated to maintain a stable perfusing blood pressure. Of note, although often readily available, the drug propofol is compounded in a 10% lipid solution and therefore not applicable for similar use. The volume of propofol solution needed to reverse bupivacaine toxicity would require the administration of a toxic dose of propofol.[48–50]

Adding epinephrine to a local anesthetic agent increases both the amount of drug that can be administered and the duration of action.[4,14] It also decreases bleeding into the surgical field. There are, however, significant drawbacks to the use of epinephrine. This includes increased pain of infiltration, increased wound inflammation, increased wound infection rates, uncomfortable side effects in susceptible patients (e.g., palpitations, tremors, syncope), and the potential for severe tissue ischemia if used in regions of end arterial circulation such as the digits, the tip of the nose, the pinna, or the penis.[12] Emergency Medicine dogma cautions against the use of an epinephrine containing local anesthetic agent in these regions in order to avoid potential distal tissue infarction and necrosis. However, the clinical evidence supporting this concern is questionable, and the little that does exist is over 50 years old. A study of elective hand procedures demonstrated no adverse consequences following over 3000 digital injections of epinephrine containing local anesthetic solutions.[51,52] Literature focused on the inadvertent infiltration of epinephrine into fingers via improperly used autoinjectors has failed to demonstrate a single significant case of tissue necrosis. The majority of these cases demonstrate a spontaneous return of perfusion with only conservative treatments (i.e., warm soaks and digital massage). Prolonged vasospasm and ischemia in these areas can be reversed with the subcutaneous infiltration of 1.0 mL of 1:1000 phentolamine (i.e., 1 mg) diluted with saline in a 1:1 mixture at the local anesthetic injection site.[53–57] A less invasive alternative is to apply topical nitroglycerine paste to the affected area. Caution must be used when administering epinephrine to patients who are elderly, taking beta-blockers, or with a history of coronary artery disease, hypertension, hyperthyroidism, or pheochromocytoma.[6,12] Inadvertent intravascular injection of epinephrine can have fatal consequences.[58,59]

The potential systemic complications unique to epinephrine are not often an issue. Using 1:100,000 preparations, one must infiltrate 30 mL of local anesthetic solution to attain a cumulative dose of 0.3 mg, a quantity commonly used subcutaneously in the practice of Emergency Medicine. Such a large volume is rarely encountered with infiltrative anesthesia. Consider an alternative anesthetic technique if such a large volume of local anesthetic solution containing epinephrine is required. Rare reports of patient mortality secondary to an inadvertent intravenous injection have been reported. Extreme care should be taken when using such preparations in any patient with suspected cardiovascular disease.

True allergic reactions are rare adverse events to the local anesthetic class of medications. Effective management of an allergic reaction depends upon its severity and may include the use of epinephrine, antihistamines, steroids, and vasopressors. A complete review of the management of allergic reactions and anaphylaxis can be found in standard Emergency Medicine textbooks.

Methemoglobinemia has been reported to occur following the use of both classes of local anesthetic agents. It is most commonly seen after the use of the topical agent benzocaine.[60] The use of this medication is discussed elsewhere in this book. The Emergency Physician must be aware of this potential complication and intervene appropriately.

Injection of local anesthetic agents can cause complications in the area of the infiltration. These agents have not been shown to increase the incidence of wound infections. Do not inject local anesthetic agents into a joint prior to obtaining synovial fluid. They

can result in false-negative culture results, false-negative crystal analysis, and false-positive (anesthetic crystals) crystal analysis. Needle punctures of arteries, nerves, and veins are usually a temporary inconvenience with no long-lasting consequences. Intraneural injection can result in temporary or permanent nerve injury. Never inject local anesthetic agents if the patient experiences paresthesias (indicating intraneural needle placement). Withdraw the needle 1 to 2 mm and allow the paresthesias to resolve before infiltrating with the local anesthetic solution. Never redirect the needle when more than the tip is subcutaneous to prevent needle breakage.

SUMMARY

Local anesthetic agents have become an indispensible tool in the practice of Emergency Medicine. Emergency Physicians often rely on local anesthetic agents to relieve patient discomfort and provide wound care. Infiltrative anesthesia represents one of the most prevalent uses for these agents. It is relatively quick, easy to perform, well tolerated, and when performed correctly, has a large margin of safety. Complications can and do arise. The Emergency Physician must be ready to recognize the warning signs of local anesthetic toxicity and intervene appropriately. An expertise in the use of these agents plays an important role in the practice of the art of medicine. For hundreds of years physicians have sought to relive the pain and suffering of our patients. These agents allow us to come closer to attaining that goal.

124 Topical Anesthesia

Erika D. Schroeder and Peter Taillac

INTRODUCTION

Invasive procedures can cause significant anxiety in patients both young and old, much of which is related to fear of the associated pain. Topical anesthesia has been shown to decrease pain and anxiety surrounding procedures such as lumbar puncture, intravenous access, and laceration repair.[1] This chapter will discuss topical anesthetic agents and the range of techniques that are available for delivery of these agents.

ANATOMY AND PATHOPHYSIOLOGY

Mechanical, thermal, and chemical stimuli are detected by nerve endings called nociceptors. These pain receptors are located in the skin, specifically in the dermis and the epidermis, below the stratum corneum (**Figure 124-1**). Nociceptors are free nerve endings that have their cell bodies outside the spinal column in the dorsal root ganglia. The intact stratum corneum, the outer layer of cornified epithelial cells of the skin, is an effective barrier to the outside environment. Local anesthetics must transverse the stratum corneum to be delivered to the terminals of cutaneous sensory nerve fibers.

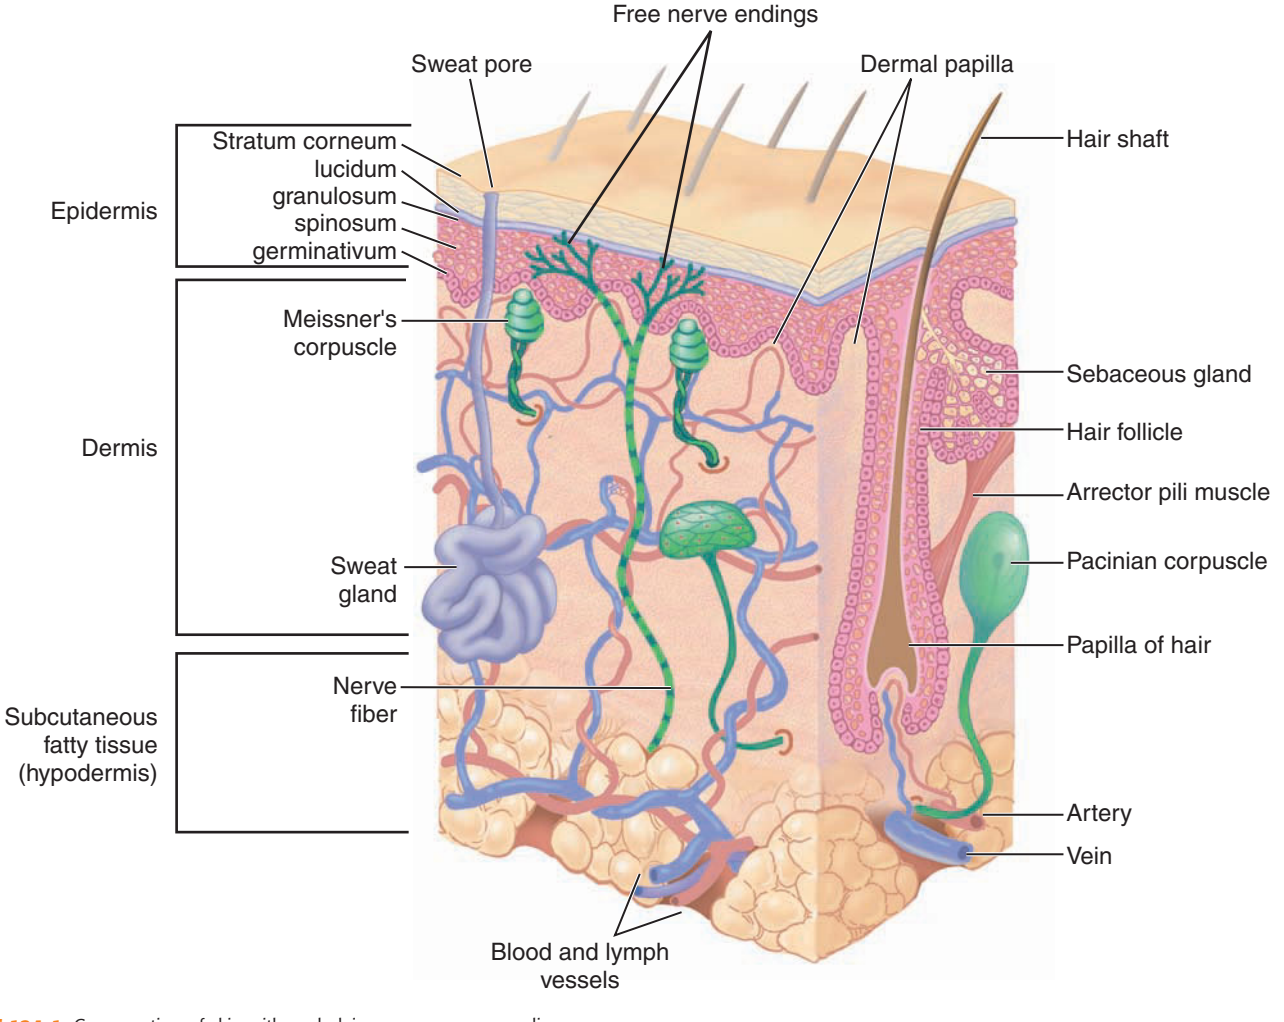

FIGURE 124-1. Cross section of skin with underlying sensory nerve endings.

The three methods by which the stratum corneum can be bypassed to deliver a local anesthetic are direct injection, passive diffusion, and needle-free drug delivery strategies. Refer to Chapter 123 for the complete details regarding the direct injection of local anesthetic solution. This chapter will discuss techniques for enhancing passive diffusion and needle-free administration of local anesthetic agents, collectively known as topical anesthesia.

INDICATIONS

Topical anesthesia is commonly utilized in the Emergency Department in two situations. The first is the patient experiencing pain from an injury such as a laceration, abrasion, or contusion. The second is in the patient who will undergo a painful procedure such as venipuncture, lumbar puncture, abscess incision and drainage, or laceration repair.

Topical anesthetic agents offer several potential advantages over local infiltration anesthesia. They are less painful to apply, do not distort the wound margins, and decrease the need for sedation.[2] The major limitations of topical anesthesia have been the extended time required to achieve anesthesia and the lack of sufficient analgesia in many clinical situations that often requires supplemental infiltration anesthesia. These constraints have limited the use of topical anesthesia in the Emergency Department. Several new agents and delivery techniques have addressed these limitations with some success, offering the Emergency Physician more options for providing anesthesia.

CONTRAINDICATIONS

There are very few contraindications to the use of topical anesthetics. The topical anesthetic agent is typically not systemically absorbed to any significant degree. However, they can cause local adverse reactions and should not be used in patients who are allergic to the medication or its components (such as preservatives). **Use care when applying topical anesthetics to mucous membranes, as absorption is typically more rapid and efficient than through skin and more substantial systemic absorption can occur.** A relative contraindication to using topical anesthetic agents are patients taking Class 1 antiarrhythmics such as mexiletine and tocainide, as they can produce additive and possibly toxic effects. Many of the topical anesthetics are contraindicated or require special ophthalmic formulations for use in the eye. When using topical anesthetics in neonatal patients, special care and attention to dosing is imperative to avoid toxicity. Specific contraindications and concerns for each topical agent and application technique are addressed later in this chapter as well as in Chapter 123.

EQUIPMENT

General Supplies

- Alcohol swabs
- Povidone iodine or chlorhexidine solution
- Gauze squares, 2 × 2 and 4 × 4
- Gloves

Topical Cream, Gel, or Liquid

- TAC (0.5% tetracaine, 1:2,000 epinephrine, and 11.8% cocaine)
- LET (0.5% tetracaine, 1:2,000 epinephrine, and 4% lidocaine)
- EMLA (2.5% lidocaine and 2.5% prilocaine)
- LMX-4 or LMX-5 (4% or 5% liposomal lidocaine)
- Topicaine (4% lidocaine gel)

Iontophoresis

- 2% lidocaine hydrochloride containing 1:100,000 epinephrine
- Device to administer iontophoresis (e.g., Phoresor II or Dupel)
- Iontophoresis System

Ultrasound-assisted Local Anesthetic Delivery

- Ultrasound device (e.g., SonoPrep)
- Topical local anesthetic agent

Powdered Anesthetics

- Needle-free powder lidocaine delivery system

Lidocaine Needle-free Injection

- Needle-free injection system, prefilled or fillable
- 1% or 2% lidocaine

Heat-enhanced Diffusion

- Lidocaine–tetracaine thermal patch

Laser-assisted Transdermal Passage

- Cutaneous resurfacing laser
- Topical anesthetic agent

Topical Vapocoolant Sprays

- Topical vapocoolant spray

PATIENT PREPARATION

Discuss the procedure, its risks, benefits, complications, and alternatives with the patient and/or their representative. Take precautions to prevent further injury or pain to the patient. Cleanse the skin of any dirt and debris. Apply povidone iodine or chlorhexidine solution to the skin and allow it to dry. Consider administering a supplemental anxiolytic or procedural sedation if required.

PASSIVE DIFFUSION OF LOCAL ANESTHETIC AGENTS

Topical local anesthetic agents are often applied in the form of a gel or cream. There are numerous combinations of anesthetic agents to use topically on wounds. TAC (tetracaine, adrenaline, and cocaine), LET (lidocaine, epinephrine, and tetracaine), and EMLA (eutectic mixtures of lidocaine and prilocaine) are three commonly applied combinations (**Table 124-1**). Other topical local anesthetic agents include lidocaine gel and liposomal lidocaine.

TAC

Many Emergency Departments use TAC for topical anesthesia. It is a combination of 0.5% tetracaine, 1:2000 or 0.05% adrenalin (epinephrine), and 11.8% cocaine. TAC can be purchased or Hospital Pharmacists can compound these agents into a gel or liquid. It can be partitioned into individual use vials for easy application. The degree of anesthesia achieved with TAC is comparable to that of local infiltration with lidocaine for wounds on the face and scalp.[3] The effects are less profound, however, for wounds on the trunk and extremities.

The cocaine component in TAC is a powerful and effective local anesthetic agent as well as a vasoconstrictive agent. Unfortunately, TAC is a controlled substance. This makes it's storage, utilization, and monitoring subject to stringent regulation and documentation requirements. This may limit the availability and use of TAC in some institutions.

Dose recommendations generally call for 5 mL of TAC for lacerations smaller than 3 cm in length and 10 mL for lacerations greater

TABLE 124-1 Characteristics of Topical Anesthetic Agents

Medication or method	Time to anesthesia (min)	Side effects
Liposomal lidocaine (LMX-4 and LMX-5)	15–30	Skin erythema
Lidocaine, epinephrine, and tetracaine (LET)	15–30	None
Tetracaine, adrenaline, and cocaine (TAC)	20–30	Seizures, cardiac arrest (rare)
Lidocaine gel (Topicaine)	30	Local skin reactions
Eutectic mixture of lidocaine and prilocaine (EMLA)	60	Local skin reactions
Iontophoresis with lidocaine with epinephrine	10–20	Burns, local skin reactions
Ultrasound-assisted delivery	5	Local skin reactions
Powdered lidocaine injector	1–3	Contusions, minor bleeding, cellulitis
Jet lidocaine injection	1–3	Contusions, minor bleeding, cellulitis, administration pain
Heat-enhanced diffusion	10	Local skin reactions
Laser-assisted transdermal	5	Local skin reactions, administration pain
Vapocoolant sprays	0.1–0.2	Frostbite, skin erythema

than 3 cm in length.[3] Apply the chosen volume of TAC liquid or gel onto a 2 × 2 gauze square or a cotton ball. Invert the gauze square or cotton ball to apply TAC within the wound margins. Allow TAC to remain for up to 15 minutes or until visible skin blanching occurs. **Blanching indicates the presence of vasoconstriction and adequate analgesia.** The gauze pad can be held in place by the patient's gloved hand, the patient's representatives gloved hand, or with tape.

TAC is not free of complications. **Always wear gloves when handling TAC to prevent percutaneous absorption.** Do not apply TAC to tissues with an end-arteriole supply. This includes the fingers, toes, nose, ear, and penis. There is the possibility of vasoconstrictive ischemic injury to these tissues. The systemic absorption of cocaine as a result of TAC administration has been implicated in rare episodes of respiratory arrest, seizures, and death.[4,5]

LET

LET is an alternative to TAC. It is a combination of 4% lidocaine, 0.1% (1:1000) adrenaline (epinephrine), and 0.5% tetracaine. It is considered safer, similarly effective, more practical, and more cost effective to use than TAC. LET does not contain a controlled substance and has no potential for abuse. The resultant security and documentation requirements are therefore much less complicated than those required for TAC. Hospital Pharmacists can compound this agent.

Apply liquid LET by dripping it into the wound or taping a LET soaked cotton ball or 2 × 2 gauze square over the wound. The addition of methylcellulose to liquid LET makes a gel that is more adherent and can be painted on wounds. The gel form will not drip or run. Similar to TAC, it should not be placed on the digits, ear, nose, penis, or other areas that are supplied by end arteries due to the strong vasoconstrictive effect and risk of ischemia. This dogma is currently being challenged.[6]

EMLA CREAM

The use of EMLA (eutectic mixture of local anesthetics) cream has gained significant popularity, particularly in pediatric patients. It is an emulsion of 2.5% lidocaine and 2.5% prilocaine in a 1:1 ratio by weight. Each gram of EMLA contains 25 mg of lidocaine and 25 mg of prilocaine. **Apply EMLA only onto intact skin and not into open wounds.** It is nonsterile and preservative free. It is also commercially available in prepackaged transdermal disks.

EMLA is indicated prior to performing venipuncture, arterial punctures, accessing indwelling ports and reservoirs, lumbar puncture, minor skin procedures, or regional nerve blockade. Apply EMLA cream to intact skin and cover it with an occlusive dressing (e.g., Tegaderm) or apply a transdermal disk. Allow at least 1 hour for the EMLA to take effect. Analgesia is usually satisfactory after 1 hour, peaks at 2 hours, and persists for about 1 hour after it is removed from the skin. The prolonged time required for anesthesia to take effect limits its practical use in the Emergency Department. EMLA should not be applied to infants less than 3 months of age due to the risk of methemoglobinemia.[7]

LIPOSOMAL AGENTS

Liposomal Lidocaine (LMX-4 or LMX-5) is a 4% or 5% lidocaine cream that is a liposome-encapsulated formulation. The encapsulation of lidocaine keeps it from being rapidly metabolized. The lipid content of the liposomes allows for better drug penetration of the stratum corneum. The LMX-4 cream has several advantages over other topical anesthetic agents. This includes a more rapid onset of action and not requiring an occlusive dressing.[1] The most frequent adverse reaction is local erythema. Although no serious side effects have been reported with the use of LMX-4, it is recommended that it be applied to an area less than 100 cm^2 in patients who weigh less than 20 kg.[8] When compared to a placebo, intravenous cannulation after the application of LMX-4 showed improved success rates on the first attempt.[9] LMX-4 is as effective as EMLA.[10] However, buffered lidocaine injection decreased the pain associated with intravenous catheter insertion to a greater extent than lidocaine cream.[1]

TOPICAINE

Topicaine is a 4% lidocaine gel that is used for a number of procedures in the Emergency Department including placement of Foley catheters and nasogastric tubes. It is readily available and easy to use. Patients can develop a contact dermatitis, particularly if they have an allergy to amide-type local anesthetic agents. Apply Topicaine for 30 minutes prior to a procedure for maximum efficacy.

ACTIVE NEEDLE-FREE LOCAL ANESTHETIC DELIVERY

An alternative to either the injection of local anesthetic solution or the use of topical creams and gels are needle-free drug delivery systems. These techniques utilize various strategies designed to speed the delivery of the local anesthetic agent across the stratum corneum.

IONTOPHORESIS

Iontophoresis is a process by which direct electrical current facilitates dermal penetration of positively charged lidocaine molecules when placed under a positive electrode. The dose is calculated by multiplying the duration of delivery with the current used to deliver the local anesthetic agent. Studies evaluating this method typically use 20 to 30 mA and 2% lidocaine hydrochloride with 1:100,000 epinephrine.[11,12] It takes approximately 10 to 20 minutes to obtain adequate analgesia for intravenous catheter placement. The side effects of iontophoresis include skin blanching, erythema, tingling, itching, and burning sensations. Burns have been reported to rarely

occur during iontophoresis with an incidence of 1 per 15,000 to 20,000 treatments.[13] Iontophoresis has been successfully used prior to intravenous catheter placement and lumbar puncture.[14]

ULTRASOUND-ASSISTED LOCAL ANESTHETIC DELIVERY

Ultrasound has been utilized to accelerate the delivery of topical anesthetic agents. Ultrasound disrupts the layers of the stratum corneum forming temporary pores that facilitate the distribution of topical anesthetic agents below the epidermis.[15] Focal ultrasound followed by a 5 minute application of 4% liposomal lidocaine provided more effective anesthesia when compared with a placebo or standard care.[16,17] Ultrasound reduces the time to achieve anesthesia with EMLA cream from 60 minutes to 5 minutes.[18] The use of ultrasound prior to a 5 minute application of liposomal lidocaine produced the same amount of pain relief as the typical 30 minute application of liposomal lidocaine.[19] Ultrasound-assisted delivery is effective for intravenous catheter placement and phlebotomy.[20]

POWDERED ANESTHETICS

Another alternative to the injection of lidocaine solution is the transepithelial injection of powdered lidocaine using a specialized delivery system. The delivery system is a prefilled, disposable, single use device that is designed to produce rapid analgesia for venipuncture and intravenous catheter placement. The system is applied 3 minutes prior to venipuncture or intravenous cannulation. The device works by releasing pressurized helium, which in turn ruptures a cassette of lidocaine powder. The particles of lidocaine powder are accelerated to a velocity that is sufficient to penetrate the stratum corneum and become deposited in the subepithelial layer. The onset of anesthesia is approximately 1 to 3 minutes after the injection.[21] When compared with a placebo, this delivery system results in a significant reduction in pain.[22] The potential adverse effects of powdered lidocaine administration include local skin contusion, application site bleeding, and a subsequent cellulitis.

JET LIDOCAINE

Another form of needle-free lidocaine injection is commonly referred to as jet lidocaine. The device uses pressurized CO_2 to inject up to 0.5 mL of aqueous lidocaine into the subcutaneous tissue. To use the device, the lidocaine is drawn up into the reservoir and it is then held firmly against the skin where the proposed procedure is to occur. The CO_2 cartridge is activated, forcing the microaerosolized lidocaine thru the stratum corneum, depositing it the subcutaneous tissues. The onset of anesthesia is approximately 1 to 3 minutes after the injection. Approximately 19.5% of patients in a randomized trial experienced pain from administration of the system.[23] Other complications include device failure 10% of the time and minor local bleeding. In studies comparing jet lidocaine to EMLA or liposomal lidocaine, jet lidocaine was found to provide more effective anesthesia.[24,25] Jet lidocaine has been found to be more effective than placebo.[26,27] Interestingly, a study compared jet lidocaine to jet placebo (saline).[28] It found jet lidocaine to be no more effective at providing local anesthesia, suggesting that the injection itself may play a role in providing anesthesia.

HEAT-ENHANCED DIFFUSION

The application of heat improves the dermal absorption of topical anesthetics. The lidocaine–tetracaine topical patch consists of 70 mg of each local anesthesia agent, combined with an air-activated heating system incorporated into an adhesive patch. It is specifically designed to warm the skin which, in turn, accelerates the absorption of the local anesthetic agents. The heating component of the patch is automatically activated when the patch is removed from its packaging. The lidocaine–tetracaine patch can be used for minor invasive procedures such as lumbar puncture, intravenous catheter placement, and arterial puncture. The lidocaine–tetracaine patch can provide effective anesthesia after 10 minutes. It was more effective than EMLA or a placebo at all application times shorter than 60 minutes.[29,30] Common side effects include skin erythema, blanching, and edema.

LASER-ASSISTED TRANSDERMAL PASSAGE

Another technique to break down the stratum corneum skin barrier involves the use of a laser.[31] A cutaneous resurfacing laser is used to ablate the outer layer of skin, generally an area about 6 mm in diameter. Topical anesthetic is then applied to this area and is able to rapidly penetrate through the ablated skin to the subcutaneous pain receptors. The ablation procedure is typically painless. Anesthesia occurs approximately 5 minutes after the local anesthetic application. The amount of energy used for the ablation varies but typically is in the range of 2.0 to 3.5 J/cm^2. Side effects may include mild pain, erythema, and itching at the ablation site. In addition, patients may experience temporary hyperpigmentation or hypopigmentation at the treatment site. The biggest drawback to this technique is the cost of the handheld laser.

VAPOCOOLANT SPRAYS

Vapocoolant sprays, also known as vapocoolants and refrigerant sprays, are an alternative to topical local anesthetic agents. Vapocoolant sprays are a good choice for patients requiring brief procedures or with allergies to the medications used in topical anesthetics. Vapocoolant sprays work immediately, are easy to use, cost-effective, and may be repeatedly applied without the risk of methemoglobinemia or systemic toxicity. Vapocoolant sprays are sterile liquids that vaporize upon contact with the skin. As the liquid vaporizes, it cools the skin surface and provides brief topical anesthesia. Commonly used vapocoolants include ethyl chloride, fluorohydrocarbons, and alkane mixtures.

They are commercially available in containers with a tip that directs a precise stream of liquid to the desired area. The vaporization of the liquid lowers the skin temperature in the area of contact to approximately −20°C (−4°F) as it vaporizes. The skin becomes temporarily cold then frozen. Vapocoolant sprays are convenient, effective, "needle-less", and provide immediate anesthesia.[32] Their use is limited by a very brief duration of action of approximately 30 seconds. **These sprays only provide superficial anesthesia.** Vapocoolant sprays can be used prior to accessing indwelling ports and reservoirs, arterial puncture, venipuncture, intravenous catheter placement, intramuscular injections, local anesthetic injection, lumbar puncture, and minor skin procedures.[33]

Using the vapocoolant spray is very simple. Assemble and gather all the equipment required for the procedure to be performed. Clean and prep the skin. Apply sterile drapes if applicable. Hold the inverted container of refrigerant spray 10 to 15 cm above the skin surface. Spray the liquid onto the skin until a white frost appears and the skin turns white. This usually takes 7 to 12 seconds. Immediately perform the procedure to ensure an adequate anesthetic effect.

Avoid spraying the liquid onto the skin for prolonged periods as it may result in frostbite. Do not use vapocoolant sprays on mucous membranes. The vapocoolants are significantly absorbed through mucous membranes and can result in adverse reactions and toxicity. These agents are highly volatile and must be used in well-ventilated

areas. Never spray around open flames or an electrocautery unit as some vapocoolant sprays are highly flammable. Do not use vapocoolant spray on open wounds as it may delay wound healing. The application of ice packs work just as well but takes longer to achieve anesthesia.

MUCOUS MEMBRANE ANESTHESIA

Mucous membranes warrant a special note as the systemic absorption from mucous membranes is much more rapid and effective than absorption through the skin and results in higher blood levels of the anesthetic agent. Numerous agents may be used to provide anesthesia to mucous membranes. This commonly includes benzocaine, cocaine, lidocaine, and tetracaine. These local anesthetic agents produce only superficial anesthesia. They do not provide for any pain relief that originates submucosally or deeper. The total dose applied should be one-third to one-half the dose used for infiltration. Use these agents cautiously on the oral mucosa as they can suppress the gag reflex and increase the risk for aspiration.

Benzocaine is a commonly used mucous membrane anesthetic. It is available in spray, liquid, and gel form in a concentration of 14% to 20% (e.g., Cetacaine, Hurricaine, Americaine). It is nontoxic when applied to intact mucous membranes due to its poor water solubility. It provides brief analgesia. Overuse of benzocaine has the potential to produce methemoglobinemia.[34,35]

Cocaine is supplied in solution at concentrations of 4% and 10%. It is an extremely effective mucous membrane anesthetic with significant vasoconstrictive properties. Systemic absorption is enhanced when it is applied to inflamed mucous membranes. The maximum dose is 3 mg/kg. This dose still has the potential to result in toxicity and serious complications. **Do not use cocaine in patients with hypertension, cardiomyopathy, known or suspected coronary artery disease, or patients sensitive to exogenous catecholamines.**

Lidocaine is available in jelly and liquid form with a concentration of 2% to 10%. The 2% and 4% viscous solutions are often used in the Emergency Department. Instruct the patient to swish the solution in their mouth for 30 to 60 seconds then spit it out. It can result in significant systemic absorption if swallowed. The maximal dose is 300 mg in adults (15 mL of 2% or 7.5 mL of 4%) and 3 mg/kg in children. **Use extreme caution when sending patients home with viscous lidocaine for intraoral use.** Frequent use and swallowing can both result in elevated blood levels of the parent drug and its metabolites, both of which can result in potential adverse and toxic effects.[36,37]

Tetracaine is available in liquid and aerosol form with a concentration of 0.25% to 1.0%. It has significant cardiotoxic effects. It is therefore not often used for mucous membrane anesthesia. Tetracaine should not be used for mucous membrane anesthesia in the Emergency Department.

MISCELLANEOUS AGENTS

Several alternative topical anesthetic techniques have been used to provide analgesia. S-Caine Peel (Zars Pharma) has been developed as a local anesthetic peel. It is applied to an area for 20 to 30 minutes. It dries into a flexible membrane that can be peeled off after the application period. This agent is easily applied to non-flat body surfaces. Its primary use has been for laser vein treatments and laser tattoo removal.[38–40] Acupressure has been used for hundreds of years to relieve pain. It has been recently used in acute painful conditions.[41] The ShotBlocker (Bionix, Toledo, Ohio) is a plastic device that is pressed against the skin just before and during an injection.[42] It may be used to decrease the pain of local anesthetic injections. These techniques all have the potential to decrease the pain due to procedures. More information and trials are required before these can be used in the Emergency Department.

ASSESSMENT

It is important to wait long enough after the topical agent is administered to allow the onset of adequate anesthesia before the planned procedure is started. The period of time necessary for the onset of anesthesia is highly variable and dependent on the topical anesthetic used and the delivery technique utilized. A simple examination of the area being anesthetized with fine touch and pinprick is important to insure adequate anesthesia prior to the procedure. It may be necessary to apply additional anesthetic or use an alternative anesthetic technique in areas of continued sensitivity, keeping in mind the total dose applied to avoid toxicity.

AFTERCARE

The Emergency Physician should observe the patient for a minimum of 15 minutes following the use of topical anesthesia to ensure no evidence of an adverse reaction. The patient need not wait in the Emergency Department for normal sensation to return prior to discharge.

COMPLICATIONS

There are case reports of patients developing CNS toxicity after the application of topical anesthetics.[43] There have been cases of methemoglobinemia reported in patients, particularly with the use of benzocaine.[34] Topical anesthetics in patients taking Class 1 antiarrhythmics such as mexiletine and tocainide can produce additive and possibly toxic effects. EMLA has been reported to cause ulceration of the gingival mucosa and thus should not be used for mucosal anesthesia.[44] Many of the topical anesthetics are contraindicated or require special ophthalmic formulations for use in the eye. When using topical anesthetics in neonatal patients, special care and attention to dosing are imperative to avoid toxicity.

SUMMARY

There are a number of effective techniques available to decrease the pain and anxiety associated with invasive procedures. Topical anesthetic agents, particularly those with fast acting properties, are excellent adjuncts for use in the Emergency Department. Topical anesthetic creams, active medication delivery, or alternative techniques should be considered prior to performing a painful invasive procedure.

125 Hematoma Blocks

Thomas P. Graham

INTRODUCTION

Distal extremity fractures are commonly seen in the Emergency Department. These fractures often require closed reduction by manipulation, which can be a painful and frightening experience for the patient. Achieving adequate analgesia is important to facilitate reduction and to minimize patient discomfort. However, studies suggest that Physicians frequently provide inadequate analgesia to patients, and particularly children, with extremity fractures.[1,2]

ANATOMY AND PATHOPHYSIOLOGY

The hematoma block is a technique to inject a local anesthetic solution into the hematoma between the fractured bone fragments. Fracture manipulation can then often be undertaken painlessly or with significantly reduced pain. Hematoma blocks of the distal forearm are considered safe in children and adults.[3–8] Another advantage is the relative ease of the procedure. A hematoma block may be superior to intravenous sedation in alleviating discomfort during fracture reduction.[9] The hematoma block, unlike procedural sedation, avoids the side effects of sedating drugs, does not require intravenous access and cardiac monitoring, and is not associated with a prolonged recovery phase. One Physician can safely perform a hematoma block, whereas the presence of two Physicians is generally recommended for procedural sedation. The disadvantages of the hematoma block include the discomfort and anxiety resulting from injecting into the fracture site, and the potential for a rare complication.

Extremity fractures, when displaced or angulated, generally result in the formation of a hematoma between the fracture fragments. The hematoma is easily accessible with a needle and the injection of local anesthetic solution can significantly alleviate pain. The majority of important neurovascular structures in the upper extremity are contained in the volar soft tissue, making the dorsal or lateral approach preferred. The majority of important neurovascular structures in the lower extremity are contained in the proximal anterior thigh or posteriorly in the leg, making the lateral approach preferred in the proximal thigh and the anterior or lateral approach from the mid-thigh distally.

Other techniques are available to provide analgesia and anesthesia. Some authors have concluded that a Bier block (intravenous regional anesthesia, Chapter 127) may lead to more effective anesthesia and require fewer re-manipulations for the reduction of forearm fractures when compared to the hematoma block.[10–12] However, the Bier block is a technique that most Emergency Physicians are not familiar and have not developed proficiency, requires equipment not commonly available in the Emergency Department, and can be associated with adverse outcomes. Intraarticular injection of local anesthetic solution for the reduction of intraarticular fracture-dislocations, though not as well studied or widely utilized as a hematoma block, have also been advocated as safe and effective.[13,14] The joints of the extremities are easily entered by performing an arthrocentesis (Chapter 77). Local anesthetic solution injected intraarticularly diffuses throughout the joint cavity and exits through the fracture site to alleviate pain.

INDICATIONS

A hematoma block is indicated in adult and pediatric patients with closed fractures of the extremity that require manipulation or closed reduction. Consider performing a hematoma block when medical resources are limited or scarce. It is an alternative when procedural sedation is impossible or impractical. A hematoma block may be performed purely for analgesia when fracture manipulation is unnecessary and/or other methods of analgesia are ineffective or contraindicated.

CONTRAINDICATIONS

Hematoma blocks are contraindicated when there is a history of allergic reactions to local anesthetic agents. The procedure is also contraindicated in the setting of an open fracture, cellulitis overlying the fracture site, or the presence of a neurovascular deficit. A hematoma block should not be performed if a sterile field cannot be maintained or the safety of the medical staff cannot be assured due to an uncooperative patient. Relative contraindications include patients with bleeding disorders and those taking anticoagulants. The potential additional hemorrhage from the injection of local anesthetic solution into a closed space may result in a compartment syndrome.

EQUIPMENT

- Sterile gloves and gown
- Face mask and cap
- Povidone iodine or chlorhexidine solution
- Sterile drapes
- Local anesthetic solution without epinephrine, usually 1% lidocaine
- Syringes, various sizes
- 22 or 23 gauge, 2-inch long needles
- Spinal needles for obese patients

Optional Equipment

- Ultrasound machine
- 7.5 to 10 MHz ultrasound probe
- Sterile ultrasound gel
- Sterile ultrasound probe cover

PATIENT PREPARATION

Explain the risks, benefits, complications, and alternatives to the patient and/or their representative. The technique for adult and pediatric patients is identical. An adult usually tolerates the hematoma block injection without any supplemental analgesia or sedation. Some adults and children may require supplemental nitrous oxide, intravenous sedation, or an intravenous anxiolytic agent to facilitate the hematoma block.

Prepare for the procedure. **The hematoma block must be performed using strict aseptic technique.** Cleanse the skin of any dirt and debris over the fracture site and surrounding skin. Apply povidone iodine or chlorhexidine solution onto the skin and allow it to dry. Apply sterile drapes to form a sterile field. The Emergency Physician should be wearing sterile gloves and a sterile gown during the procedure. The use of a face mask and cap is also recommended. Using aseptic technique, draw up sterile 1% lidocaine without epinephrine into a syringe armed with a 22 or 23 gauge, 2-inch long needle. A longer spinal needle may be required in the obese patient. Fill the syringe with 0.3 mL/kg to a maximum of 10 mL of lidocaine, the volume to be injected. Larger volumes maybe required in adults and larger fractures. Always be aware of the maximum safe dose of 4.5 mg/kg when using lidocaine without epinephrine.

TECHNIQUES

HEMATOMA BLOCK FOR DISTAL RADIUS FRACTURES

Follow strict aseptic technique throughout the procedure. Inform the patient of the early signs of local anesthetic toxicity. These include circumoral and tongue numbness, dizziness, lightheadedness, mental status decline, tinnitus, and visual disturbances. Instruct the patient to inform you immediately if they experience any of these symptoms.

Place a wheal of 1% lidocaine subcutaneously over the fracture site. Allow 1 to 2 minutes for the anesthetic to take effect. Slowly insert and advance the 23 gauge needle attached to the lidocaine-filled syringe through the skin wheal and aimed at the fracture site.

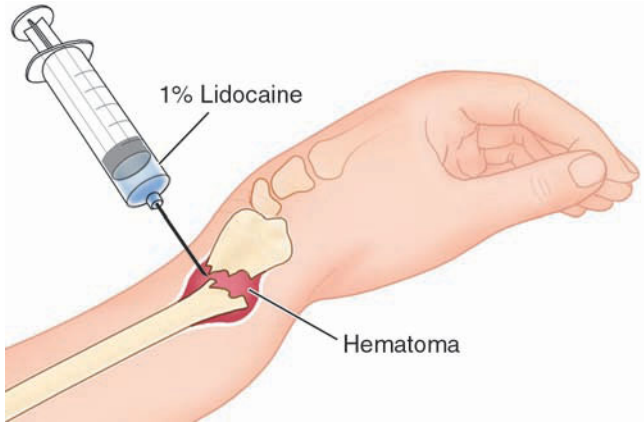

FIGURE 125-1. The hematoma block. The needle is inserted into the hematoma near the fracture fragments. Local anesthetic solution is injected into the hematoma.

Continue to slowly advance the needle toward and into the expected location of the gap between the fracture fragments (**Figure 125-1**). Aspirate with the syringe. A flash of blood indicates entry into the hematoma. If the needle strikes bone or if no flash of blood is returned, withdraw the needle and re-direct it in an attempt to enter the hematoma. Slowly inject the contents of the syringe into the hematoma. Withdraw the needle. Apply a bandage to the skin puncture site.

Some physicians reposition the needle to different areas within the hematoma and inject small amounts of the local anesthetic solution into each area. This technique distributes the local anesthetic solution to increase the efficacy of the hematoma block. Injection into multiple areas also minimizes the risk of intravascular injection of the entire dose of local anesthetic solution.

HEMATOMA BLOCK FOR INTRAARTICULAR FRACTURE-DISLOCATIONS

The procedure is identical to that described above except for the anatomic landmarks and the volume of local anesthetic solution injected. Refer to Chapter 77 for the complete details of arthrocentesis.

ULTRASOUND-GUIDED HEMATOMA BLOCK

Identify the fracture site and hematoma using ultrasound (US). Place the US probe on the patient's skin above the fracture site. Turn the US probe so its long axis is aligned with the long axis of the bone. Identify the fracture site and hematoma. Rotate the US probe 90° to visualize the short axis or cross-sectional view of the fracture site and hematoma.

Clean, prep, and sterilely drape the patient as described previously. Prepare the US probe. Apply US gel to the footprint of the US probe. Apply a sterile probe cover or a sterile glove over the US probe. Squeeze any air out of the space between the US probe and the cover. Apply sterile US gel on the probe cover.

Grasp the sterile US probe with the nondominant hand. Align the long axis of the US probe along the long axis of the bone and approximately 8 to 10 mm proximal to the fracture site. Aim the syringe containing the local anesthetic solution downward and in the direction of the fracture site. Slowly insert and advance the needle through the skin under US guidance. Advance the needle into the hematoma at the fracture site. Inject the local anesthetic solution. Remove the needle and apply a bandage to the skin puncture site.

ALTERNATIVE TECHNIQUES

Several adjuncts to the hematoma block may aid in increasing its efficacy. The addition of hyaluronidase to the local anesthetic solution has been advocated and become routine at some centers as a means of increasing the speed and efficiency of the hematoma block. The hyaluronidase breaks down the connective tissue and allows better penetration of the local anesthetic solution into the area. The evidence for the efficacy of hyaluronidase is currently lacking.[15] Based on available data, it is not currently recommend to add hyaluronidase to the local anesthetic solution. The use of ultrasound can facilitate the injection into the correct site.[16,17] Some authors recommend the use of other agents, such as anxiolytics, in combination with the hematoma block for fracture manipulation. Combining the hematoma block with nitrous oxide has shown positive results.[18]

ASSESSMENT

Reassess and document a thorough neurologic and vascular examination distal to the fracture site immediately after the injection. Assess the patient's level of pain with gentle range of motion in 10 minutes. A second injection of local anesthetic solution may be performed if required for analgesia if the patient is not experiencing any side effects or toxicity and the total combined doses do not exceed the maximum allowable limit of 4.5 mg/kg.

AFTERCARE

The extremity can be manipulated to reduce the fracture once adequate analgesia has been obtained. Splint the extremity. Perform and document another neurologic and vascular examination of the extremity after any manipulation and splinting. Instruct the patient to immediately return to the Emergency Department for severe pain, significant swelling, numbness, paresthesias, or pallor of the extremity. Arrange appropriate follow-up with an Orthopedic Surgeon. Prescribe analgesics as appropriate.

COMPLICATIONS

The complications associated with a hematoma block are rare. These include a compartment syndrome, local anesthetic toxicity, and osteomyelitis.[19–25] The early signs of local anesthetic toxicity include circumoral and tongue numbness, dizziness, lightheadedness, mental status decline, tinnitus, and visual disturbances. The cardiovascular toxic effects include asystole, atrioventricular blocks, bradycardia, cardiac depression, dysrhythmias, and hypotension. The neurologic toxic effects include agitation, coma, confusion, headaches, seizures, and possibly death. Seizures associated with local anesthetic toxicity are usually short lasting and respond to barbiturates, benzodiazepines, and propofol. Please refer to Chapters 123 and 127 for the complete details regarding local anesthetic complications and toxicity. Introducing bacteria into a previously closed fracture and injury to vascular structures are also potential complications. These can be minimized or eliminated by using strict aseptic technique and carefully identifying the anatomic landmarks.

SUMMARY

A hematoma block is an effective technique to facilitate manipulation of extremity fractures and intraarticular fracture-dislocations in adults and children. It may also be performed purely for

analgesia when no manipulation is required. Complications are rare if proper techniques are used. The procedure requires fewer Emergency Department resources than procedural sedation or a Bier block. Consider performing a hematoma block when procedural sedation is impractical or contraindicated. Patient preference should also be considered. Many patients would likely prefer a shorter Emergency Department stay with a hematoma block rather than a much longer one involving procedural sedation and the associated risks.

126 Regional Nerve Blocks (Regional Anesthesia)

Eric F. Reichman, Jehangir Meer, and Nikesh Seth

INTRODUCTION

Regional anesthesia or regional nerve blocks are defined as infiltration of a peripheral nerve with local anesthetic agents to attenuate motor output and sensory input. It provides anesthesia to allow conditions to be treated efficiently and with minimal discomfort. Patients typically tolerate nerve blocks better than direct wound infiltration. Nerve blocks often require less local anesthetic solution than does infiltration of large wounds.

Regional anesthesia provides sensory blockade of a region without altering the normal anatomic features of the area to be repaired. It may be considered for use in the repair of extensive wounds, incision and drainage of abscesses, foreign body removal, wound exploration, burn care, fracture reduction, or pain control. Once familiar with the body's sensory innervation, the Emergency Physician can easily employ regional anesthesia techniques within the Emergency Department.

Locating and anesthetizing a peripheral nerve is accomplished in one of four ways. First is to identify the general location of the nerve using anatomy and landmarks. Infiltrate local anesthetic solution at that site and allow it to diffuse over the area. The second is to locate a nerve by using the injecting needle to elicit paresthesias. Once paresthesias are elicited, withdraw the needle 1 to 2 mm and allow the paresthesias to resolve before injecting the local anesthetic solution. A nerve stimulator can be used to accurately locate peripheral nerves with motor fiber components. Use of a nerve stimulator does not require cooperation on the part of the patient. However, due to its complexity, a physician skilled in its use is required. Nerve stimulators are rarely available in the Emergency Department. US can be used to locate nerves.

The traditional method used by Anesthesiologists to perform regional anesthesia involves a combination of surface landmarks and nerve stimulation. Over the past 10 to 15 years, ultrasound (US) has gained a prominent role in guiding nerve blocks. It offers the advantages of visualizing the nerve and the needle, as well as directly visualizing the deposition of local anesthetic solution around the nerve. Several small studies have shown that Emergency Physicians can safely perform US-guided nerve blocks.[1–4]

It is common to encounter children complaining of pain in the Emergency Department. Regional anesthesia is frequently overlooked in children. Its use is increasing and serves as an excellent opportunity to minimize pain in the pediatric population.[5] It can be administered safely and effectively in these patients. A child may require intravenous or intramuscular sedation in conjunction with nerve blockade in more complicated cases. The use of nitrous oxide with pediatric patients in the Emergency Department has been found to be successful when used for forearm fracture manipulation.[6] It can also be used for other procedures. Refer to Chapter 128 regarding the use of nitrous oxide as a supplement or to perform the regional nerve block. The disadvantages of regional nerve blocks in children include the extra time required to perform the block, mandatory technical dexterity, and assistant support because the child may not remain still for the procedure.

This chapter covers regional anesthetic blocks of the head, neck, upper extremity, lower extremity, and two of the many torso blocks (**Table 126-1**). Dental blocks are discussed in Chapter 176. Refer to Chapter 123 for a more complete discussion on the properties of local anesthetic agents.

ANATOMY AND PATHOPHYSIOLOGY

There is a topographic arrangement of axons within peripheral nerves (**Figure 126-1A**).[7,8] Axons located in the outer or mantle layer innervate proximal structures. Axons in the center of the nerve or core layer innervate distal structures. Local anesthetic solution injected near a nerve diffuses from the mantle layer to the core layers. **This explains why anesthesia slowly spreads along the nerve distribution in a proximal to distal direction.**

Avoid intraneural injection when performing peripheral nerve blocks. The nerve has a tough, fibrous outer sheath that acts as a physical barrier to trap intraneural fluid (**Figure 126-1B**). Injection of local anesthetic agents into the nerve bundle will compress the fragile axons and their capillary blood supply.[9,10] This can result in axonal necrosis and permanent nerve damage. **Paresthesias elicited**

TABLE 126-1 Nerves and Anatomical Areas That Can Be Anesthetized in the Emergency Department Using a Regional Block

Head and neck	Lower extremity	Upper extremity	Torso
Supraorbital nerve block	Femoral nerve block	Brachial plexus block	Intercostal block
Supratrochlear nerve block	Saphenous nerve block	Median nerve block	Penile nerve block
Infraorbital nerve block	Lateral femoral cutaneous nerve block	Ulnar nerve block	
Mental nerve block	Obturator nerve block	Radial nerve block	
Greater occipital nerve block	Sciatic nerve block	Wrist block	
Lesser occipital nerve block	Popliteal fossa block	Digital nerve block	
Greater auricular nerve block	Common peroneal nerve block		
Scalp block	Superficial peroneal nerve block		
External ear block	Deep peroneal nerve block		
External auditory canal block	Sural nerve block		
Cervical plexus block	Posterior tibial nerve block		
	Ankle block		
	Digital nerve block		

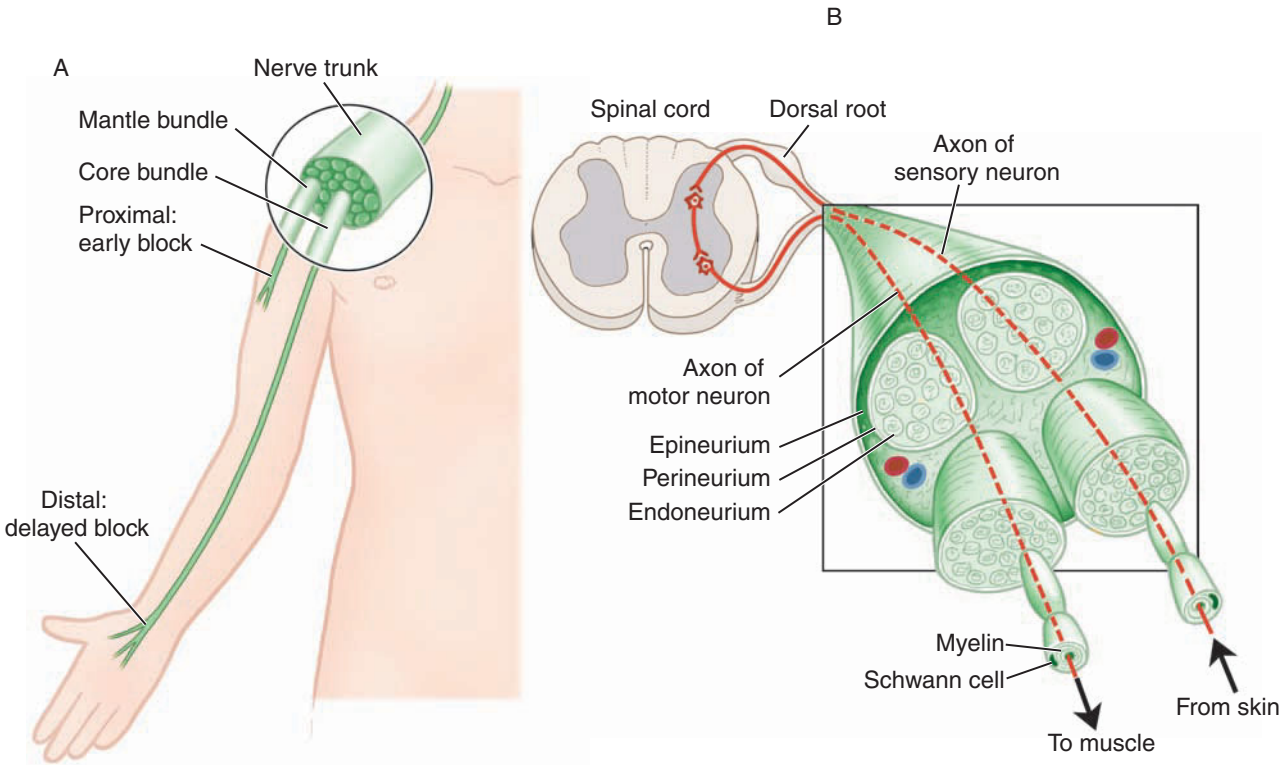

FIGURE 126-1. The anatomy and topographic arrangement of axons in a peripheral nerve. **A.** The gross anatomy of a peripheral nerve. **B.** The microscopic anatomy of a peripheral nerve.

upon needle insertion indicate that the tip of the needle is within the nerve bundle. Withdraw the needle 1 to 2 mm and allow the paresthesias to resolve, usually within 15 to 30 seconds. The anesthetic agent can be safely injected when the paresthesias resolve.

Cutaneous innervation is referenced to a segment known as a dermatome.[7] This is defined as an area of skin supplied by a single spinal or segmental nerve. This type of innervation is best represented in worms, where each body segment has its own nervous supply. The pattern of segmental innervation still holds true with some minor modifications as one moves up the phylogenetic tree. The truncal dermatomes in humans are represented as simple bands while the extremity dermatomes are serpiginous and follow the embryonic rotation of the limb buds. The most commonly used dermatomal chart is that developed by Keegan and Garrett (**Figure 126-2**).[8] Their model of the extremity dermatomes is in strips of innervation, all originating from the limb base and extending distally. This system is used in clinical medicine today.

INDICATIONS

Regional anesthesia produces profound analgesia with minimal physiologic or anatomic alteration. These techniques are especially useful in large or extensive lacerations that would otherwise require infiltration of a large and potentially toxic volume of local anesthetic solution. Nerve blocks can avoid a patient being taken to the Operating Room because the volume of local anesthetic required for extensive wound repair may require toxic doses. These techniques are also useful in cosmetic repairs where local infiltration may cause distortion of tissues or loss of anatomic landmarks making approximation and repair difficult. The necessity to palpate deep tissue for excision is also an indication for regional anesthesia.[11,12] Regional nerve blocks can be performed prior to burn care, dislocation or fracture reduction, foreign body removal, incision and drainage of abscesses, pain control, wound exploration, and wound care.

US-guided regional anesthesia offers a number of advantages when compared with the anatomic landmark. It is safer and results in fewer complications (e.g., vascular puncture, pneumothorax, and intravascular injection of local anesthetic).[13] US achieves higher rates of successful block (over 95%) and delivers a more rapid onset of anesthesia. In addition, a smaller volume of local anesthetic solution is required for the block.[13] US can eliminate the need for procedural sedation and analgesia (PSA) and its potential complications (e.g., apnea, hypoxia, and hypotension). Preprocedural fasting is not required as it is a potential requirement in PSA. US-guided nerve blocks reduce Emergency Department lengths of stay compared with patients receiving PSA.[1] It facilitates procedures in patients with higher American Society of Anesthesiology (ASA) classification scores, who would otherwise be put at higher risk for complications by the administration of PSA.

CONTRAINDICATIONS

There are few contraindications to regional anesthesia.[7,14] Absolute contraindications include injection through infected tissue, history of a bleeding disorder or a coagulopathy, or an allergy to the anesthetic agent. Relative contraindications include preexisting neurologic damage prior to the procedure. This should carefully be documented before any anesthetic injection. Additionally, patient uncooperativeness can make the procedure technically more difficult. Therefore, procedural sedation may be a necessary adjunct.[5,15] This is particularly true of the pediatric population and those with an altered mental status.[16]

There are no patient contraindications to the use of US to guide nerve blocks. Emergency Physician contraindications include the lack of familiarity and training with the procedure. Psychomotor

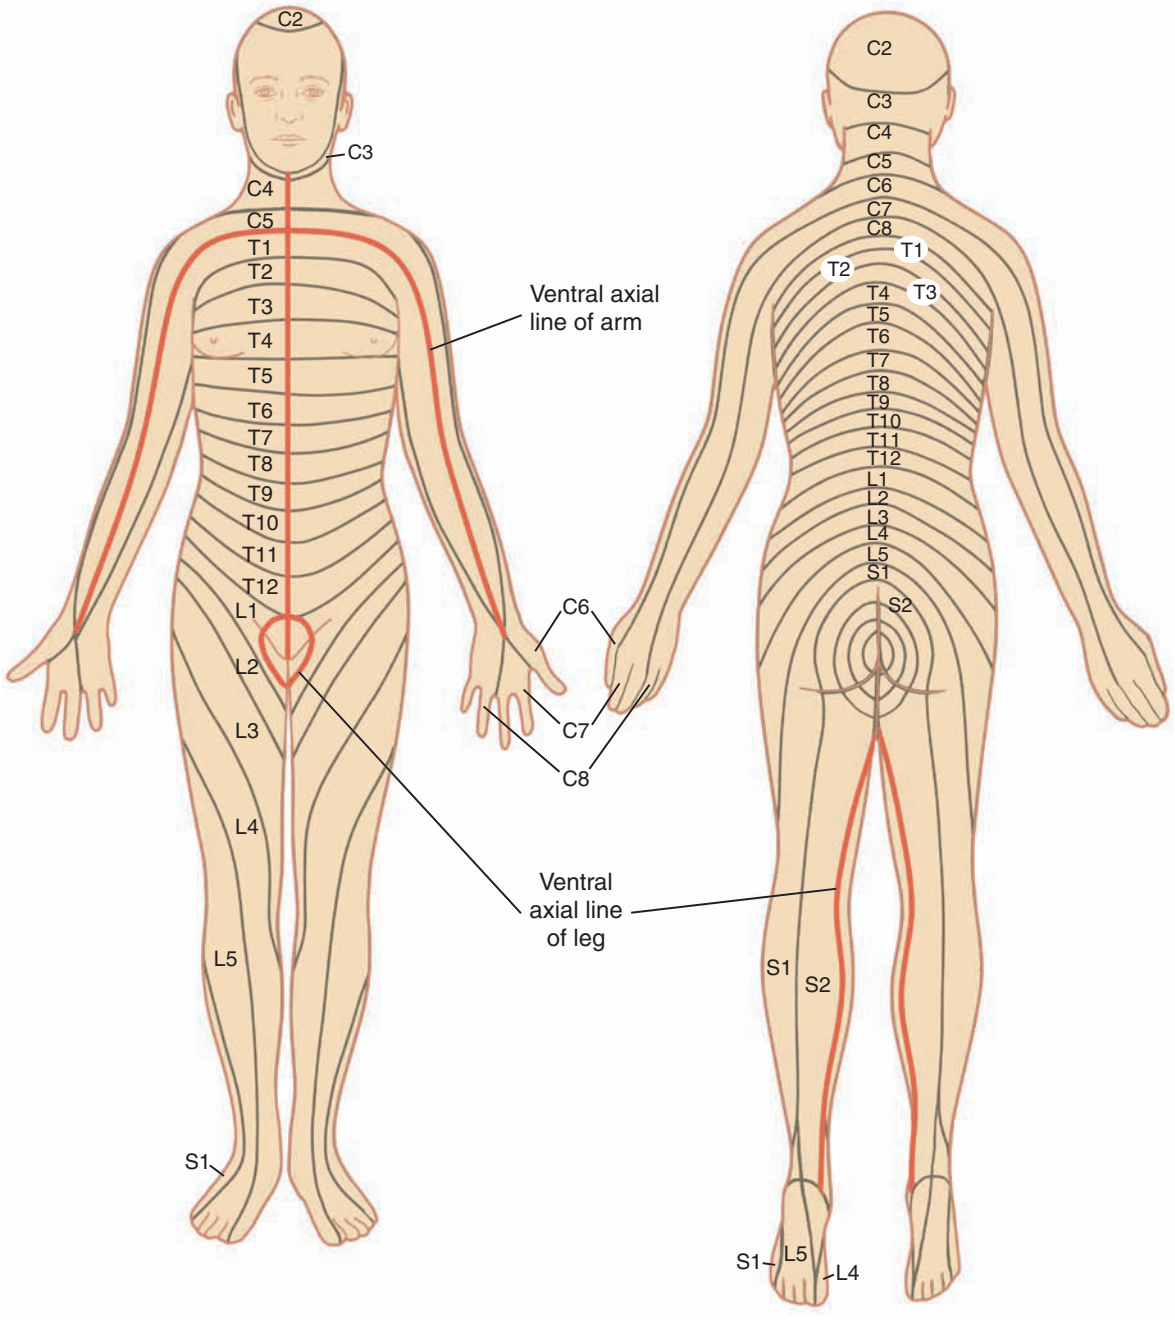

FIGURE 126-2. The dermatomal chart of the human body.

coordination and experience with US are required. Caution is advised for the novice ultrasonographer.

EQUIPMENT

Anatomic Landmark-Guided Nerve Blocks

- Sterile gloves
- Sterile drapes
- Povidone iodine or chlorhexidine solution
- Alcohol swabs
- Local anesthetic solution (**Table 126-2** and Chapter 123)
- 18 gauge needle to draw up local anesthetic solution
- 20 to 27 gauge noncutting or Quincke needles for injection, 2 inches long
- 22 to 24 gauge noncutting or Quincke spinal needles
- 1, 3, 5, 10, and 60 mL syringes
- Intravenous extension tubing

US-Guided Nerve Blocks

- Above listed supplies
- US machine
- High frequency, linear-array, US probe
- Sterile US probe cover
- Sterile US gel

TABLE 126-2 Maximum Doses of Local Anesthetic Agents

Anesthetic agent	Maximum dose (mg/kg)	Duration of action (min)
Procaine (2%)	6	15–30
Procaine (2%) with epinephrine	8	30–90
Tetracaine (0.25%)	1	120–140
Tetracaine (0.25%) with epinephrine	2	240–280
Chloroprocaine (2%)	8	15–30
Chloroprocaine (2%) with epinephrine	10	30–90
Lidocaine (1%)	3	30–120
Lidocaine (1%) with epinephrine	5	60–400
Etidocaine (0.5%)	3	30–120
Etidocaine (0.5%) with epinephrine	4	60–200
Mepivacaine (1%)	3	30–120
Mepivacaine (1%) with epinephrine	5	60–400
Bupivacaine (0.25%)	1.75	120–240
Bupivacaine (0.25%) with epinephrine	2.25	240–480
Prilocaine (4%)	5	30–60
Prilocaine (4%) with epinephrine	6	120–300

All of the required equipment is readily available in any Emergency Department. Some have a pre-prepared tray or tackle box containing all the required equipment.

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Emphasize that there are few complications with this procedure. However, all possible complications should be discussed beforehand. Inform the patient of the possibility of paresthesias during the procedure and of the expected duration of action of the local anesthetic agent (**Table 126-2**). **Obtain an informed consent for the regional nerve block in addition to the procedure for which it is performed.** Ideally, the consent should be documented in the medical record and signed by the patient. Some Emergency Physicians prefer to note on the patient's chart "Indications, risks, and benefits were discussed with the patient" rather than having the patient sign a consent form. This decision is specific to each Emergency Physician, their institution, and state requirements.

Perform and document a neurological examination of the area to be anesthetized before performing regional anesthesia. Include a description of any neurological deficit in the document of informed consent for the procedure. Have the patient sign an agreement that the defect was present prior to the administration of the local anesthetic solution.

Position the patient based upon the specific regional block to be performed. Place the patient supine on a gurney or procedure table prior to the procedure in most cases. If the patient must sit upright, place the patient on an adjustable bed. The patient's comfort should be optimized to prevent unexpected complications such as vasovagal syncope.[7,17,18] Expose the area of the injection and identify the anatomic landmarks required for proper needle placement. Clean all dirt and debris from the skin. Scrub the needle insertion site with povidone iodine or chlorhexidine solution and allow it to dry. Apply sterile drapes to delineate a sterile field.

If using US-guidance, prepare the US probe. **Always use a sterile US probe cover and sterile US gel when performing nerve blocks to prevent deep infections.** Set up a sterile field on a bedside table. Open the US probe cover set onto the sterile field. Instruct an assistant to hold the US probe upright and place standard or sterile US gel on the footprint of the US probe (**Figure 50-6A**). Apply the sterile probe cover over the US probe (**Figure 50-6B**). Smooth all the air bubbles away from the footprint of the US probe to prevent imaging artifacts. Secure the cover with rubber bands to prevent it from sliding off the US probe (**Figure 50-6C**). Place the US probe on the sterile field (**Figure 50-6D**). Apply sterile US gel onto the cover over the US probe footprint just before scanning.

TECHNIQUE

The general procedure will first be described and specifics will be addressed with each individual nerve block.

ANATOMIC LANDMARK TECHNIQUE

Position the patient. Identify the nerve or nerves to be blocked and their associated anatomic landmarks. Carefully clean and prepare the skin over the injection site in a sterile fashion. Draw up the local anesthetic solution to be injected. The amount will vary based upon the specific block. Always keep in mind the maximum allowable dose of local anesthetic (**Table 126-2**). Reidentify the anatomic landmarks. Insert the needle into the site. Withdraw the plunger to ensure that the tip of the needle is not within a blood vessel, thus avoiding intravascular injection. If paresthesias are elicited, withdraw the needle 1 to 2 mm and allow them to resolve. Inject the local anesthetic solution. Apply an appropriate bandage to the site. Allow 5 to 15 minutes for the block to take effect. Confirm that anesthesia has been achieved with pinprick prior to performing the procedure for which regional anesthesia was performed. Document the regional anesthesia procedure, the procedure for which regional anesthesia was performed, and any complications in the medical record. A sample regional anesthesia procedure note is described in **Table 126-3**.

US-GUIDED TECHNIQUE

Position and prepare the patient as described above for the anatomic landmark technique. Find the general location of the nerve using anatomic landmarks. Use US to identify the targeted nerve. Use a longitudinal needle approach for all US-guided nerve blocks. The US probe should image the nerve bundle in the short axis, allowing the entire length of the needle to be visualized as it approaches the nerve. Use a noncutting needle, such as a Quincke spinal needle, to reduce the risk of intraneural injection or nerve injury. Place the US machine on the patient's opposite side to allow the Emergency Physician to glance easily and quickly from the field to the US monitor. It is recommended to use an assistant to inject the local anesthetic solution. This allows the Emergency Physician to use their hands to hold the US probe with one hand and manipulate the needle with the other hand. Center the target nerve on the screen.

An important concept regarding the injection of local anesthetic solution around the nerve bundle is the "donut sign." This is the circumferential spread of local anesthetic solution around the nerve. This is the desired location of the local anesthetic solution around the nerve and it is usually associated with a successful block.

TABLE 126-3 A Sample Regional Anesthesia Procedure Note

After informed consent and identification of the necessary landmarks, the skin overlying _____ (location) was cleaned and prepped with povidone iodine or chlorhexidine solution. Using sterile technique, a skin wheal of local anesthetic solution was placed. A ____ gauge needle was used to anesthetize the _____ nerve with mL ____ of ____ % _____ (lidocaine, marcaine, procaine, etc.). Anesthesia was confirmed with needle pinprick testing. No complications were noted.

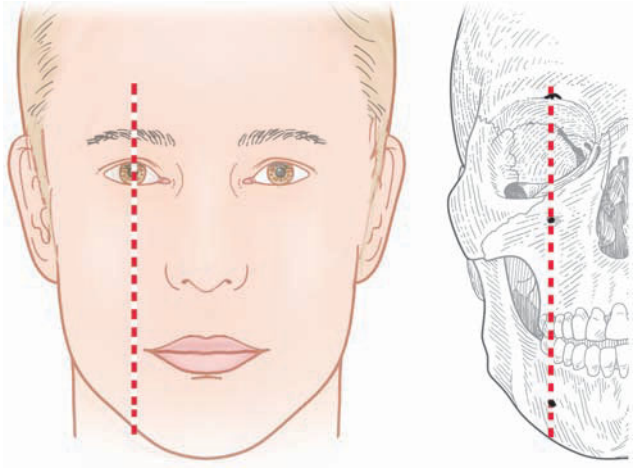

FIGURE 126-3. The supraorbital foramen, the infraorbital foramen, and the mental foramen all lie along a straight line drawn through the pupil in the midposition.

REGIONAL ANESTHESIA TECHNIQUES FOR THE HEAD AND NECK

SUPRAORBITAL NERVE BLOCK

Anatomy The supraorbital foramen lies on the supraorbital ridge along a line drawn through the pupil in the midposition (**Figures 126-3 & 126-4**). The supraorbital foramen may be palpable as an indentation. The supraorbital nerve is a branch of the ophthalmic division of the trigeminal nerve. It emerges through the supraorbital foramen, or notch, at the midline of the superior orbital ridge (**Figure 126-4A**). Its area of innervation includes the forehead, beginning at the superior orbital ridge and extending superiorly to the vertex of the scalp. It is blocked simultaneously with the supratrochlear nerve, as there is considerable overlap in their areas of innervation.

Patient Positioning Place the patient supine, or sitting, and facing the Emergency Physician.

Landmarks Identify, under the eyebrow, the superior orbital rim and the supraorbital foramen by palpation.

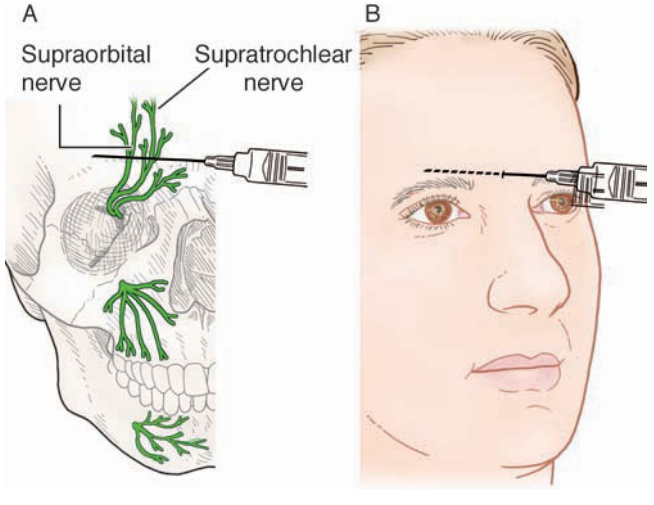

FIGURE 126-4. The supraorbital and supratrochlear nerve block. **A.** The location of the nerves. **B.** Insertion of the needle.

Needle Insertion and Direction Place a skin wheal of local anesthetic solution over the midline of the forehead at the level of the eyebrow. Insert a 25 or 27 gauge needle through the skin wheal and aimed laterally (**Figure 126-4B**). Advance the needle while infiltrating subcutaneously with 3 to 5 mL of local anesthetic solution. Always maintain the needle just above the supraorbital ridge while advancing it (**Figure 126-4B**). Stop infiltrating when the needle passes the midline of the bony orbit.

Remarks This technique will anesthetize both the supraorbital and supratrochlear nerves. Infiltrate 2 mL of local anesthetic solution directly over the supraorbital foramen, or notch, if it is palpable rather than subcutaneously infiltrating above the supraorbital ridge.

SUPRATROCHLEAR NERVE BLOCK

Anatomy The supratrochlear nerve is a branch of the ophthalmic division of the trigeminal nerve. It emerges through the trochlea at the supermedial aspect of the bony orbit (**Figure 126-4A**). It provides innervation to the middle of the forehead beginning at the superior orbital ridge and extending superiorly to the vertex of the scalp. It is often blocked simultaneously with the supraorbital nerve, because there is considerable overlap in their areas of innervation.

Patient Positioning Place the patient supine, or sitting, and facing the Emergency Physician.

Landmarks Identify, under the eyebrow, the superior orbital rim by palpation.

Needle Insertion and Direction Place a skin wheal of local anesthetic solution over the midline of the forehead at the level of the eyebrows. Insert a 25 or 27 gauge needle through the skin wheal, aimed laterally (**Figure 126-4B**). Advance the needle while infiltrating subcutaneously with 2 to 3 mL of local anesthetic solution. Always maintain the needle just above the supraorbital ridge while advancing it (**Figure 126-4B**). Stop infiltrating when the needle passes the midline of the bony orbit.

Remarks Stop infiltrating 1.5 cm from the skin wheal so as to block only the supratrochlear nerve.

INFRAORBITAL NERVE BLOCK, EXTRAORAL APPROACH

Anatomy The infraorbital nerve is a branch of the maxillary division of the trigeminal nerve. It emerges through the infraorbital foramen, 1 cm below the middle to medial third of the inferior orbital ridge (**Figure 126-5A**). It lies in the same plane as the supraorbital foramen and pupil that is in the midposition (**Figures 126-3 & 126-5**).

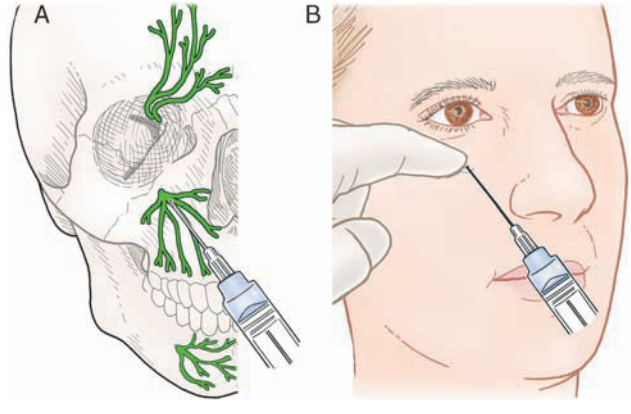

FIGURE 126-5. The extraoral approach to the infraorbital nerve block. **A.** Location of the nerve. **B.** Insertion of the needle.

The nerve exits the infraorbital foramen and travels inferiorly and medially. It provides sensory innervation to the medial cheek, nasal ala, upper lip, and the skin between the upper lip and nose. The infraorbital nerve terminates as the anterior and middle superior alveolar nerves. They provide sensory innervation to the maxillary incisors, canine, and premolar teeth, as well as their bony support and surrounding soft tissues.

Patient Positioning Place the patient supine, or sitting, and facing the Emergency Physician.

Landmarks Identify the infraorbital foramen by palpation. Significant tenderness will be elicited when the infraorbital nerve is palpated as it exits the infraorbital foramen.

Needle Insertion and Direction Insert a 25 or 27 gauge needle just above the infraorbital foramen (**Figure 126-5B**). Advance the needle until the maxilla is contacted. Inject 1 to 2 mL of local anesthetic solution.

Remarks The infraorbital nerve can be blocked intraorally. The intraoral route results in the patient experiencing less pain than the extraoral route.

INFRAORBITAL NERVE BLOCK, INTRAORAL APPROACH

Anatomy The anatomy and innervation of the infraorbital nerve is described in the previous section.

Patient Positioning Place the patient supine, or sitting, and facing the Emergency Physician.

Landmarks Identify the infraorbital foramen by palpation. It lies in a plane with the supraorbital foramen and the pupil in the midposition (**Figures 126-3 & 126-6A**).

Needle Insertion and Direction Place the index finger of the nondominant hand over the infraorbital foramen (**Figure 126-6B**). Use the nondominant thumb to retract the upper lip. Insert a 2.5 to 4.0 cm, 25 or 27 gauge needle through the mucous membranes, directed at the index finger. Advance the needle until its tip is palpable at the infraorbital foramen by the index finger. The estimated depth of needle penetration is 1.0 to 1.5 cm. Inject 2 mL of local anesthetic solution.

Remarks This is the preferred route to block the infraorbital nerve. It can also be blocked extraorally.

MENTAL NERVE BLOCK, EXTRAORAL APPROACH

Anatomy The mental nerve is a branch of the mandibular division of the trigeminal nerve. It emerges from the mental foramen. The foramen lies in a vertical plane with the supraorbital foramen, the infraorbital foramen, and the pupil that is midposition

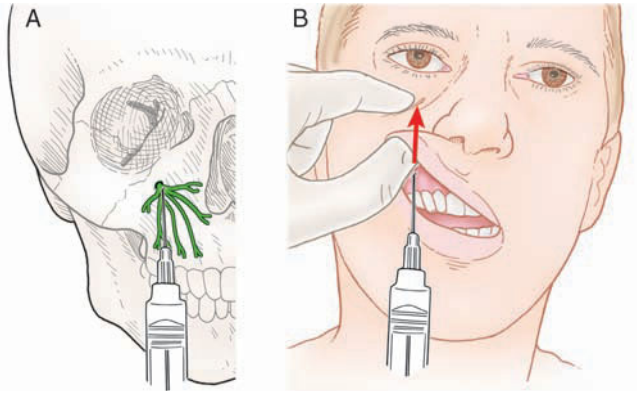

FIGURE 126-6. The intraoral approach to the infraorbital nerve block. **A.** Location of the nerve. **B.** Insertion of the needle.

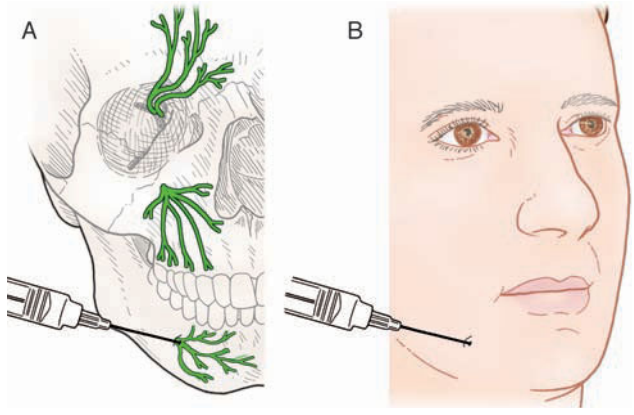

FIGURE 126-7. The extraoral approach to the mental nerve block. **A.** Location of the nerve. **B.** Insertion of the needle.

(**Figures 126-3 & 126-7**). The nerve travels inferiorly and anteriorly to provide sensory innervation to the skin of the lower lip and chin.

Patient Positioning Place the patient supine, or sitting, and facing the Emergency Physician.

Landmarks Identify the vertical plane consisting of the supraorbital foramen, the infraorbital foramen, and the midposition pupil. Identify the point where the vertical plane crosses the middle of the body of the mandible (**Figure 126-7A**). This is where the mental nerve exits the mental foramen.

Needle Insertion and Direction Insert a 25 or 27 gauge needle at the above identified landmark (**Figure 126-7B**). Place a skin wheal of local anesthetic solution at this intersection. Advance the needle through the skin wheal until the mandible is contacted. Inject 1 to 2 mL of local anesthetic solution.

Remarks This nerve can also be blocked intraorally.

MENTAL NERVE BLOCK, INTRAORAL APPROACH

Anatomy The anatomy and innervation of the mental nerve is described in the previous section.

Patient Positioning Place the patient supine, or sitting, and facing the Emergency Physician.

Landmarks Retract the lower lip and identify the junction of the first and second premolars. The patient's mouth may be open or closed.

Needle Insertion and Direction Insert a 25 or 27 gauge needle directed inferiorly and posteriorly through the gingival mucosa at the junction of the first and second premolars (**Figure 126-8**). Advance the needle one-third the depth of the mandibular body and contact the mandible. Inject 1 to 2 mL of local anesthetic solution.

Remarks This is the preferred approach to block the mental nerve. The intraoral route results in the patient experiencing less pain than the extraoral route.

GREATER OCCIPITAL NERVE BLOCK

Anatomy The greater occipital nerve is a branch of the dorsal ramus of the second cervical nerve. It provides sensory innervation to the posterior neck, extending superiorly to the vertex of the scalp (**Figure 126-9**). It emerges on the posterosuperior neck, just below the line connecting the external occipital protuberance and the mastoid process (**Figure 126-10**). The posterior occipital artery accompanies the greater occipital nerve.

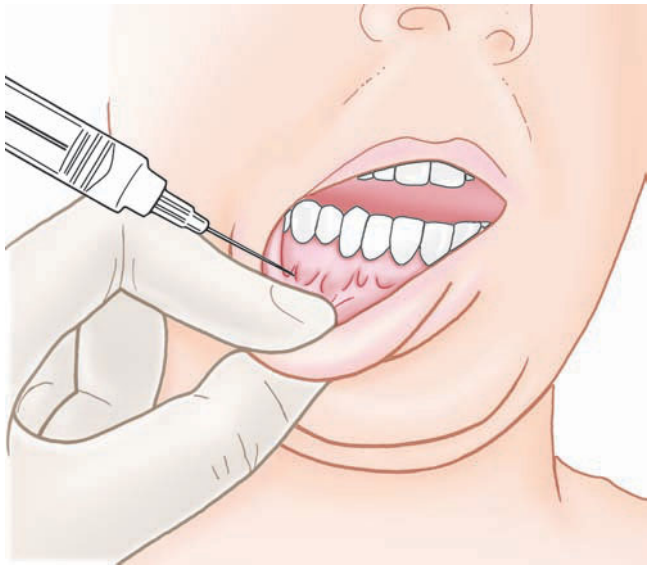

FIGURE 126-8. The intraoral approach to the mental nerve block.

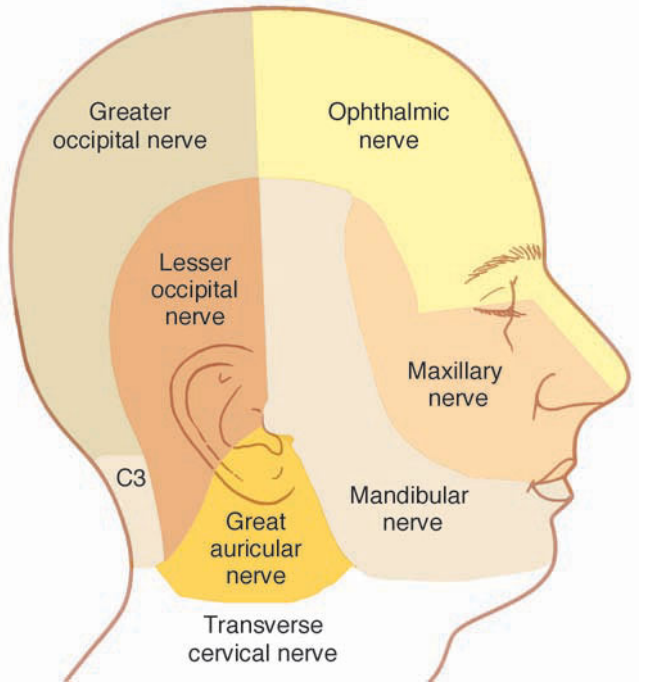

FIGURE 126-9. The cutaneous nerve supply to the face, scalp, and upper neck.

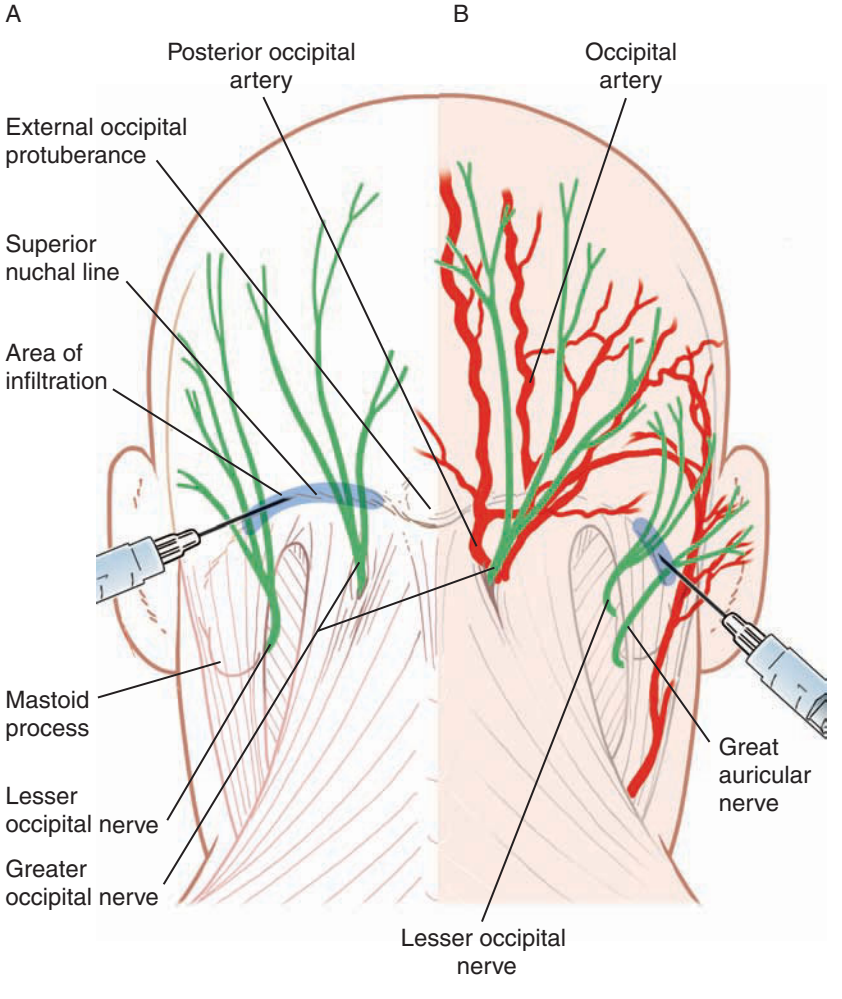

FIGURE 126-10. Regional anesthesia of the posterolateral scalp. **A.** The greater occipital nerve block. **B.** The lesser occipital and great auricular nerve blocks.

Patient Positioning Place the patient prone.

Landmarks Identify the external occipital protuberance and mastoid process by palpation (**Figure 126-10A**). Connect these landmarks with a line. Identify the occipital artery by its palpable pulse, approximately one-third the distance from the external occipital protuberance.

Needle Insertion and Direction Place a skin wheal of local anesthetic solution over the pulse of the occipital artery. Insert a 25 gauge needle 1 to 2 mm to the left of the occipital artery pulse. Inject 1 mL of local anesthetic solution. Redirect the needle 1 to 2 mm to the right of the pulse and inject 1 mL of local anesthetic solution.

Remarks This block is useful for laceration repair as well as relief of occipital muscular or tension headaches. If the pulse of the posterior occipital artery is not palpable, divide the line between the external occipital protuberance and the mastoid process into thirds. Infiltrate the middle third subcutaneously with 5 to 8 mL of local anesthetic solution (**Figure 126-10A**). This technique will also anesthetize the lesser occipital nerve.

LESSER OCCIPITAL NERVE BLOCK

Anatomy The lesser occipital nerve is a branch of the cervical plexus. It provides sensory innervation to the skin and scalp between the ear and the mastoid process (**Figure 126-9**). It emerges at the middle third of the posterior border of the sternocleidomastoid muscle and travels superiorly toward the mastoid process (**Figure 126-10**).

Patient Positioning Place the patient supine or sitting with their head turned toward the side opposite that being anesthetized.

Landmarks Identify the mastoid process by palpation.

Needle Insertion and Direction Place a skin wheal of local anesthetic solution just posterior to the mastoid process. Insert a 25 gauge needle directed anteriorly through the skin wheal. Advance the needle while infiltrating local anesthetic solution subcutaneously until the posterior ear is contacted (**Figure 126-10B**). This requires 3 to 7 mL of local anesthetic solution.

Remarks The lesser occipital nerve can be blocked at the level of the cervical plexus. Refer to the section on cervical plexus blockade below.

GREAT AURICULAR NERVE BLOCK

Anatomy The great auricular nerve is a branch of the cervical plexus. It emerges at the middle third of the posterior border of the sternocleidomastoid muscle and travels superiorly with the external jugular vein (**Figure 126-10B**). This nerve provides sensory innervation to the skin and scalp behind the ear, the posterior ear, and the lobule (**Figure 126-9**).

Patient Positioning Place the patient supine with their head turned toward the side opposite that being anesthetized.

Landmarks Identify the lobule of the ear, the mastoid process, and the sulcus behind the ear.

Needle Insertion and Direction Place a skin wheal of local anesthetic solution just posterior to the mastoid process. Insert a 25 gauge needle directed anteriorly through the skin wheal. Advance the needle while infiltrating local anesthetic solution subcutaneously until the posterior ear is contacted (**Figure 126-10B**). This requires 3 to 7 mL of local anesthetic solution. Complete and successful anesthesia occurs within 10 minutes.

Remarks The great auricular nerve block is indicated for lacerations of the auricle, debridement, and hematoma evacuations. It is rarely performed without simultaneous blockade of the auriculotemporal nerve. The great auricular nerve can be blocked at the level of the cervical plexus. Refer to the section on cervical plexus blockade below.

SCALP BLOCK

Anatomy The scalp receives its sensory innervation from branches of the trigeminal nerve anteriorly and the cervical plexus posteriorly (**Figure 126-11**). The scalp may be anesthetized anywhere along the anterior midline to the posterior midline. This involves blocking the supratrochlear, supraorbital, auriculotemporal, lesser occipital, great auricular, and greater occipital nerves.

Patient Positioning Place the patient supine with their head turned toward the side opposite that being anesthetized.

Landmarks Identify the glabella and the external occipital protuberance by palpation.

Needle Insertion and Direction Place a skin wheal of local anesthetic solution over the glabella. Insert a 25 gauge needle through the skin wheal. Infiltrate a continuous line of local anesthetic solution subcutaneously between the glabella and the external occipital protuberance (**Figure 126-11B**). This requires 15 to 20 mL of local anesthetic solution.

Remarks Infiltrate the local anesthetic solution subcutaneously along the scalp base inferior to the area in which the procedures will be performed to block only a portion of the scalp. It is useful to add epinephrine (1:200,000) to the local anesthetic solution to cause vasoconstriction and prevent excessive blood loss. Significant systemic absorption of the local anesthetic agent does not occur despite the extensive vascularity of the scalp. Scalp blocks provide anesthesia for laceration repair, drainage of superficial abscesses, and the exploration of scalp wounds. Complications are fairly rare. There is a case report of a temporary facial nerve palsy after a scalp block.[19]

EXTERNAL EAR BLOCK

Anatomy The ear is a difficult structure to anesthetize. It is innervated by a large number of sensory fibers that originate from the cervical plexus, the trigeminal nerve, and the vagus nerve. The external ear, or pinna, is innervated by the cervical plexus and the auriculotemporal branch of the trigeminal nerve (**Figures 126-9 & 126-11**).

Patient Positioning Place the patient supine or sitting upright with their head turned toward the side opposite that being anesthetized.

Landmarks Identify the angle of the mandible by palpation.

Needle Insertion and Direction Place a skin wheal of local anesthetic solution over the angle of the mandible. Insert a 25 gauge needle through the skin wheal. Infiltrate local anesthetic solution subcutaneously in an anterior and superior direction, from the angle of the mandible to the superior surface of the ear, to block the auriculotemporal nerve (**Figure 126-12A**). Infiltrate local anesthetic solution subcutaneously in a posterior and superior direction, from the angle of the mandible to the superior surface of the ear, to block the great auricular and lesser occipital nerves (**Figure 126-12A**). This requires a total of 8 to 10 mL of local anesthetic solution.

Remarks Some may prefer to anesthetize the auriculotemporal nerve trunk by injecting local anesthetic solution just above the posterior aspect of the zygomatic arch (**Figure 126-12B**). It requires less local anesthetic solution and hurts less than subcutaneous infiltration. An alternative technique is to circumferentially infiltrate local anesthetic solution subcutaneously around the ear (**Figure 126-12C**).

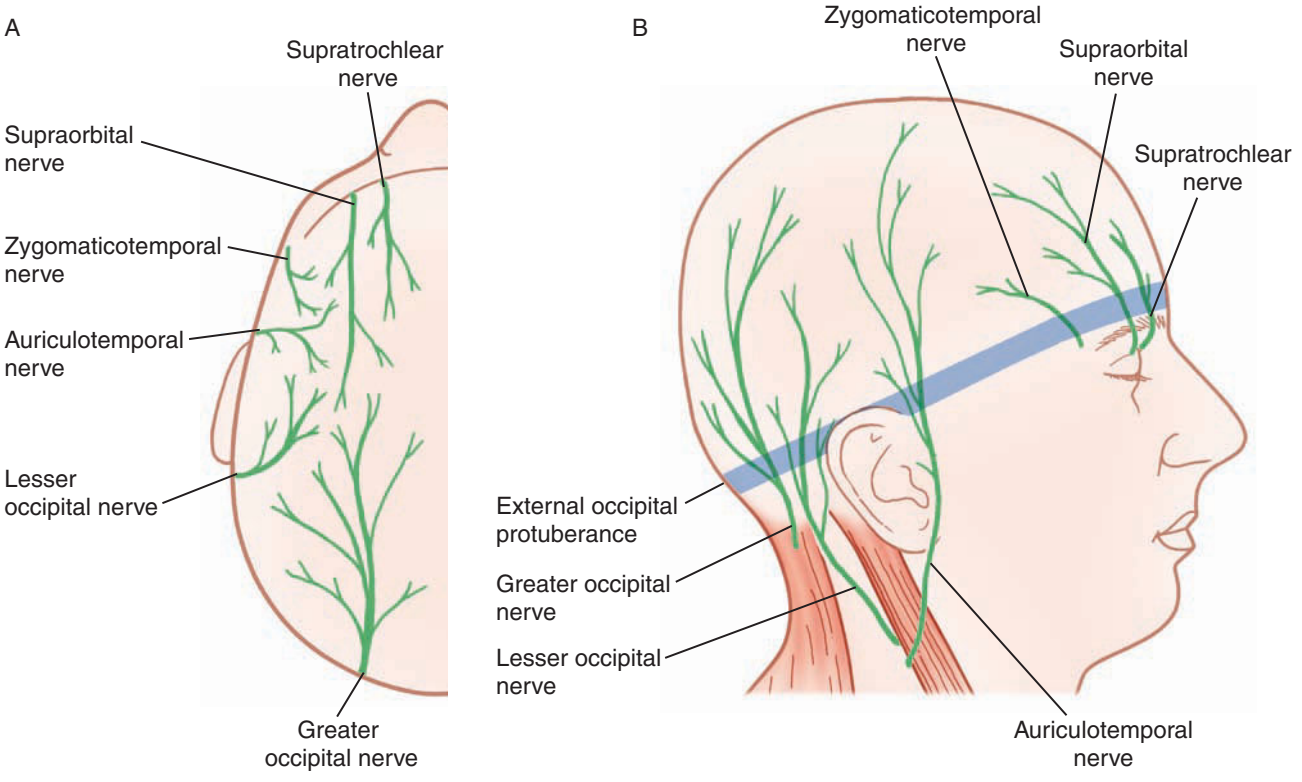

FIGURE 126-11. The scalp block. **A.** The sensory innervation of the scalp. **B.** Local anesthetic solution is injected subcutaneously along the base of the scalp.

EXTERNAL AUDITORY CANAL BLOCK

Anatomy The external auditory canal (and the tympanic membrane) receives its innervation from the auriculotemporal nerve and the vagus nerve.

Patient Positioning Place the patient sitting upright or supine with their head turned toward the side opposite that being anesthetized.

Landmarks Identify the helix, the tragus, and the lobule of the ear to be anesthetized (**Figure 126-13**).

Needle Insertion and Direction Anesthetize the external auditory canal using a four-quadrant block (**Figure 126-13**). Insert a 25 gauge needle, advance it 0.5 to 0.75 cm, and inject 1 mL of local anesthetic solution at each of the four landmarks identified in **Figure 126-13**.

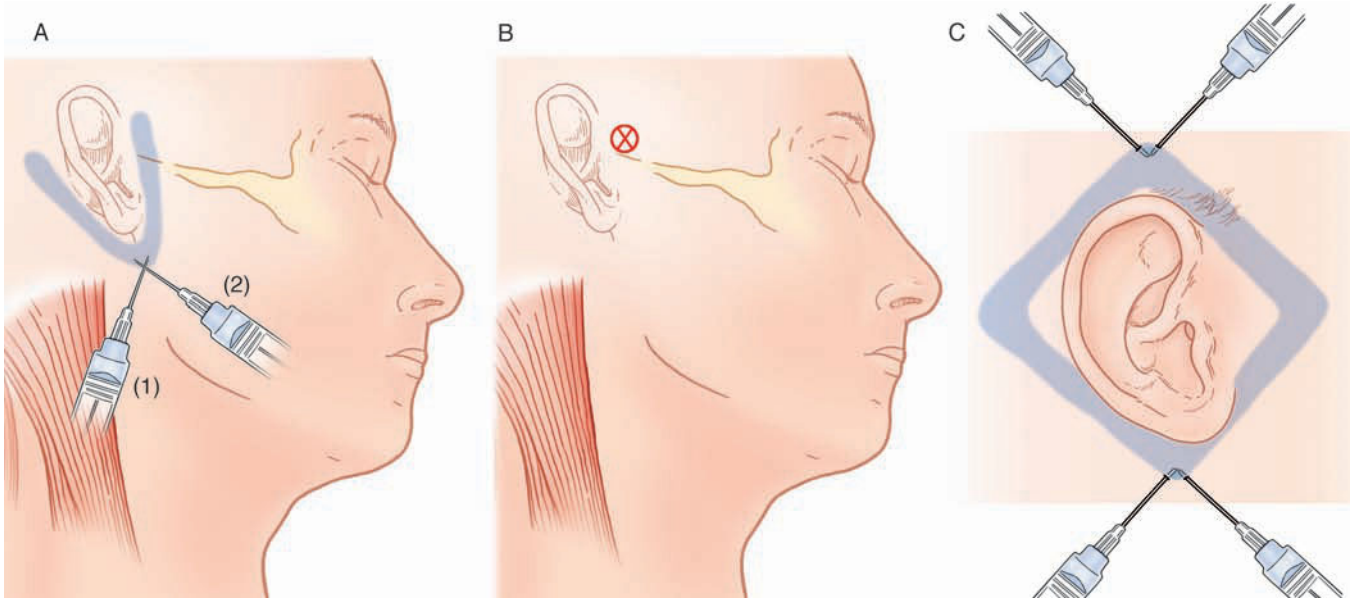

FIGURE 126-12. The external ear block. **A.** Infiltration of local anesthetic solution from the angle of the mandible to the anterior (1) and posterior (2) superior surfaces of the ear. **B.** The site for anesthetizing the trunk of the auriculotemporal nerve. **C.** An alternative method.

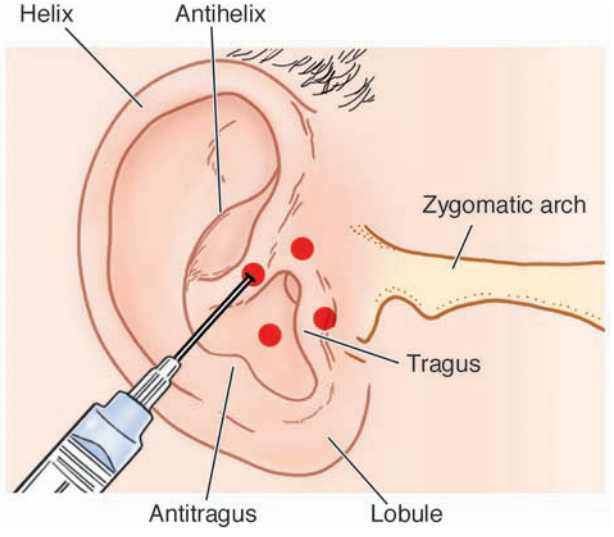

FIGURE 126-13. External auditory canal block. Inject local anesthetic solution at each of the four landmarks. This block also anesthetizes the tympanic membrane.

Remarks This block can be quite painful for the patient. The authors recommend to first anesthetize the external ear before anesthetizing the external auditory canal. This block also anesthetizes the tympanic membrane.

CERVICAL PLEXUS BLOCK

Anatomy The cervical plexus originates from the anterior rami of cervical nerves two through four. These rami form numerous loops that anastomose to form nerves that provide sensory innervation to the anterolateral neck, the scalp, the ear, and the infraclavicular area. The four nerves of the cervical plexus become superficial at the midportion of the posterior border of the sternocleidomastoid muscle and then distribute to their respective sensory areas (**Figure 126-14A**). The cervical plexus provides motor innervation to the strap muscles of the neck.

The four superficial nerves of the cervical plexus are the lesser occipital nerve, the great auricular nerve, the anterior (or transverse) cervical nerve, and the supraclavicular nerve (**Figure 126-14A**). The lesser occipital nerve travels superiorly and posteriorly to provide sensory innervation to part of the posterior surface of the upper ear and the postauricular skin. The great auricular nerve travels superiorly and anteriorly to provide sensory innervation to the skin over the posterior surface of the ear, the anterior lower half of the ear, and over the angle of the mandible. The anterior, or transverse, cervical nerve of the neck travels anteriorly to provide sensory innervation to the skin of the neck, from the inferior border of the mandible to the sternum. The supraclavicular nerves travel from the clavicle down to the second rib.

Patient Positioning Place the patient supine with their head turned toward the side opposite of that being anesthetized.

Landmarks Identify the posterior border of the sternocleidomastoid muscle by palpation. Divide this border into thirds.

Needle Insertion and Direction Place a skin wheal of local anesthetic solution over the middle third of the posterior border of the sternocleidomastoid muscle. Insert a needle through the skin wheal. Infiltrate 5 to 10 mL of local anesthetic solution subcutaneously over the middle third of the posterior border of the sternocleidomastoid muscle (**Figure 126-14B**).

Remarks This block is useful when managing burns or suturing lacerations on the anterolateral neck.

REGIONAL ANESTHESIA TECHNIQUES FOR THE UPPER EXTREMITY

BRACHIAL PLEXUS BLOCK

The brachial plexus innervates the entire upper extremity. Blockade of the brachial plexus can be performed to repair tendons or extensive lacerations, to reduce fractures and dislocations, or to provide

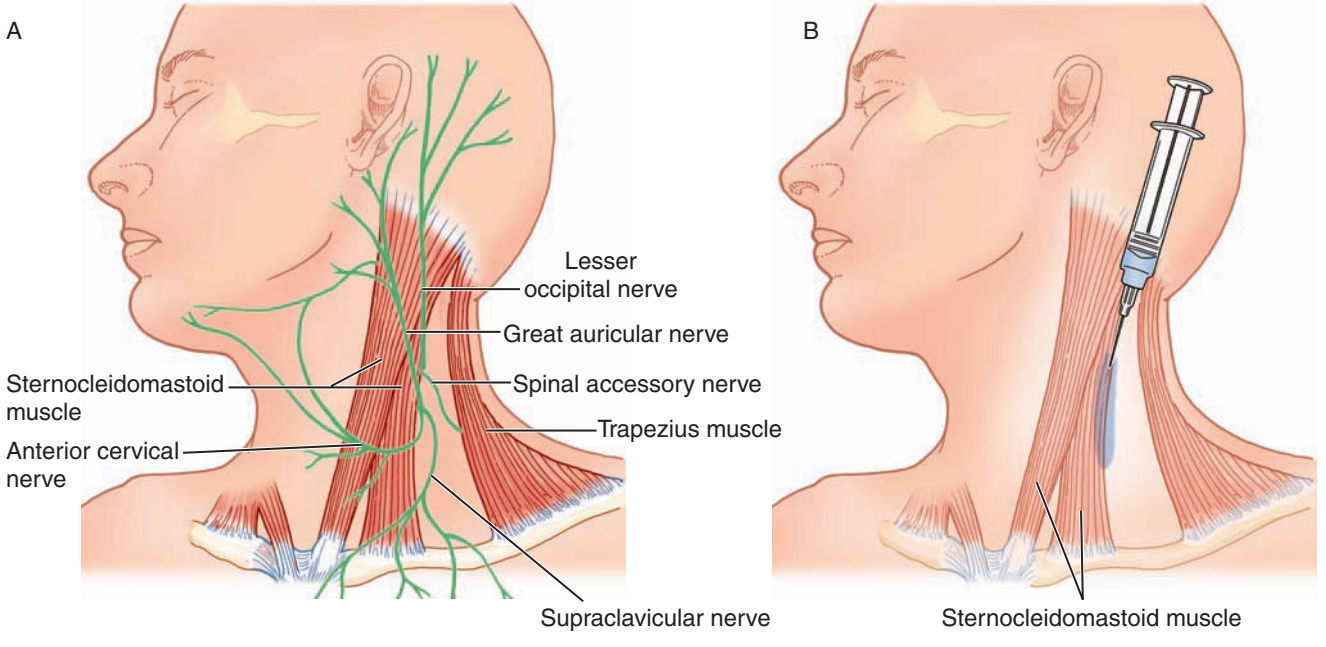

FIGURE 126-14. The cervical plexus block. **A.** The cutaneous nerves of the cervical plexus. **B.** Injection of local anesthetic solution posterior to the middle third of the sternocleidomastoid muscle.

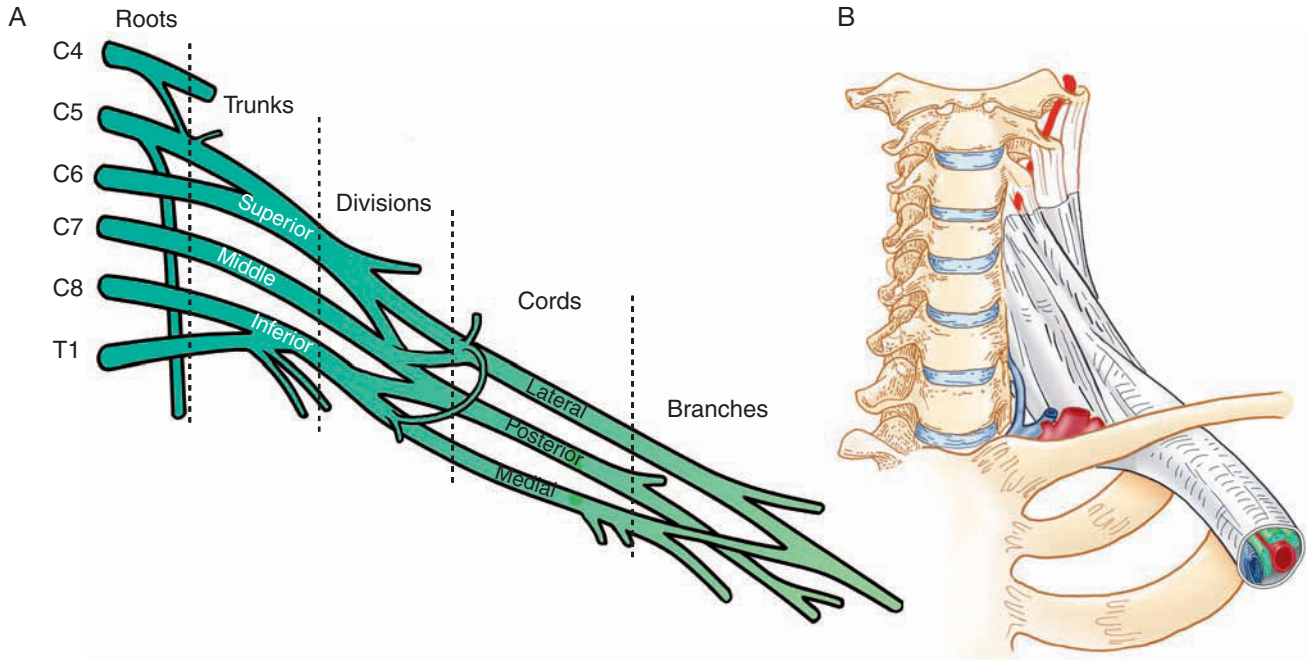

FIGURE 126-15. The brachial plexus. **A.** The anatomy of the brachial plexus. **B.** The brachial plexus is contained within a sheath. The subclavian artery and vein enter the sheath at the level of the clavicle.

anesthesia for burn care, to name a few uses. Protect the arm from injury if this procedure is to be performed by properly supporting the arm, padding the ulnar nerve and pressure points, and not extending or displacing the arm posteriorly.

The brachial plexus arises from the C5 to T1 nerve roots (**Figure 126-15**). The nerve roots fuse to form three trunks. Each trunk divides into an anterior and posterior division that then redistributes to form the lateral, medial, and posterior cords. These cords divide in the region of the axilla to form the musculocutaneous nerve, the median nerve, the ulnar nerve, the axillary nerve, the radial nerve, and several cutaneous nerves. The brachial plexus crosses the midclavicle to enter the axilla (**Figure 126-16A**).

The brachial plexus may be blocked from the supraclavicular, interscalene, infraclavicular, or axillary approach. The preferred method for the Emergency Physician is the axillary block.

BRACHIAL PLEXUS BLOCK, SUPRACLAVICULAR APPROACH

Anatomy The anatomy of the brachial plexus is described above. This approach blocks the brachial plexus at the level of the trunks, where it is most compactly arranged.

Patient Positioning Place the patient supine with their head turned 45° from the midline and toward the side opposite that being anesthetized (**Figure 126-16A**). Place the ipsilateral arm in any position of comfort for the patient.

Landmarks The subclavian artery is the main landmark. Palpate the subclavian artery immediately lateral to the clavicular head of the sternocleidomastoid muscle in the interscalene groove. Identify the midpoint of the clavicle.

Needle Insertion and Direction Place a skin wheal of local anesthetic solution 2 cm above the midclavicle. Insert a 25 gauge needle directed caudally through the skin wheal (**Figures 126-16B & C**). Advance the needle until the patient experiences paresthesias. Withdraw the needle 1 mm and allow the paresthesias to resolve. Aspirate to ensure that the tip of the needle is not within a blood vessel. Inject 40 mL of local anesthetic solution. Reduce the volume based upon the patient's body size and the maximal allowable dose to prevent toxicity.

US-Guided Block Place the US probe in an oblique coronal plane above the clavicle and lateral to the sternocleidomastoid muscle (**Figure 126-16D**). Locate the subclavian artery. It is a pulsatile, round, and hypoechoic structure in cross section. The trunks of the brachial plexus are located adjacent to the subclavian artery (**Figure 126-16E**). Posterior to the subclavian artery lies the first rib, and the pleural line can be seen sliding in real time. Use color/power Doppler to confirm the location of the subclavian artery and any branches or take-offs, all of which must be avoided (**Figure 126-16F**). Anesthetize the skin. Position the spinal needle lateral to the US probe and parallel to its long axis. Slowly insert and advance the needle. Visualize the entire length of the needle as it is introduced through the subcutaneous tissue toward the brachial plexus. Advance the needle through the nerve sheath. Aspirate to ensure the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of anesthetic around the nerves. If it is satisfactory, inject the remainder of the local anesthetic solution to achieve the "donut sign" (**Figure 126-16G**). If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks This block is characterized by a quick onset of anesthesia and a complete block. A high volume of anesthetic is required with a quick onset of anesthesia. There is no chance of missing peripheral or proximal nerve branches because of failure of the local anesthetic solution to spread along the sheath of the brachial plexus. Unfortunately, this technique is difficult to teach and to master without considerable experience. This technique has a high incidence of an iatrogenic pneumothorax, reportedly up to 6%. Other complications include blockade of the phrenic nerve, subclavian artery puncture, and Horner's syndrome. Unintentional intravascular injection can result in high blood levels of the local anesthetic agent.

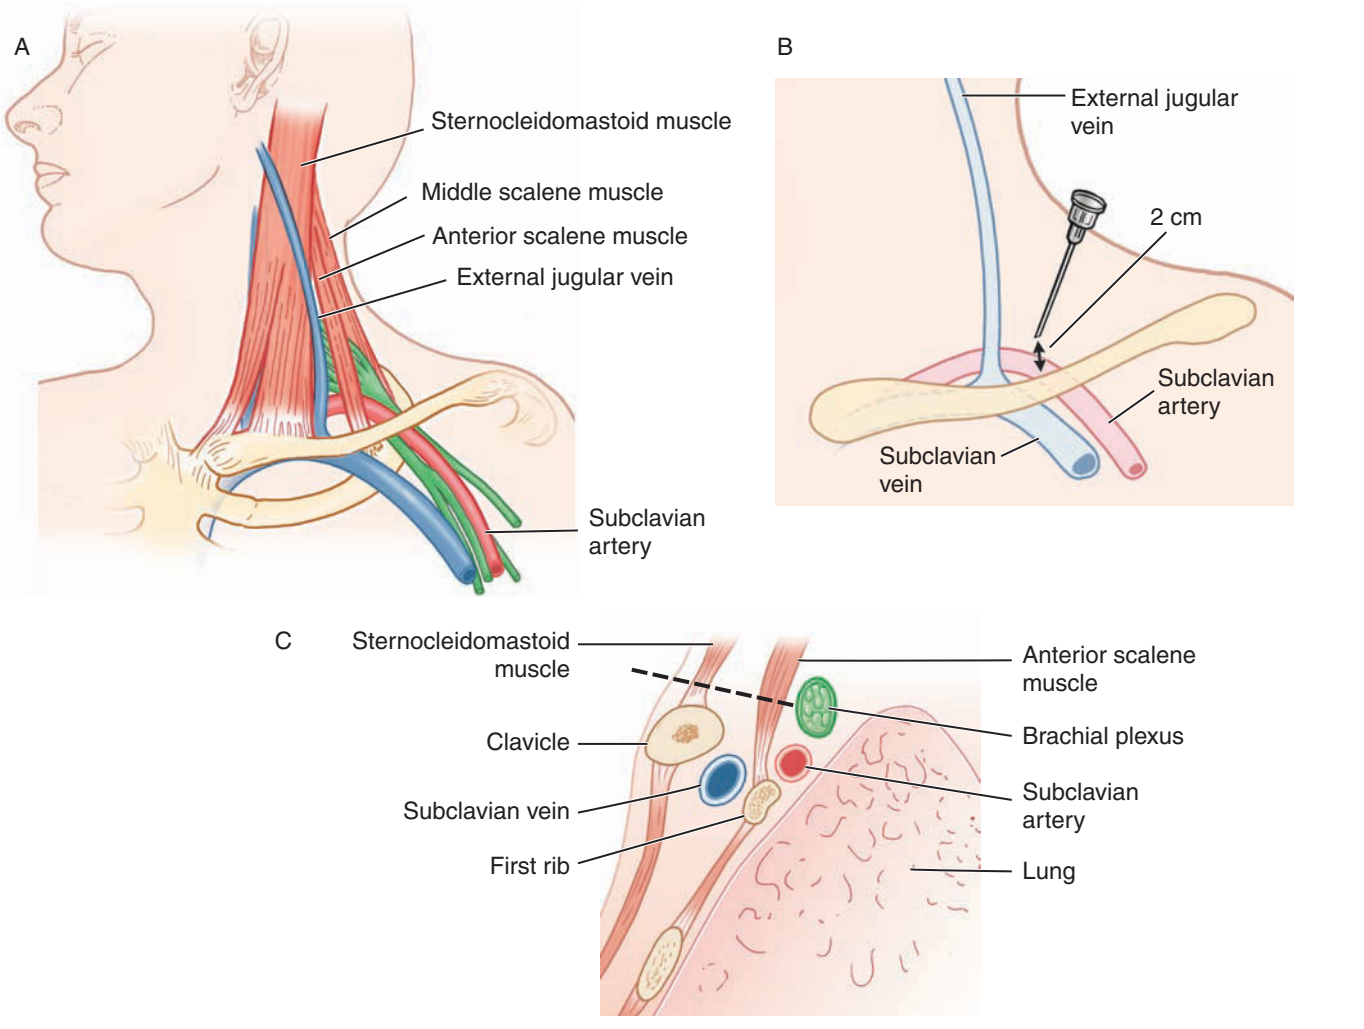

FIGURE 126-16. The supraclavicular approach to the brachial plexus block. **A.** The course of the brachial plexus. **B.** The needle is inserted perpendicular to the skin and 2 cm superior to the middle of the clavicle. **C.** Sagittal section demonstrating the trajectory of the needle (*dotted line*). **D.** US probe and needle placement. **E.** The supraclavicular brachial plexus (*arrowheads*) is adjacent to the subclavian artery (SA). The first rib is denoted by the arrows.

BRACHIAL PLEXUS BLOCK, INTERSCALENE APPROACH

Anatomy The anatomy of the brachial plexus is described above. This approach blocks the brachial plexus at the level of the trunks (**Figure 126-17A**).

Patient Positioning Place the patient supine with their head turned 45° from midline and toward the side opposite that being anesthetized (**Figure 126-17A**). Place the ipsilateral arm in any position of comfort for the patient.

Landmarks Identify the posterior border of the clavicular head of the sternocleidomastoid muscle by palpation. Move the palpating

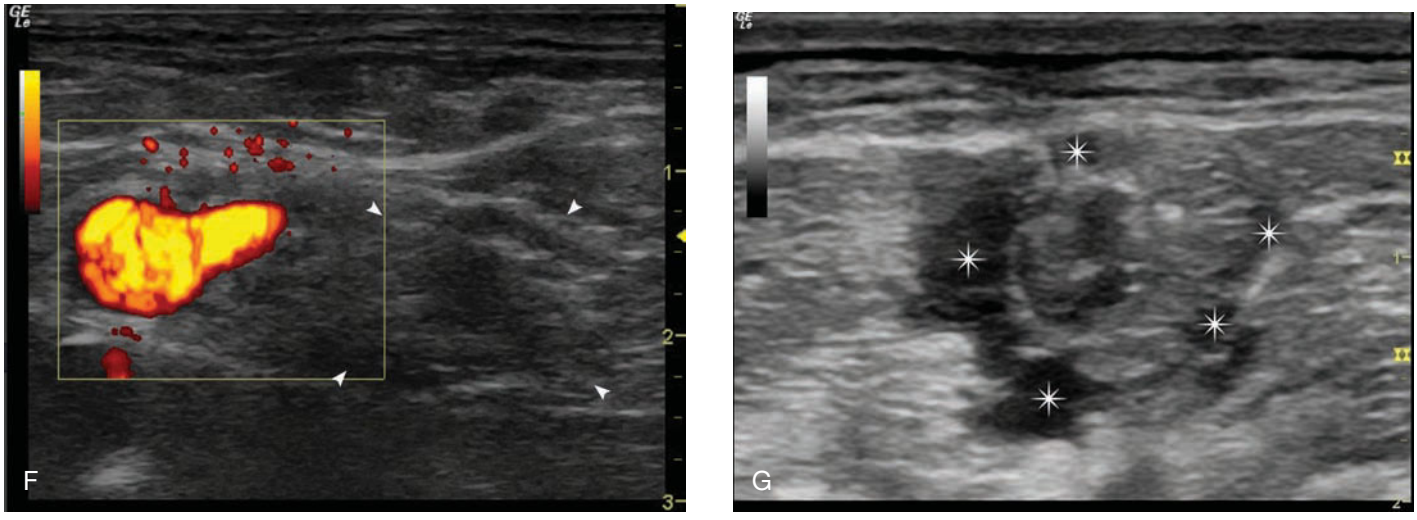

FIGURE 126-16. (*continued*) **F.** Color Doppler of the supraclavicular brachial plexus (*arrowheads*). The subclavian artery and a branch are visible in color. **G.** The "donut sign." Local anesthetic solution (*) surrounds the nerve bundles.

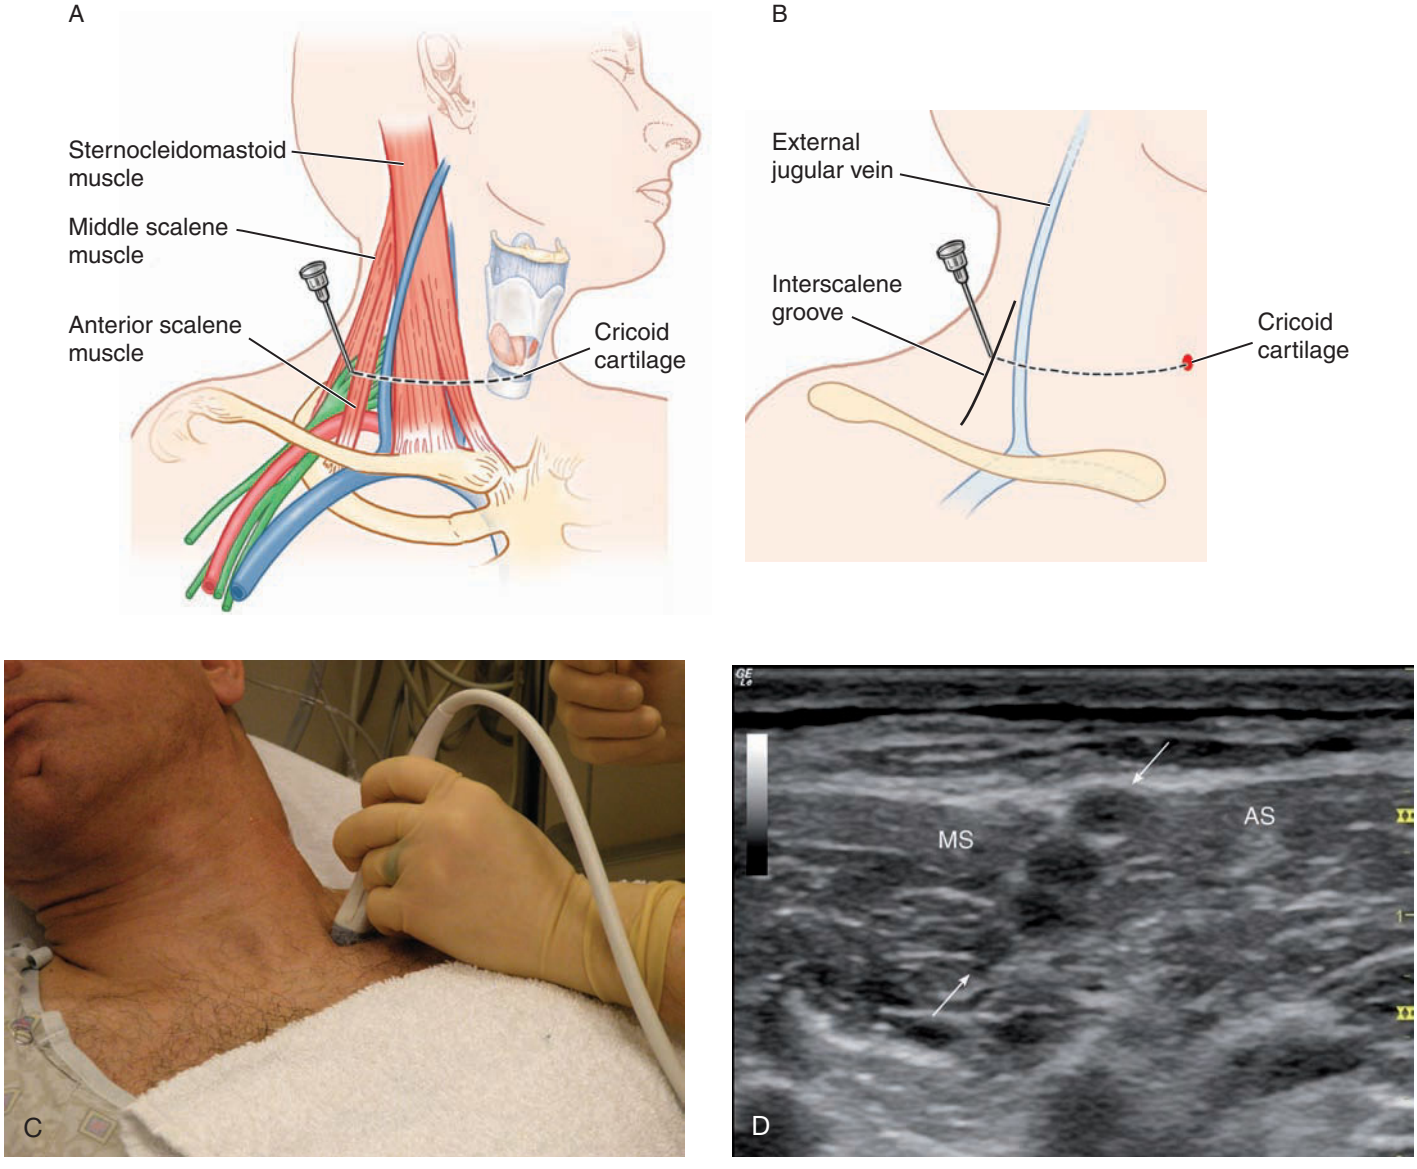

FIGURE 126-17. The interscalene approach to the brachial plexus block. **A.** The anatomy of the region. **B.** The needle is inserted into the interscalene groove at the level of the cricoid cartilage. **C.** US probe placement. **D.** The brachial plexus (between the *arrows*) is located between the anterior scalene (AS) and the middle scalene (MS) muscles.

finger laterally until it rolls into the interscalene groove between the anterior and middle scalene muscles, at the level of the cricoid cartilage (**Figure 126-17B**).

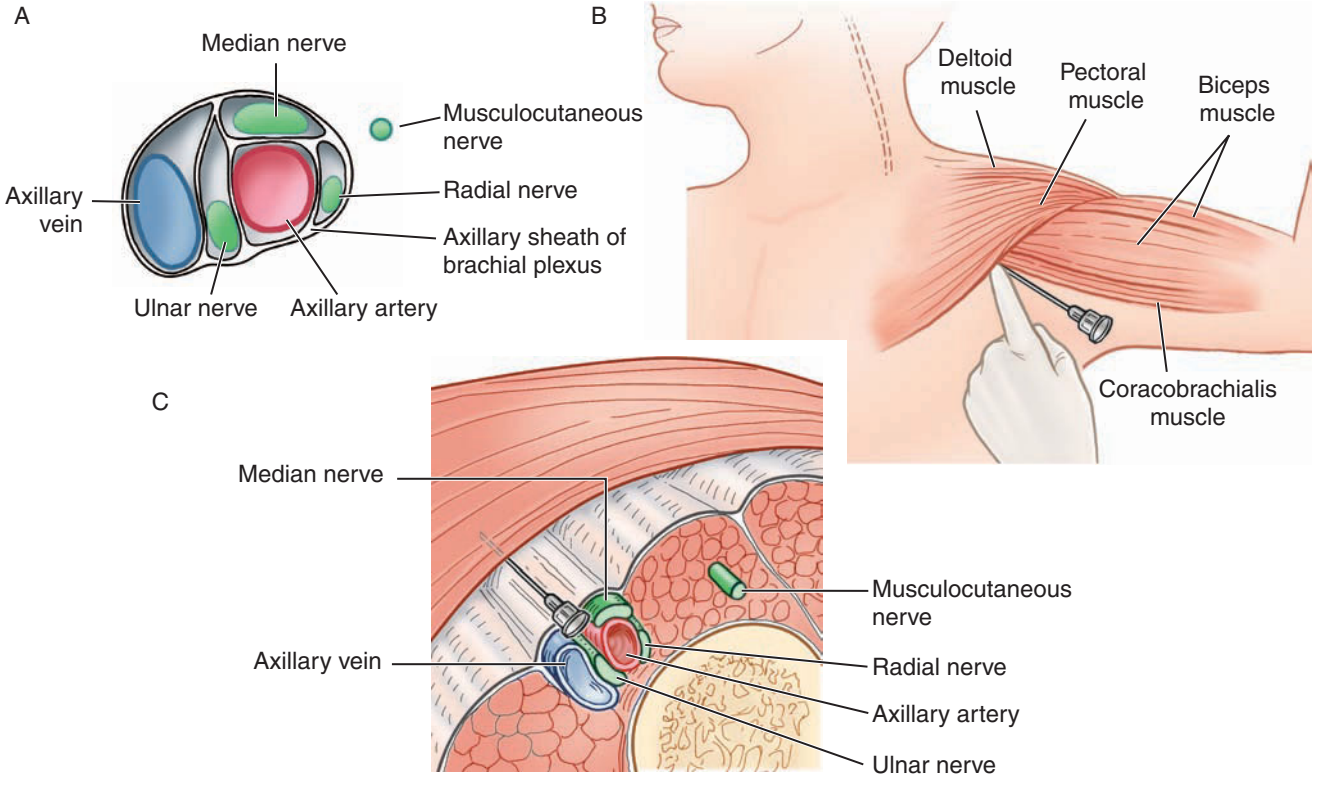
Needle Insertion and Direction Place a skin wheal of local anesthetic solution in the interscalene groove, at the level of the cricoid cartilage. Slowly insert a 25 gauge needle through the skin wheal in a dorsal, medial, and caudal direction (**Figure 126-17B**). Advance the needle until the patient experiences paresthesias. Withdraw the needle 1 mm and allow the paresthesias to resolve. Aspirate to ensure that the tip of the needle is not within a blood vessel. Inject 30 to 40 mL of local anesthetic solution. Reduce the volume based upon the patient's body size and the maximal allowable dose to prevent toxicity.

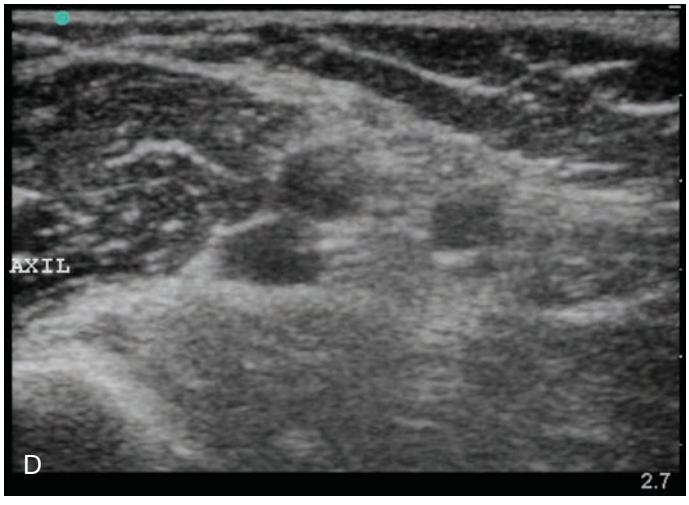
US-Guided Block This block is performed at the level of the internal jugular vein and carotid artery in the neck. Place the US probe on the neck, less than a third of the way up from the clavicle (**Figure 126-17C**). Identify the carotid artery and internal jugular vein. Move the US probe laterally to find the muscle bellies of the anterior and middle scalene muscles (**Figure 126-17D**). Between the muscles lie the nerve roots of the brachial plexus in cross section. It is represented by hypoechoic circles within the hyperechoic rings of the nerve sheaths (**Figure 126-17D**). Use color Doppler to identify any blood vessels in the field, and note their location so as to avoid them. Anesthetize the skin. Using a posterior approach, insert the spinal needle connected by extension tubing to a 20 mL syringe filled with local anesthetic solution. Advance the needle and visualize it approaching the brachial plexus. The needle path will usually go through the middle scalene muscle. Once the brachial plexus is close to the needle tip, use a short and controlled jab to penetrate through the nerve sheath. Aspirate to verify that the needle tip is not in a blood vessel. Instruct an assistant to deliver a test dose of 1 to 2 mL of local anesthetic solution. If the anesthetic spreads around the nerves, slowly deliver the remainder of the local anesthetic solution to obtain the "donut sign." If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks The advantages and disadvantages are similar to those of the supraclavicular approach with the exception of possibly not achieving anesthesia of the lower trunk. This may require supplementary blockade of the median and ulnar nerves. The interscalene brachial plexus block, although ideal for regional anesthesia of the shoulder, has been associated with recurrent laryngeal nerve paralysis and an almost 100% incidence of phrenic nerve paralysis.[20] This can be significant in patients with respiratory comorbidities (e.g., COPD, obesity).[21] The supraclavicular brachial plexus block is associated with lower rates of these complications.[2]

BRACHIAL PLEXUS BLOCK, AXILLARY APPROACH

Anatomy The anatomy of the axillary brachial plexus nerve block is rather simple. The neurovascular bundle is easily found at the anterior axillary fold by palpating for the pulsations of the axillary artery. The neurovascular bundle is surrounded by the fibrous axillary sheath (**Figure 126-18A**). The axillary sheath is bound medially by skin and connective tissue, anteriorly by the biceps and coracobrachialis muscles, inferiorly by the triceps muscle, and laterally by the neck of the humerus. The axillary artery is the central reference structure within the neurovascular bundle. Within the axillary sheath, the median nerve is anterior, the radial nerve is posterolateral, and the ulnar nerve is posterior to the axillary artery. The axillary vein is medial to the artery. The medial antebrachial cutaneous





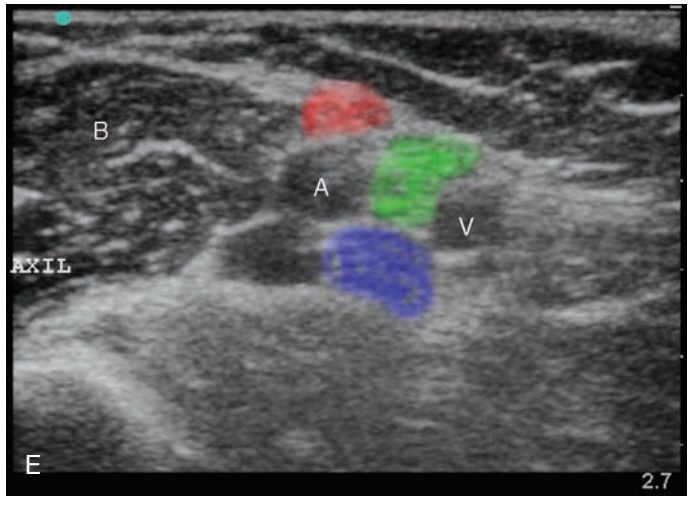


FIGURE 126-18. The axillary approach to the brachial plexus block. **A.** The topographical arrangement of the contents of the axillary sheath at the level of the blockade. **B.** The patient is positioned and the axillary artery pulse is palpated with one finger. The needle is inserted above the pulse and along the course of the axillary sheath. **C.** The needle may travel above the sheath and enter it at a higher level.

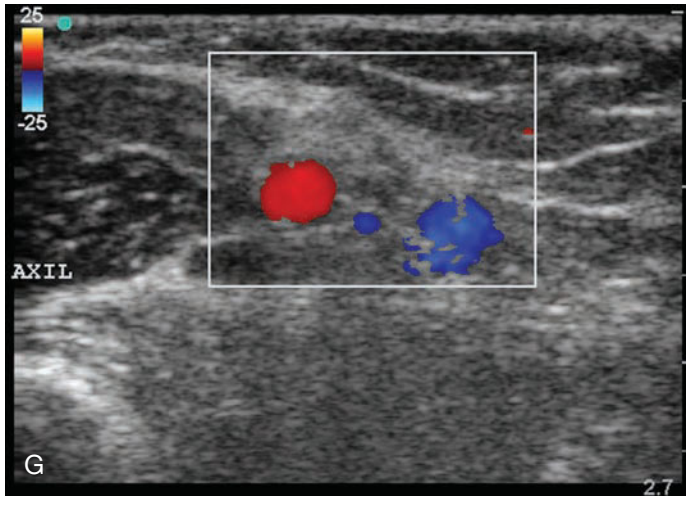

FIGURE 126-18. (*continued*) **D.** US image of the axillary brachial plexus. **E.** Same image as (**D**) with labels (A–axillary artery, B–biceps muscle, V–axillary vein, red oval–median nerve, green oval–ulnar nerve, blue oval–radial nerve). **F.** US probe and needle placement. **G.** Color Doppler of the axillary artery (red) and vein (blue).

nerve and the medial brachial cutaneous nerve are medial to the artery (**Figure 126-18A**). The only sensory nerve outside the neurovascular bundle is the musculocutaneous nerve. This nerve exits the axillary sheath as it crosses the clavicle.

Patient Positioning Place the patient supine with their head turned toward the side opposite that being anesthetized (**Figure 126-18B**). Abduct the arm 90°. Flex the elbow 90° so that the forearm is parallel to the long axis of the body and the palm is facing upward.

Landmarks Identify the brachial artery by its palpable pulse. Trace it proximally to the anterior axillary fold, formed by the pectoralis major muscle. Use the index and middle fingers of the nondominant hand to secure the neurovascular bundle (identified by the pulse) against the humerus (**Figure 126-18B**).

Needle Insertion and Direction Place the skin wheal of local anesthetic solution overlying the axillary artery pulse, just posterior to the anterior axillary fold. Insert a 22 gauge spinal needle just above the fingertip on the axillary pulse, directed toward the apex of the axilla and in the direction of the neurovascular bundle (**Figure 126-18B**). Advance the needle. A "pop" will be felt as the axillary sheath is penetrated. The correct needle position is confirmed by eliciting paresthesias, observing blood flow in the needle, or observing pulsations of the needle that match the pulse (**Figure 126-18C**). Instruct an assistant to attach the distal end of intravenous extension tubing to the hub of the needle, and the proximal end to a 60 mL syringe containing local anesthetic solution. The Emergency Physician must always maintain pressure against the neurovascular bundle with the nondominant hand while stabilizing the needle with the dominant hand. Instruct the assistant to aspirate to ensure that the tip of the needle is not within a blood vessel. Withdraw the needle 2 mm if blood flow or paresthesias are elicited.

Apply digital pressure to the neurovascular bundle just distal to the tip of the needle with the nondominant fingers. This prevents the local anesthetic solution from flowing distally. Inject the local anesthetic solution into the axillary sheath after the paresthesias have resolved and a negative aspiration has been achieved. Instruct the assistant to inject a volume of approximately 40 mL in the adult patient. This volume has been shown to consistently block the entire brachial plexus. Reduce the volume based upon the patient's body size and the maximal allowable dose to prevent toxicity. **Continue to apply digital pressure to the neurovascular bundle just distal to the needle during and after injection of the local anesthetic solution.**

Withdraw the needle while the assistant simultaneously injects 3 to 5 mL of local anesthetic solution into the subcutaneous tissue.

This blocks the medial brachial cutaneous nerve and the intercostobrachial nerve. Abduct the patient's arm 30° to 45° after the needle is withdrawn. Maintain this position, while continuing to apply digital pressure to the neurovascular bundle just distal to the needle insertion site, for 2 to 3 minutes.

US-Guided Block This block is performed at the level of the terminal branches of the brachial plexus within the axillary sheath. These branches are visualized as hyperechoic nodules around the pulsatile and hypoechoic axillary artery (**Figures 126-18D & E**). Place the US probe with the marker pointing cephalad at the superior axillary crease (**Figure 126-18F**). Locate the axillary artery and vein in cross section (**Figure 126-18G**). The musculocutaneous nerve can be seen between the biceps muscle and the coracobrachialis muscle. Use color Doppler to confirm the location of the axillary artery, vein, and any branches or take-offs (**Figure 126-18G**). Anesthetize the skin. Position the spinal needle inferior or superior to the long axis of the US probe (**Figure 126-18F**). Slowly insert and advance the needle. Visualize the entire length of the needle as it is advanced. Aim the needle between the axillary artery and vein. Advance through the nerve sheath. Aspirate to ensure the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of local anesthetic solution around the subclavian artery. If it is satisfactory, inject the remainder of the local anesthetic solution to produce the "donut sign." If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks The axillary approach to the brachial plexus is the most commonly used and preferred technique. The procedure is easily mastered, has no major complications, and is easily performed in the obese patient. The disadvantages of this technique include insufficient anesthesia of the shoulder and upper arm. The musculocutaneous nerve provides sensory innervation to the radial aspect of the forearm and may be missed by the local anesthetic agent. The subcutaneous infiltration of local anesthetic solution usually blocks the musculocutaneous nerve. **Proximal flow of the local anesthetic solution is required to ensure adequate anesthesia.** Abduction of the arm while maintaining pressure on the neurovascular bundle allows proximal flow of the local anesthetic solution. It also prevents the humeral head from limiting proximal spread due to compression of the brachial plexus.

BRACHIAL PLEXUS BLOCK, INFRACLAVICULAR APPROACH

This approach to the brachial plexus has many advantages and few serious complications. Unfortunately, this technique requires considerable experience on the part of the Emergency Physician and a nerve stimulator to locate the brachial plexus (**Figures 126-19A & B**). For these reasons, the anatomic landmark approach will not be described. The US-guided technique is described below.

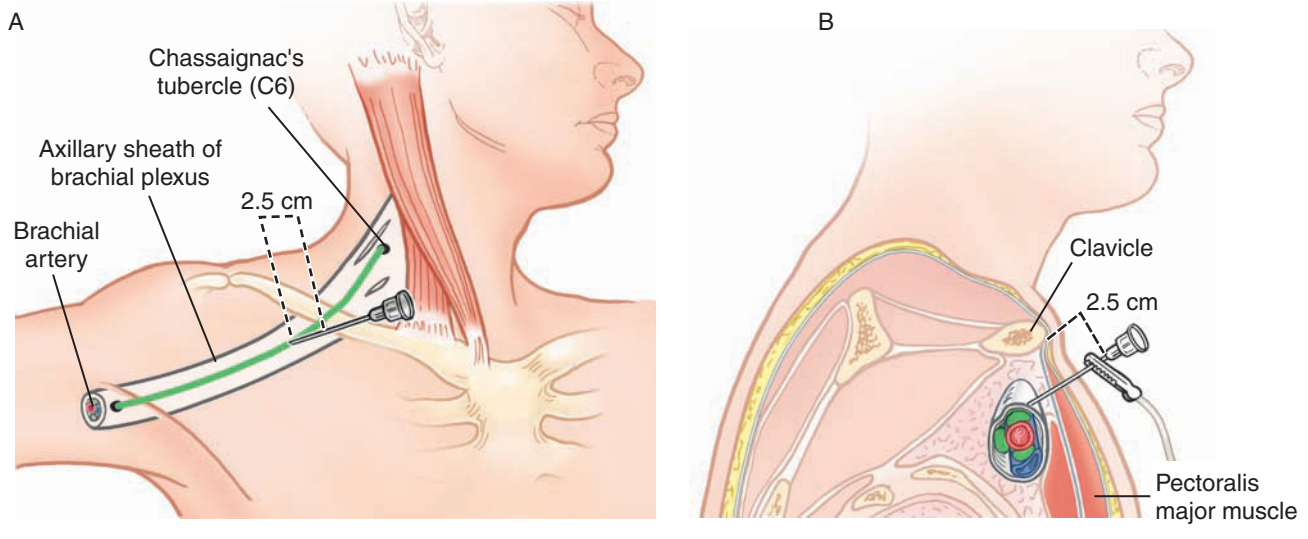
Anatomy The anatomy of the brachial plexus is described above. This approach blocks the brachial plexus at the level of the cords (**Figure 126-15A**).

Patient Positioning Place the patient supine with their head turned 45° from midline and toward the side opposite that being anesthetized (**Figure 126-19A**). Place the ipsilateral arm extended 90°.

Landmarks Identify the middle third of the clavicle.

Infraclavicular Block This block is performed below the clavicle. The cords of the brachial plexus lie below the pectoralis major and minor muscles. They appear as distinct hyperechoic nodules positioned laterally, medially, and posteriorly around the subclavian artery (**Figures 126-19C & D**). Prep and drape the infraclavicular region. Place the US probe with the marker pointing cephalad below the clavicle, medial to the coracoid process (**Figure 126-19E**). Locate the subclavian artery (which is pulsatile) and vein in cross section. Use color Doppler to confirm the location of the subclavian artery, vein, and any branches or take-offs (**Figure 126-19F**). Anesthetize the skin. Position the spinal needle inferior or superior to the long axis of the US probe (**Figure 126-19E**). Insert and advance the needle. Visualize the entire length of the needle as it is advanced. Aim the needle between the subclavian artery and vein. Advance the needle. Continue to advance the needle through the nerve sheath. Aspirate to ensure that the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of local anesthetic solution around the subclavian artery. If satisfactory, inject the remainder of the local anesthetic solution to produce the "donut sign." If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks This block can result in an iatrogenic pneumothorax due to the proximity of the needle to the lung apex.



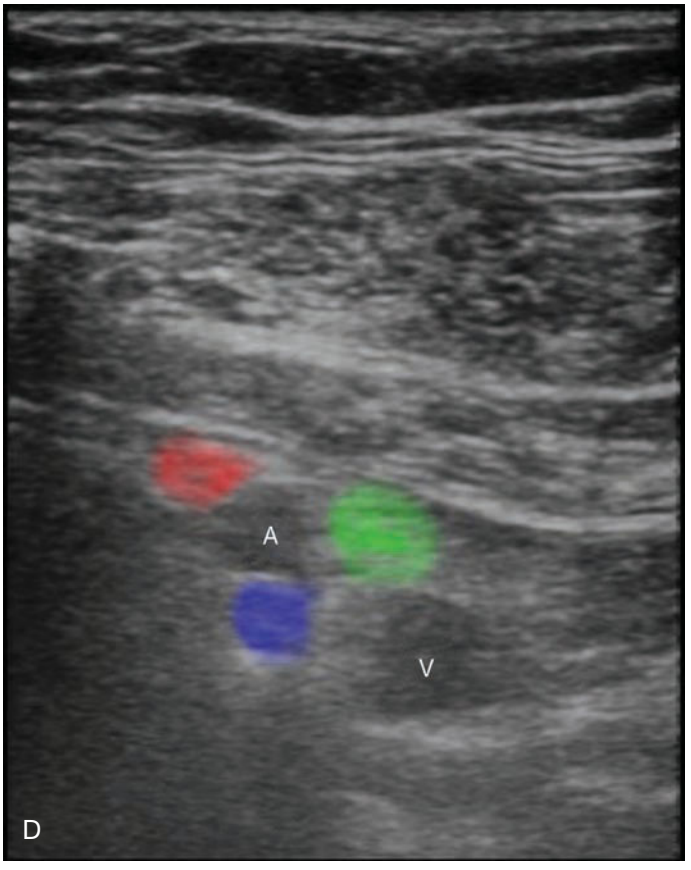


FIGURE 126-19. The infraclavicular approach to the brachial plexus block **A.** Needle insertion and direction. **B.** Sagittal section demonstrating needle insertion into the neurovascular bundle. The alligator clip is attached to a nerve stimulator.

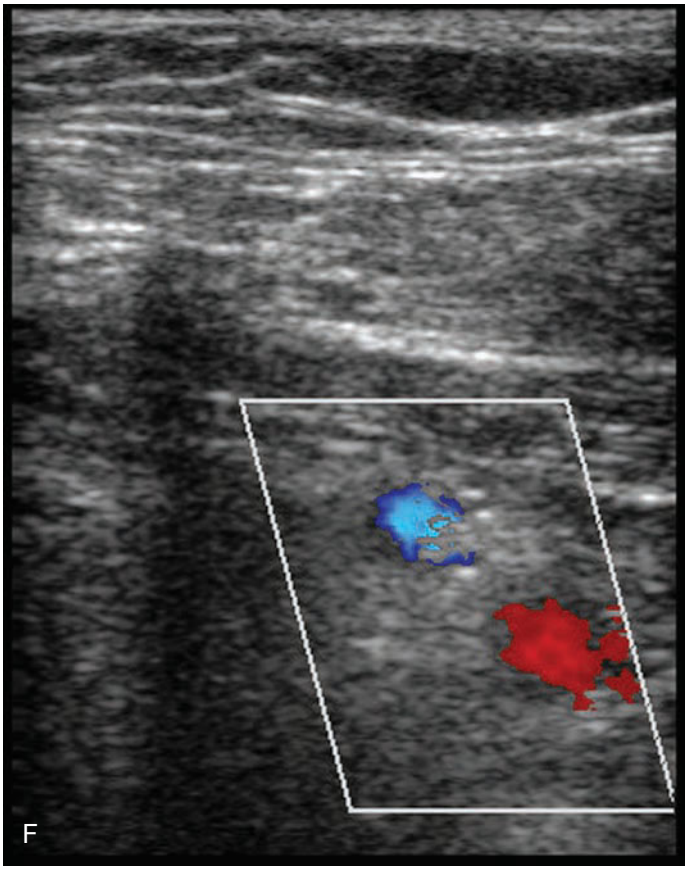

FIGURE 126-19. (*continued*) **C.** US image of the infraclavicular brachial plexus. **D.** Same image as (**C**) with labels (A–subclavian artery, V–subclavian vein, red oval–lateral cord, green oval–medial cord, blue oval–posterior cord). **E.** US probe and needle placement. The clavicle is located between the two red lines. **F.** Color Doppler of the subclavian artery (red) and vein (blue).

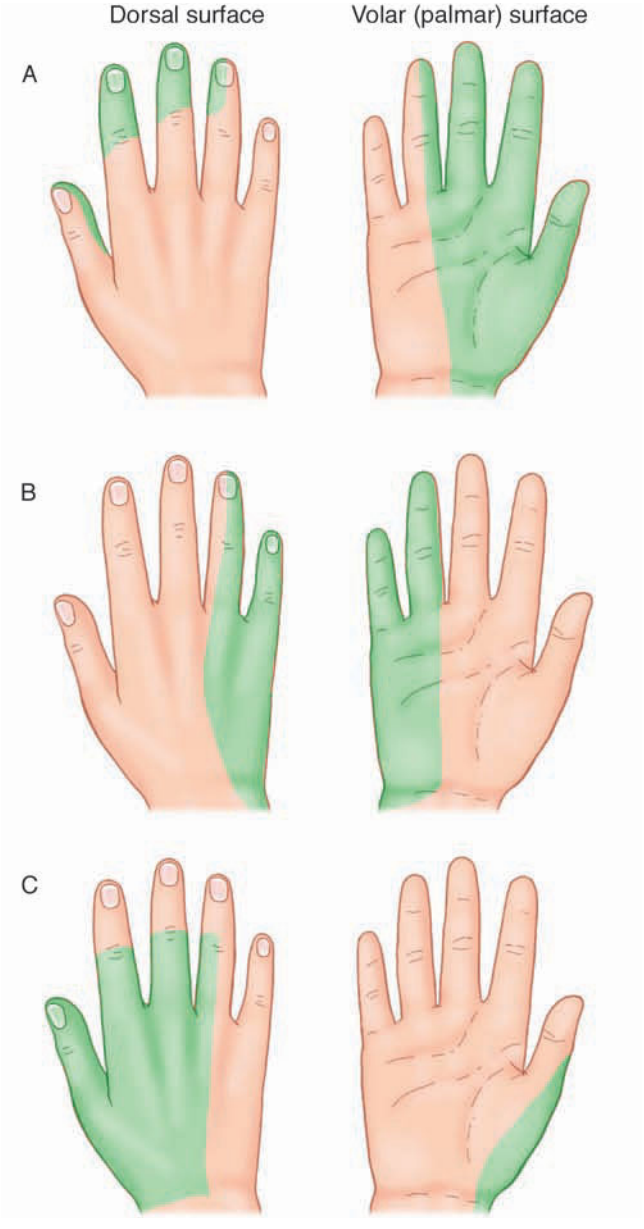

FIGURE 126-20. The sensory innervation of the hand. **A.** The median nerve. **B.** The ulnar nerve. **C.** The radial nerve.

MEDIAN NERVE BLOCK AT THE ELBOW

Anatomy The median nerve innervates all the muscles of the anterior forearm except the flexor digitorum profundus to the ring and little fingers and the flexor carpi ulnaris.[12,22,23] It innervates the thenar muscles and the lumbrical muscles to the index and middle fingers in the hand. It provides sensory innervation to the palmar aspect of the thumb, index finger, middle finger, radial portion of the ring finger, and the lateral half of the palm (**Figure 126-20A**). The median nerve provides a variable amount of sensory innervation to the dorsal distal surfaces of the lateral three and one-half fingers.[12]

Patient Positioning Place the patient supine with their arm abducted 45°, the elbow in full extension, and the hand supinated (**Figure 126-21A**).

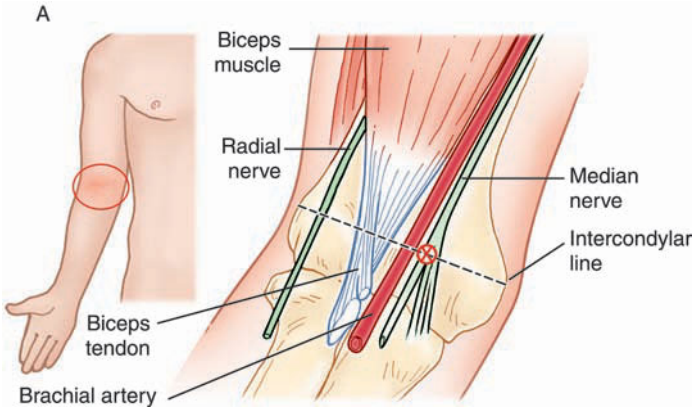
Landmarks Identify the medial and lateral epicondyle of the humerus by palpation. Connect the epicondyles with a straight line (**Figure 126-21A**). Identify the brachial artery by palpating for its pulse just medial to the biceps tendon and over the line just drawn. Mark the site of the palpable pulse with a marker.

Needle Insertion and Direction Place a skin wheal of local anesthetic solution just medial to the pulse, at the level of the intercondylar line. Insert a 25 gauge needle perpendicular to the skin and slowly advance it. If paresthesias are elicited, withdraw the needle 1 to 2 mm and allow the paresthesias to resolve. Inject 3 to 5 mL of local anesthetic solution. If paresthesias are not elicited, slowly move the needle in a fan-like pattern to elicit paresthesias. Withdraw the needle 1 to 2 mm, allow the paresthesias to resolve, and inject 3 to 5 mL of local anesthetic solution.

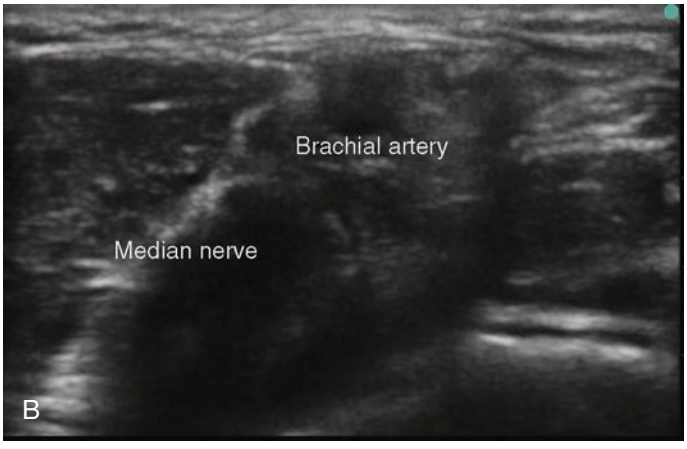
US-Guided Block Place the US probe in the crease of the antecubital fossa. Locate the pulsatile brachial artery in the middle of the antecubital fossa (**Figure 126-21B**). Anesthetize the skin medial to the brachial artery. Place the spinal needle inferior to the short axis of the US probe directly over the median nerve, which should be medial to the brachial artery. Only the tip of the needle will be visualized in this view. Insert and advance the needle until its tip is at the median nerve. Aspirate to ensure that the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of the local anesthetic solution around the median nerve. If satisfactory, inject the remainder of the local anesthetic solution to produce the "donut sign." If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks The median nerve has no sensory branches in the forearm. Therefore, there is no advantage to blocking the median nerve at the elbow. Inserting the needle to elicit paresthesias can be quite painful for the patient. Blockade at the wrist is usually easier to perform, especially in obese patients.[9]

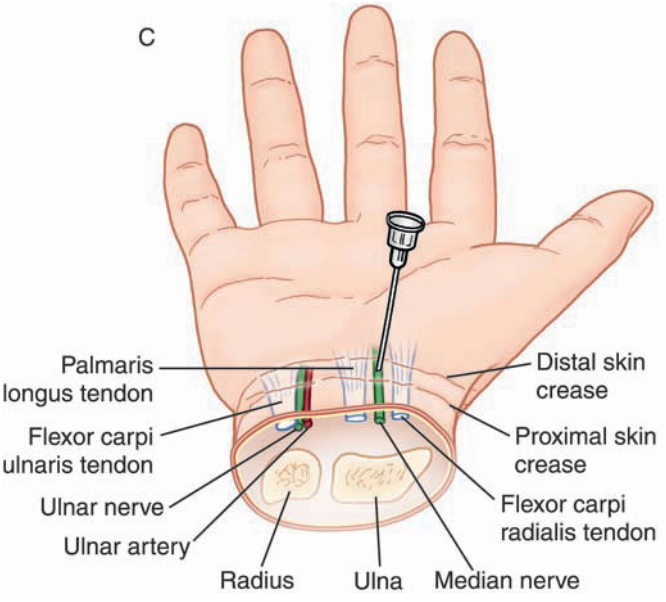
MEDIAN NERVE BLOCK AT THE WRIST



Anatomy The median nerve lies in the carpal tunnel on the volar aspect of the wrist. It is located between the tendons of the flexor carpi radialis and palmaris longus muscles (**Figure 126-21C**). The innervation of the median nerve is described in the previous section.



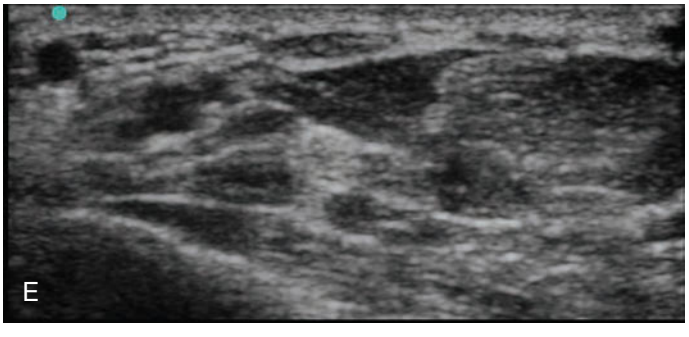
Patient Positioning Place the patient supine with their arm abducted 45°, the elbow in full extension, and the hand fully supinated (**Figure 126-21A**).



Landmarks Identify the palmaris longus tendon by flexing the patient's clenched hand against resistance. Mark the radial border of the palmaris longus tendon. Note the position of the proximal and distal wrist creases.

Needle Insertion and Direction Place a skin wheal of local anesthetic solution along the radial border of the palmaris longus tendon, between the proximal and distal wrist creases. Insert a 25 gauge needle perpendicular to the skin wheal and advance it slowly (**Figure 126-21C**). If paresthesias are elicited, withdraw the needle 1 to 2 mm and allow them to resolve. Inject 3 to 5 mL of local anesthetic solution. If paresthesias are not elicited, inject 5 to 10 mL of local anesthetic solution. **Injection of the local anesthetic solution should not raise a skin wheal and should flow effortlessly if the needle is within the carpal tunnel.**[12]

US-Guided Block Place the US probe over the middle of the wrist with the marker pointing laterally (**Figure 126-21D**). The Palmaris longus tendon should be visible in the middle of the wrist. The median nerve is hyperechoic and directly lateral to



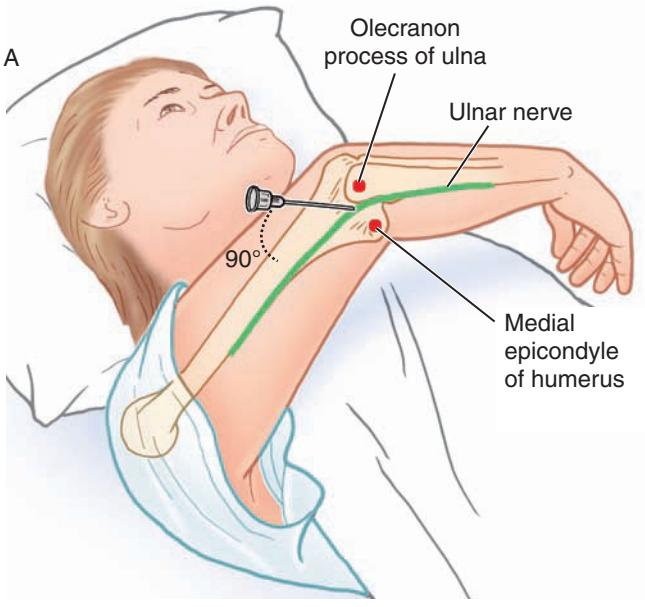


FIGURE 126-21. The median nerve block. **A.** Blockade at the level of the elbow. **B.** US image of the median nerve at the antecubital fossa. **C.** Blockade at the level of the wrist. **D.** US probe and needle placement. **E.** US image of the volar wrist. The median nerve is the round, hyperechoic structure in the center of the image.

this tendon (**Figure 126-21E**). The radial artery is lateral to the median nerve (**Figure 126-21C**). Anesthetize the skin lateral to the palmaris longus tendon. Place the needle inferior to the short axis of the US probe and directly over the median nerve (**Figure 126-21D**). Insert and advance the needle until its tip is at the median nerve. Aspirate to ensure that the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of the local anesthetic solution around the median nerve. If satisfactory, inject the remainder of the local anesthetic solution to produce the "donut sign." If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks A small percentage of the population (10% to 15%) does not have a palmaris longus tendon. Identify the flexor carpi radialis tendon by the same method as identifying the palmaris longus tendon. Inject the local anesthetic solution 1 cm medial to the ulnar edge of the flexor carpi radialis tendon, between the proximal and distal wrist creases. The technique is otherwise as noted above.

ULNAR NERVE BLOCK AT THE ELBOW

Anatomy The ulnar nerve lies in the ulnar groove of the humerus at the elbow, between the olecranon process and medial condyle of the humerus (**Figure 126-22A**). It provides motor innervation to the flexor carpi ulnaris, the ring and little finger portion of the flexor digitorum profundus, the palmaris brevis, the hypothenar muscles, the third and fourth lumbricals, the interossei,

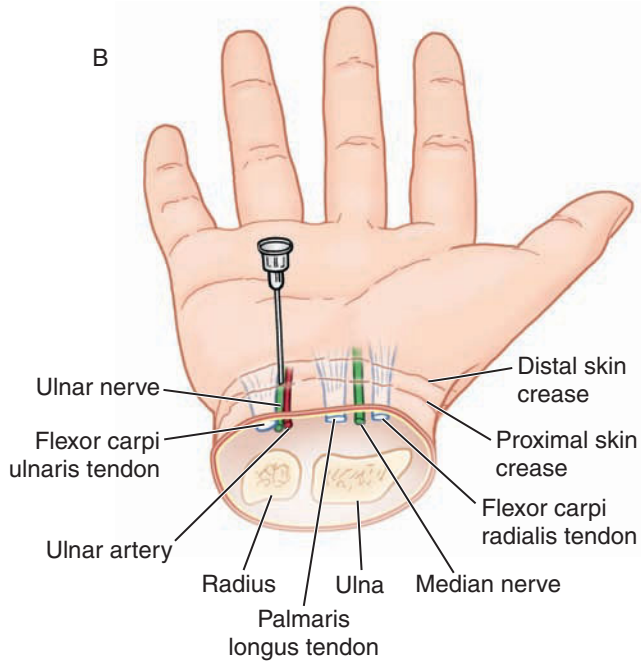

FIGURE 126-22. The ulnar nerve block. **A.** Blockade at the level of the elbow. **B.** Blockade at the level of the wrist. **C.** US probe and needle placement. **D.** US image of the volar wrist. The ulnar artery (*arrow*) is lateral to the hyperechoic ulnar nerve (in the crosshairs).

and the adductor pollicis muscles. It provides sensory innervation to the medial one-third to one-half of the palm, the palmar aspect of the ulnar half of the ring finger, and the entire little finger (**Figure 126-20B**). The ulnar nerve provides sensory innervation to the dorsomedial half of the hand, the little finger, and the ulnar half of the ring finger on the dorsal surface of the hand.[24]

Patient Positioning Place the patient supine with their elbow flexed 90° and the shoulder flexed 45° (**Figure 126-22A**).

Landmarks Identify the olecranon process and the medial epicondyle of the humerus by palpation. Palpate the groove between the olecranon process and the medial epicondyle. The ulnar nerve is located within this groove.

Needle Insertion and Direction Place a skin wheal of local anesthetic solution 1 to 2 cm proximal to the ulnar groove. Insert a 25 gauge needle through the skin wheal and directed toward the ulnar groove. Aim the needle parallel to the ulnar groove and the course

of the nerve (**Figure 126-22A**). Advance the needle into the ulnar groove and inject 5 to 7 mL of local anesthetic solution. If paresthesias are elicited, withdraw the needle 1 mm and allow them to resolve before injecting the local anesthetic solution.

US-Guided Block Place the US probe in the crease between the olecranon process and the medial epicondyle, with the marker pointing laterally. Two hyperlucent structures should be seen, the medial epicondyle medially and the olecranon process closer to the marker. The ulnar nerve is hyperechoic and courses between these two hyperlucent structures. Anesthetize the skin. Place the needle inferior to the short axis of the US probe and directly over the ulnar nerve. Only the tip of the needle will be visualized in this view. Insert and advance the needle until its tip is at the ulnar nerve. Aspirate to ensure that the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of local anesthetic solution around the ulnar nerve. If satisfactory, inject the remainder of the local anesthetic solution to produce the "donut sign." If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks The ulnar nerve has no sensory branches in the forearm and thus may be blocked at the wrist or at the elbow. Blockade of the ulnar nerve at the elbow is not recommended. A fibrous sheath surrounds the ulnar nerve at the elbow requiring intraneural injection for a successful blockade. This can lead to residual neuritis and nerve dysfunction. Blocking the ulnar nerve several centimeters above the elbow may prevent these complications. Blockade at the wrist is very reliable and does not have the associated complications as at the elbow.

ULNAR NERVE BLOCK AT THE WRIST

Anatomy The ulnar nerve lies between the distal and proximal flexor skin creases of the wrist, lateral (or radial) to the flexor carpi ulnaris tendon and medial (or ulnar) to the ulnar artery (**Figure 126-22B**). The innervation of the ulnar nerve is described in the previous section.

Patient Positioning Place the patient supine with their arm abducted 45° to 90°, the elbow fully extended, and the hand supinated (**Figure 126-22B**).

Landmarks Identify the flexor carpi ulnaris tendon by flexing the patient's clenched hand against resistance. Mark the medial aspect of the flexor carpi ulnaris tendon. Identify the ulnar artery by its palpable pulsations between the proximal and distal wrist crease. Note the position of the proximal and distal wrist creases.

Needle Insertion and Direction Place a skin wheal of local anesthetic solution in the quadrangle defined by the proximal flexor skin crease, the distal flexor skin crease, the lateral aspect of the flexor carpi ulnaris tendon, and medial to the ulnar artery. Insert a 25 gauge needle perpendicular to the skin wheal and slowly advance it 0.5 cm (**Figure 126-22B**). If paresthesias are elicited, withdraw the needle 2 mm and allow them to resolve. Inject 2 mL of local anesthetic solution once the paresthesias resolve. If paresthesias are not elicited, inject 3 to 5 mL of local anesthetic solution.

US-Guided Block Place the US probe over the middle of the wrist with the marker pointing laterally (**Figure 126-22C**). The Palmaris longus tendon should be visible in the middle of the wrist. Move the US probe medially until the ulnar artery is visible. The ulnar nerve is hyperechoic and directly medial to the ulnar artery (**Figure 126-22D**). Anesthetize the skin medial to the ulnar artery. Position the needle inferior to the short axis of the US probe and directly over the ulnar nerve (**Figure 126-22C**). Insert and advance the needle until its tip is at the ulnar nerve. Aspirate to ensure that the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of local anesthetic solution around the ulnar nerve. If satisfactory, inject the remainder of the local anesthetic solution to produce the "donut sign." If the test dose is not satisfactory, reposition the needle and inject another test dose.

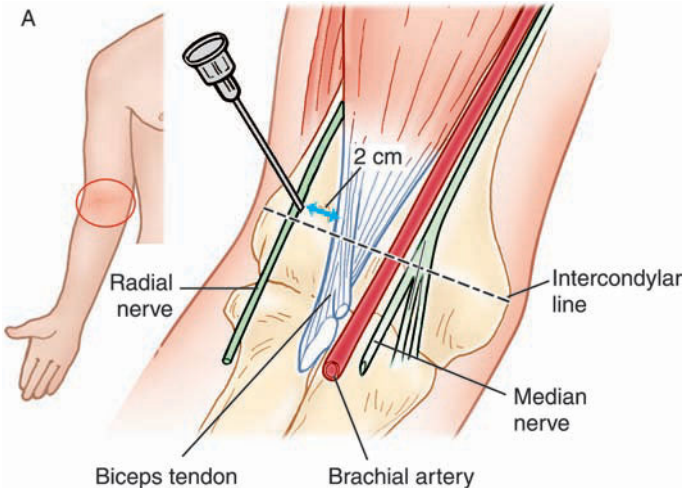
Remarks This is the preferred approach to block the ulnar nerve. Blockade of the ulnar nerve at the wrist is very reliable and does not have the associated complications as at the elbow.[25]

RADIAL NERVE BLOCK AT THE ELBOW

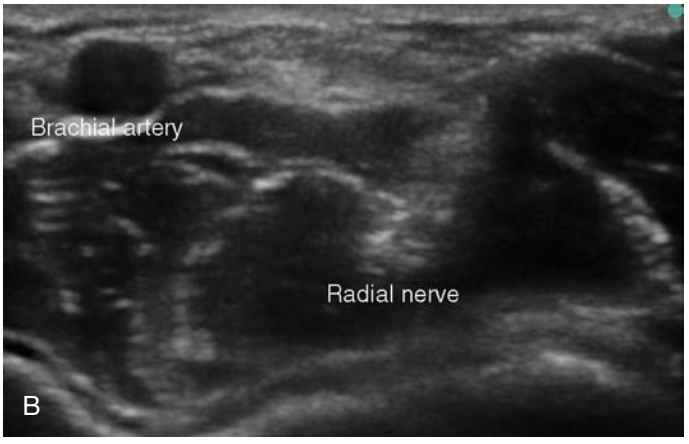
Anatomy The radial nerve and the sensory branch of the musculocutaneous nerve run together in the sulcus between the biceps and the brachioradialis muscle on the anterolateral aspect of the elbow. The radial nerve provides sensory innervation to portions of the dorsal arm and forearm, the dorsolateral half of the hand, and the dorsal proximal aspects of the thumb, index, middle, and radial half of the ring fingers (**Figure 126-20**).[12] It provides motor innervation to the muscles on the posterior aspect of the arm, forearm, and hand.

Patient Positioning Place the patient supine with their elbow flexed 15° to 30°.

Landmarks Palpate the tendon of the biceps muscle in the antecubital fossa. Identify the flexion skin crease of the elbow. Palpation of the biceps tendon is greatly facilitated by having the patient flex their elbow 90° then contract and relax their biceps muscle. Identify the medial and lateral condyles of the humerus. Draw a line between the humeral condyles (**Figure 126-23A**). This line should be located at the level of the antecubital crease.



Needle Insertion and Direction Place a skin wheal of local anesthetic solution 2 cm lateral to the biceps tendon and 1 cm proximal to the antecubital crease (**Figure 126-23A**). Insert a 25 gauge needle through the skin wheal and perpendicular to the skin (**Figure 126-23A**). Advance the needle 1 to 2 cm. Probe in a fan-like pattern until paresthesias are elicited. Withdraw the needle 1 to 2 mm and allow the paresthesias to resolve. Inject 5 to 7 mL of local anesthetic solution.



US-Guided Block Position the patient with their arm abducted 45°, the elbow in full extension, and the hand supinated. Place the US probe on the lateral aspect of the crease of the antecubital fossa. The radial nerve is lateral to the biceps tendon and the brachial artery (**Figure 126-23A**). Anesthetize the skin over the radial nerve. Place the needle inferior to the short axis of the US probe and directly over the radial nerve. Only the tip of the needle will be visualized in this view. Insert and advance the needle until its tip is at the radial nerve. Aspirate to ensure that the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of local anesthetic solution around the radial nerve. If satisfactory, inject the remainder of the local anesthetic solution to produce the "donut sign." If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks Blockade of the radial nerve at the elbow is difficult, has limited applications, is painful for the patient, and often results in a large antecubital hematoma. The preferred technique is blockade at the wrist.

RADIAL NERVE BLOCK AT THE WRIST

Anatomy The radial nerve at the wrist consists of a trunk and terminal branches that arise in the forearm (**Figure 126-23C**). The innervation of the radial nerve is described in the previous section.

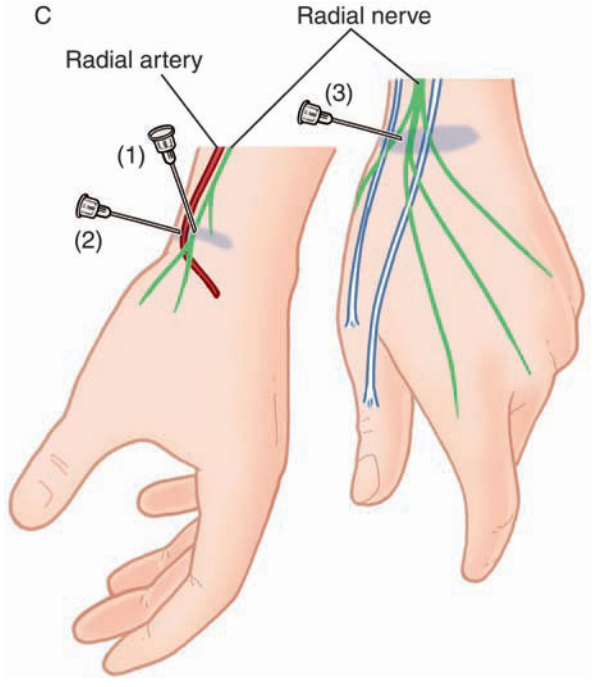


FIGURE 126-23. The radial nerve block. **A.** Blockade at the level of the elbow. **B.** US image of the radial nerve at the elbow. **C.** Blockade at the level of the wrist. The numbers represent the three injections required to anesthetize the branches of the radial nerve. **D.** US image of the wrist. The radial artery (*arrow*) is adjacent and medial to the radial nerve (in the crosshairs).

Patient Positioning Place the patient supine with their arm abducted 45°, the elbow fully extended, and the hand midway between supination and pronation (**Figure 126-23C**).

Landmarks Identify the radial artery by its pulsation at the level of the proximal wrist crease.

Needle Insertion and Direction Place a skin wheal of local anesthetic solution 1 mm lateral to the radial pulse. Insert a 25 gauge needle 1 mm lateral to the radial pulse, through the skin wheal, and perpendicular to the skin (**Figure 126-23C**). Advance the needle 0.5 cm. If paresthesias are elicited, withdraw the needle 1 to 2 mm and allow them to resolve. Inject 2 mL of local anesthetic solution. If paresthesias are not elicited, inject 3 to 5 mL of local anesthetic solution. This will anesthetize the terminal trunk of the radial nerve. Infiltrate 5 to 7 mL of local anesthetic solution at the level of the extensor wrist crease, from the lateral aspect of the radius to the base of the fourth metacarpal (**Figure 126-23C**). This will anesthetize the terminal branches that arise in the forearm.

US-Guided Block Place the US probe over the middle of the wrist with the marker pointing laterally. The palmaris longus tendon should be visible in the middle of the wrist. Move the US probe laterally until the radial artery is visualized. The radial nerve is hyperechoic and directly lateral to the radial artery (**Figures 126-23D**).

Anesthetize the skin lateral to the radial artery and directly over the radial nerve. Place the needle inferior to the short axis of the US probe and directly over the radial nerve. Insert and advance the needle until its tip is at the radial nerve. Aspirate to ensure that the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of local anesthetic solution around the radial nerve. If satisfactory, inject the remainder of the local anesthetic solution to produce the "donut sign." If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks This is the preferred technique for blockade of the radial nerve.

WRIST BLOCK

Perform the wrist block by blocking the radial, ulnar, and median nerves at the wrist. The technique for each specific nerve block was discussed previously. The wrist block provides complete anesthesia to the hand and is commonly used in hand surgery. It can be performed in the Emergency Department to provide anesthesia for burn management, foreign body removal, wound exploration, or extensive laceration repair. Wrist blockade is reliable but slow, as it requires extended time to block all three nerves at the wrist.[12]

INTERMETACARPAL NERVE BLOCK

Anatomy The principal nerves supplying the finger are the palmar digital nerves, which originate from the deep volar branches of the ulnar and median nerves in the region of the wrist. These nerves follow the artery along the lateral aspects of the bone and supply sensation to the volar skin, the interphalangeal joints, the distal finger, and the fingertip of all five digits.

Two dorsal and two palmar nerves supply each finger. These nerves run along the phalanxes in the 2, 4, 8, and 10 o'clock positions.[26] These nerves also supply the dorsal, distal aspect of the finger, including the fingertip and nail bed. The dorsal digital nerves originate from the radial and ulnar nerves that wrap around the dorsum of the hand. They supply the nail bed of the thumb and small finger and the dorsal aspect of all five digits up to the distal interphalangeal joints. The palmar and dorsal nerves need to be blocked in the case of the thumb and fifth finger.

Patient Positioning Place the patient sitting upright or supine with their hand pronated on a bedside examination table.

Landmarks Locate the web spaces and the metacarpal heads on each side of the finger to be blocked.

Needle Insertion and Direction Insert a 25 gauge needle into the dorsal aspect of the web space on one side of the digit to be anesthetized (**Figure 126-24A**). Advance the needle approximately 0.5 cm. Inject 1 mL of local anesthetic solution. Repeat the procedure on the other side of the digit to be blocked. When blocking the second and fifth digits, a half-ring block is required on the ulnar aspect of the fifth digit and radial aspect of the second digit. When blocking the thumb, infiltrate the dorsum and sides in a half-ring manner.

An alternative is the metacarpal head block. This technique can be used to anesthetize any of the fingers. Insert a 25 gauge needle perpendicular to the dorsum of the hand and adjacent to the metacarpal head on one side of the finger to be blocked (**Figure 126-24B**). Advance the needle 0.5 cm and inject 1 mL of local anesthetic solution. Repeat the procedure on the other side of the finger to be blocked. Some physicians prefer to perform this block on the volar aspect of the hand (**Figure 126-24C**). This technique is extremely painful and should be avoided.

Remarks This block produces less swelling than does the ring block. Subsequently, there is less risk of vascular compromise. This is a less painful technique than the ring block.

DIGITAL NERVE BLOCK (RING BLOCK) OF THE FINGER

Anatomy The anatomy and innervation of the digital nerves are described in the previous section.

Patient Positioning Place the patient sitting upright or supine with their hand pronated on a bedside examination table.

Landmarks Locate the dorsum of the proximal phalanx to be anesthetized.

Needle Insertion and Direction Insert a 25 gauge needle on the dorsal surface of the base of the proximal phalanx (**Figure 126-24D(1)**). Inject 1 mL of local anesthetic solution along the dorsal surface of the finger. Remove the needle and reinsert it downward, perpendicular to the phalanx and to a depth just past the base of the phalanx (**Figure 126-24D(2)**). Inject 1.0 to 1.5 mL of local anesthetic along the lateral aspect of the finger. Withdraw the needle, reinsert it on the other side of the finger to be blocked, and inject 1.0 to 1.5 mL of local anesthetic solution (**Figure 126-24D(3)**).

An alternative is the half-ring block (**Figure 126-24E**). It is a variant of the ring block (**Figure 126-24D**). Inject 1.0 to 1.5 mL of local anesthetic solution on one side of the base of the proximal phalanx to be anesthetized. Repeat this procedure on the other side of the finger. The injection of local anesthetic on one side of the finger is termed the half-ring block. It takes two half-ring blocks to anesthetize a finger.

Remarks The indications for a digital block include repair of finger lacerations and amputations, reductions of fractures and dislocations, incision and drainage of infections, removal of fingernails, and relief of pain from burns. Do not inject more than 5 mL of local anesthetic solution into a digit. Using local anesthetic agents that contain epinephrine is not recommended because the finger contains end arteries and may experience ischemia from the vasoconstrictive effects of epinephrine.

REGIONAL ANESTHESIA TECHNIQUES FOR THE TORSO

INTERCOSTAL NERVE BLOCK

Anatomy The intercostal nerves originate from the thoracic spinal cord and have four major branches (**Figure 126-25**). The first is the gray rami communicans to the sympathetic ganglion. The second branch is the posterior cutaneous nerve that supplies the paravertebral muscles and overlying skin. The third branch is the lateral cutaneous nerve that arises about the midaxillary line. It divides into an anterior and posterior division to supply most of the chest and the abdominal wall. The final branch is the terminal anterior cutaneous nerve. It supplies the anterior chest and abdominal wall adjacent to the midline. Each intercostal nerve travels within a neurovascular bundle behind the inferior border of each rib (**Figure 126-25B**). The intercostal nerve lies inferior to the intercostal vein and artery. The intercostal nerve may be blocked at several sites along its course. The most common site is at the angle of the rib. The technique described will be the blockade of the intercostal nerves at the angle of the rib.

Patient Positioning Place the patient prone with a pillow under the midabdomen to straighten the lumbar curve and increase the size of the intercostal spaces posteriorly.

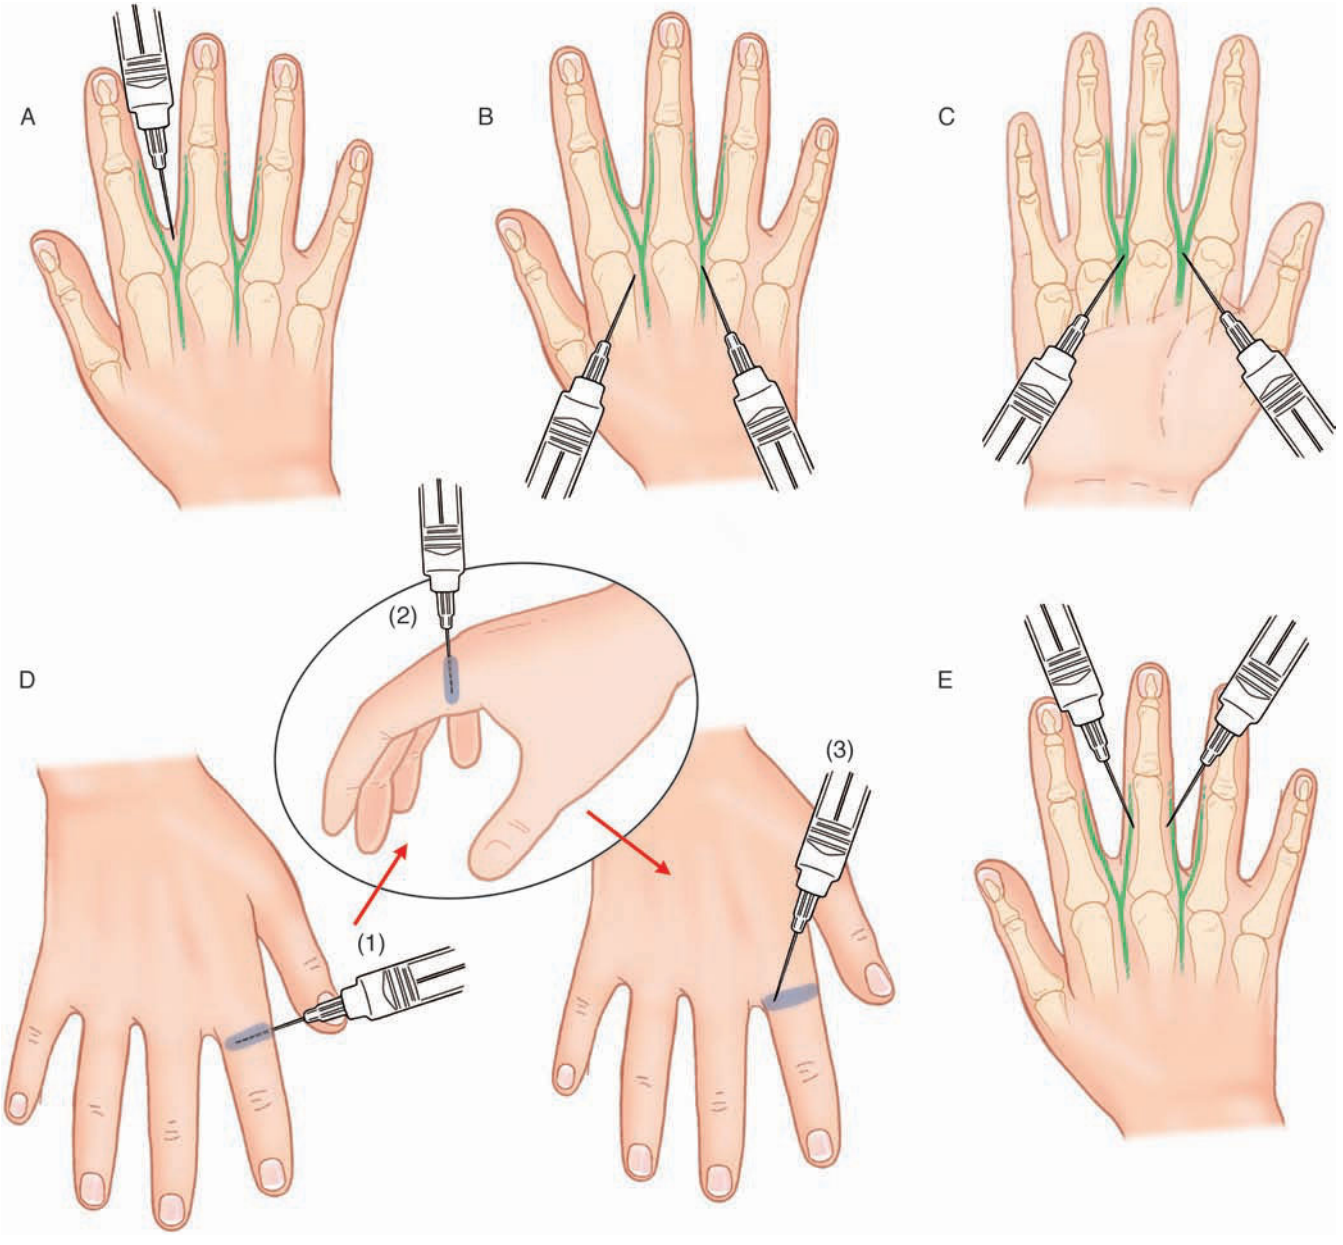

FIGURE 126-24. Techniques to anesthetize the digital nerves of the fingers. **A.** Intermetacarpal nerve block through the web space. **B.** Intermetacarpal nerve block on the dorsal surface of the hand, between the metacarpal heads. **C.** Intermetacarpal nerve block on the ventral surface of the hand, between the metacarpal heads. **D.** The ring block. **E.** The half-ring block.

Landmarks **The most important step is to correctly identify the anatomy of the patient.** Draw a line along the vertebral spines corresponding to the levels to be anesthetized. Palpate laterally from the vertebral spines to the edge of the paraspinal muscles. This is the location where the ribs are most superficial. This distance can vary from 6 to 8 cm from the midline in the average adult. Draw vertical lines parallel to the first line and along the edge of the paraspinal muscles (**Figure 126-26A**). These lines must angle slightly medially over the upper ribs to avoid the scapula. Palpate and mark the inferior edge of each rib along these two vertical lines (**Figure 126-26A**).

Needle Insertion and Direction **This procedure requires the utmost of care to prevent inducing a pneumothorax.** Inject local anesthetic solution to make a skin wheal at the intersection of the horizontal lines with the vertical paraspinal muscle lines. Use the index finger of the nondominant hand to pull the skin at the lower edge of the rib up onto the rib (**Figure 126-26B**). Grasp the syringe in the dominant hand. Insert the 25-gauge needle at a 60° angle along the tip of the nondominant index finger while the dominant hand is resting on the patient's back (**Figure 126-26C**). Advance the needle until the rib is contacted (**Figure 126-26C**, inset).

Reposition the nondominant hand so that it is resting against the patient's back and holding the needle between the thumb, index, and middle fingers (**Figure 126-26D**). Use the nondominant hand to slowly and carefully "walk" the needle off the inferior rib margin (**Figure 126-26E**). Advance the needle 3 mm with the nondominant hand (**Figure 126-26F**). **It is imperative that the needle not be advanced more than 3 mm after it is "walked" off the inferior border of the rib to prevent an iatrogenic pneumothorax.**

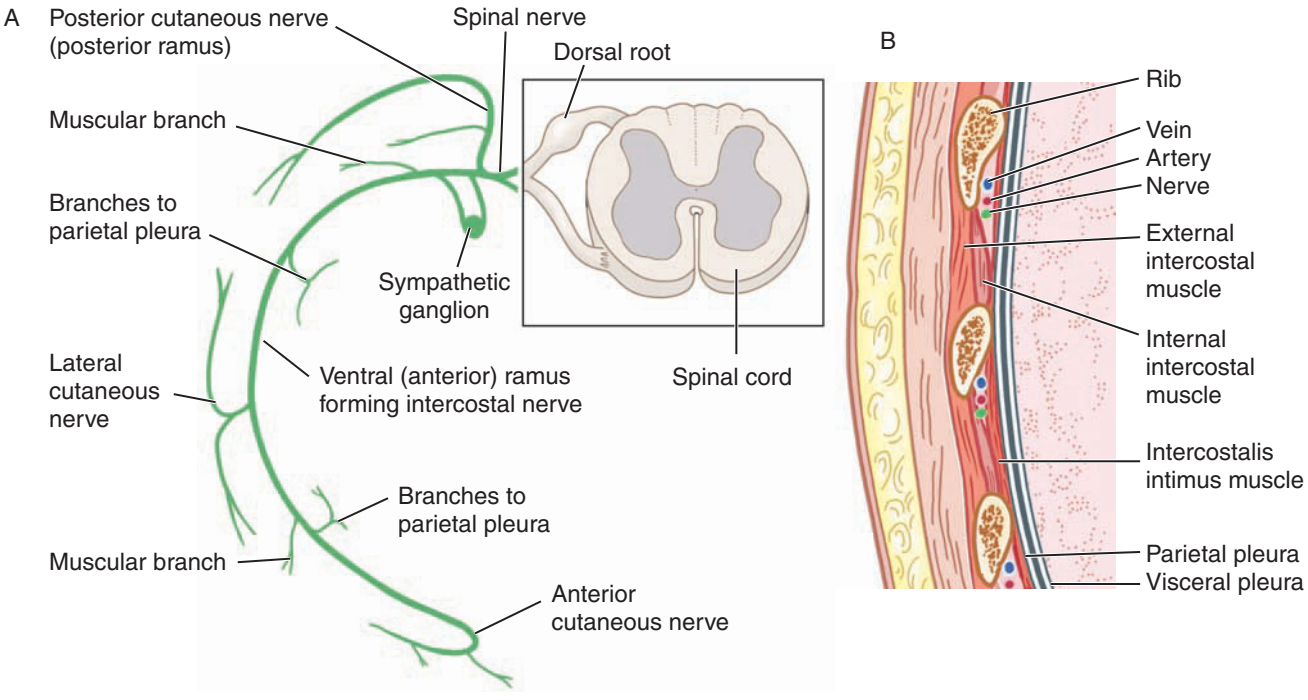

FIGURE 126-25. The intercostal nerve. **A.** The anatomy of a typical thoracic spinal nerve. **B.** Cross section through the chest wall. The intercostal nerves are contained within a neurovascular bundle that lies behind the inferior border of each rib.

Aspirate to ensure that the tip of the needle is not within a blood vessel or the lung. Inject 1 to 2 mL of local anesthetic solution (**Figure 126-26G**). Remove the needle and repeat the procedure at the other desired interspaces.

Remarks Local anesthetic solution for intercostal blocks should contain 1:200,000 or less of epinephrine. **Obtain a postprocedural upright chest radiograph to ensure that the patient does not have an iatrogenic pneumothorax.**[27]

PENILE BLOCK

The penis may be anesthetized for the purposes of circumcision, laceration repair, foreign body removal, zipper entrapment, or to perform the release of a phimosis or paraphimosis. The dorsal nerves of the penis provide sensory innervation to the penis. They emerge from under the pubis, just lateral to the symphysis, and course along the dorsal surface of the penis. These nerves are located approximately 0.5 cm from the dorsal penile midline. These nerves are blocked at the base of the penis. Refer to Chapter 146 for the complete details of the penile block.

REGIONAL ANESTHESIA TECHNIQUES FOR THE LOWER EXTREMITY

The sensory innervation of the lower extremity is illustrated in **Figure 126-27**. Note that the nerves provide patches of innervation rather than stripes of innervation beginning at the torso and extending to the foot.

FEMORAL NERVE BLOCK

Anatomy The femoral nerve is formed from the lumbar plexus. It travels in the pelvis between the iliacus and psoas major muscles. It enters the thigh below the inguinal ligament, midway between the anterior superior iliac spine and the pubic tubercle (**Figure 126-28A**). The femoral nerve lies anterior to the iliopsoas muscle and lateral to the femoral artery in the proximal thigh (**Figure 126-28B**). The femoral nerve has both sensory and motor components. It provides motor innervation to the anterior thigh muscles. It provides sensory innervation for the anterior thigh, anteromedial thigh, medial thigh, medial leg, and the medial border of the foot (**Figure 126-27**).

Patient Positioning Place the patient supine with their hip and knee extended and the leg slightly externally rotated.

Landmarks Identify the anterior superior iliac spine and the pubic tubercle by palpation. Connect these landmarks with a straight line to roughly approximate the position of the inguinal ligament. Identify the femoral artery by its palpable pulse 1 to 2 cm below the midpoint of the inguinal ligament.

Needle Insertion and Direction Place a skin wheal of local anesthetic solution just lateral to the femoral artery pulse. Insert a 25 gauge needle through the skin wheal and perpendicular to the skin (**Figure 126-28B**). Slowly advance the needle while remaining perpendicular to the skin. The femoral nerve is identified once paresthesias are elicited. Withdraw the needle 2 mm and allow the paresthesias to resolve. Inject 15 to 20 mL of local anesthetic solution.

US-Guided Block Place the US probe along the inguinal crease, midway between the anterior superior iliac spine and the pubic tubercle (**Figure 126-28C**). Identify the femoral artery and femoral vein. The femoral nerve is hyperechoic and located 0.5 to 1 cm lateral and posterior to the common femoral artery (**Figure 126-28D**). Apply pressure with the US probe to distinguish the compressible femoral vein from the incompressible femoral artery. Use color Doppler to confirm the location of the femoral artery and any branches or take-offs. Place the needle lateral to the long axis of the US probe (**Figure 126-28C**). Slowly insert and advance the needle. Visualize the entire length of the needle as it is inserted and approaches the

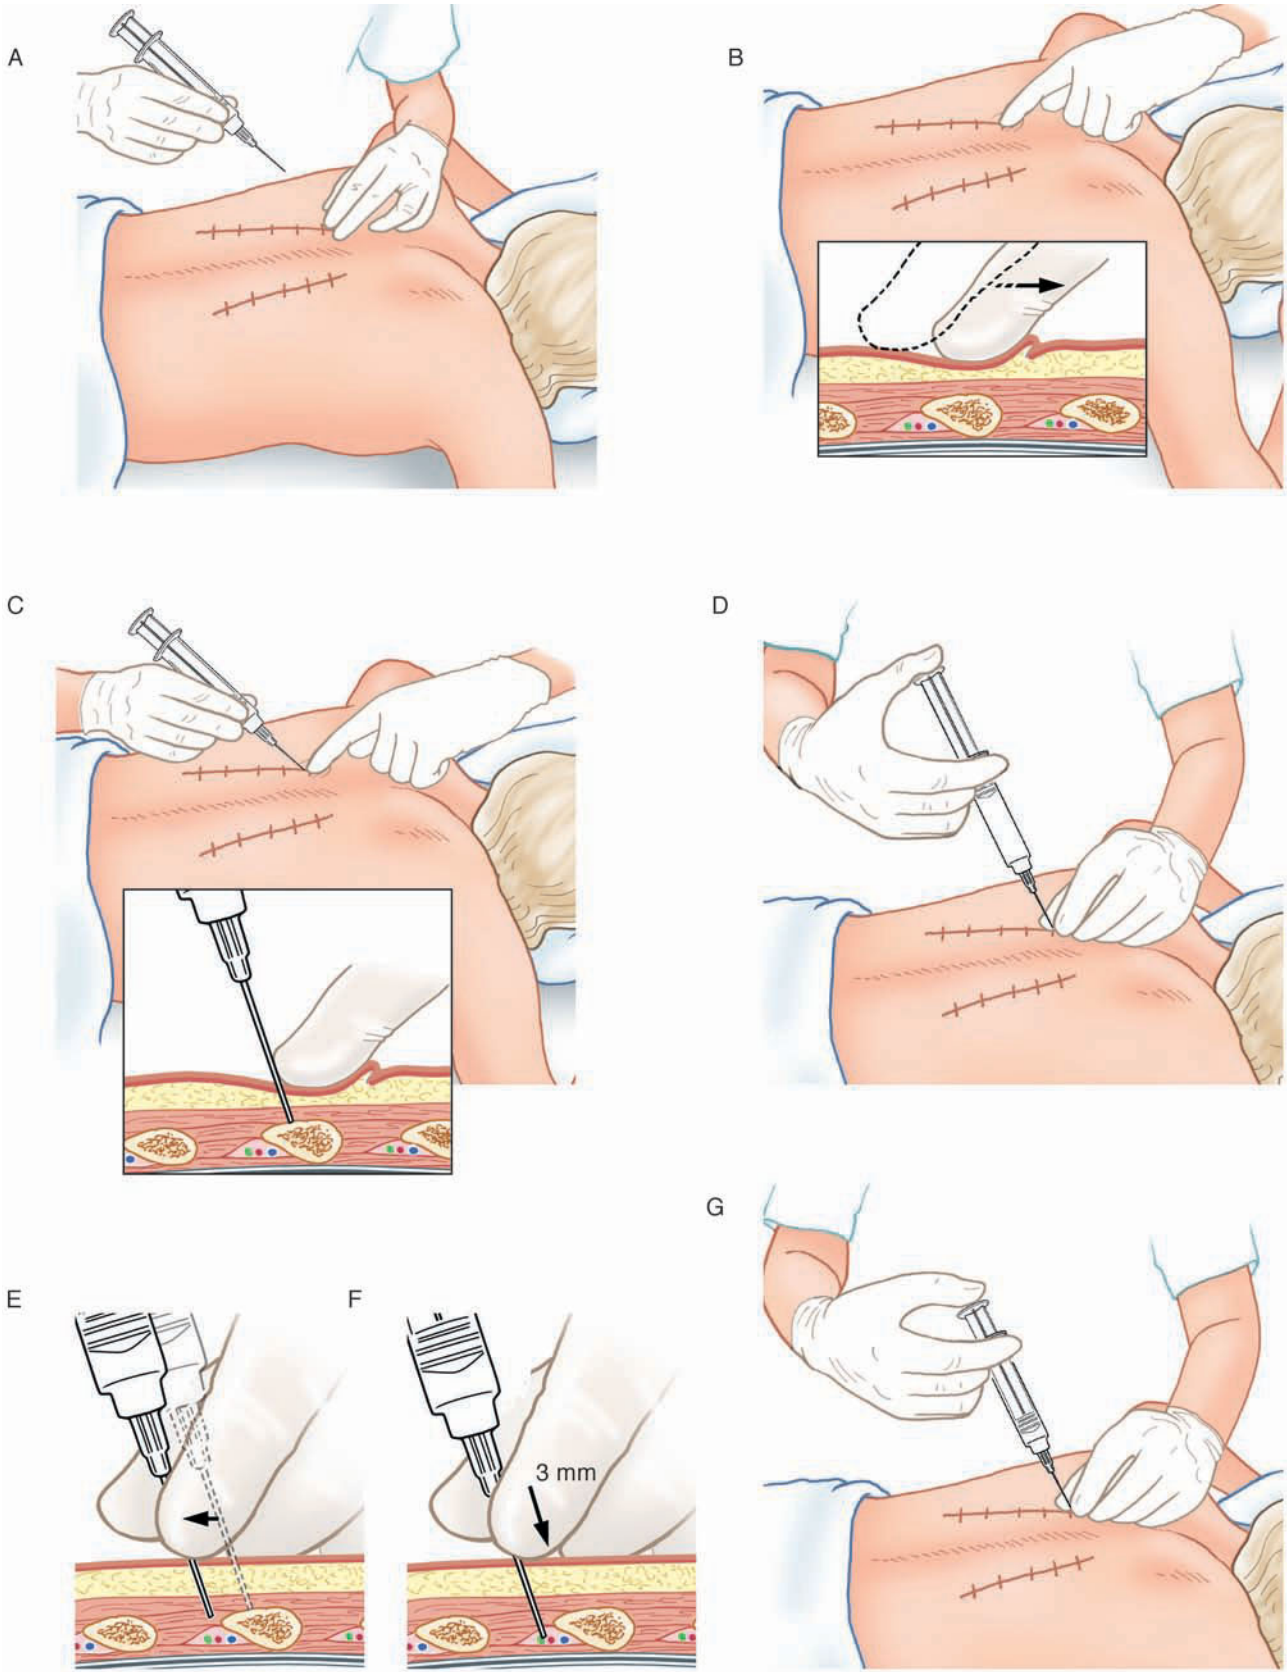

FIGURE 126-26. The intercostal nerve block. **A.** The patient is placed prone. A line is drawn along the lateral border of the paraspinal muscles. Note that the upper end is angled medially to avoid the scapula. Cross-marks are drawn to denote the inferior border of the rib and the location to perform the block. **B.** The index finger of the nondominant hand pulls the skin over-lying the inferior border of the rib upward. **C.** The dominant hand is resting against the patient. The needle is inserted at a 60° angle to the skin and advanced until the rib is contacted. **D.** The fingers of the nondominant hand grasp and stabilize the needle. **E.** The needle is "walked" off the inferior border of the rib. **F.** The needle is advanced 3 mm so that the tip is within the neurovascular bundle. **G.** Inject 1 to 2 mL of local anesthetic solution while maintaining the needle in a stable position with the nondominant hand.

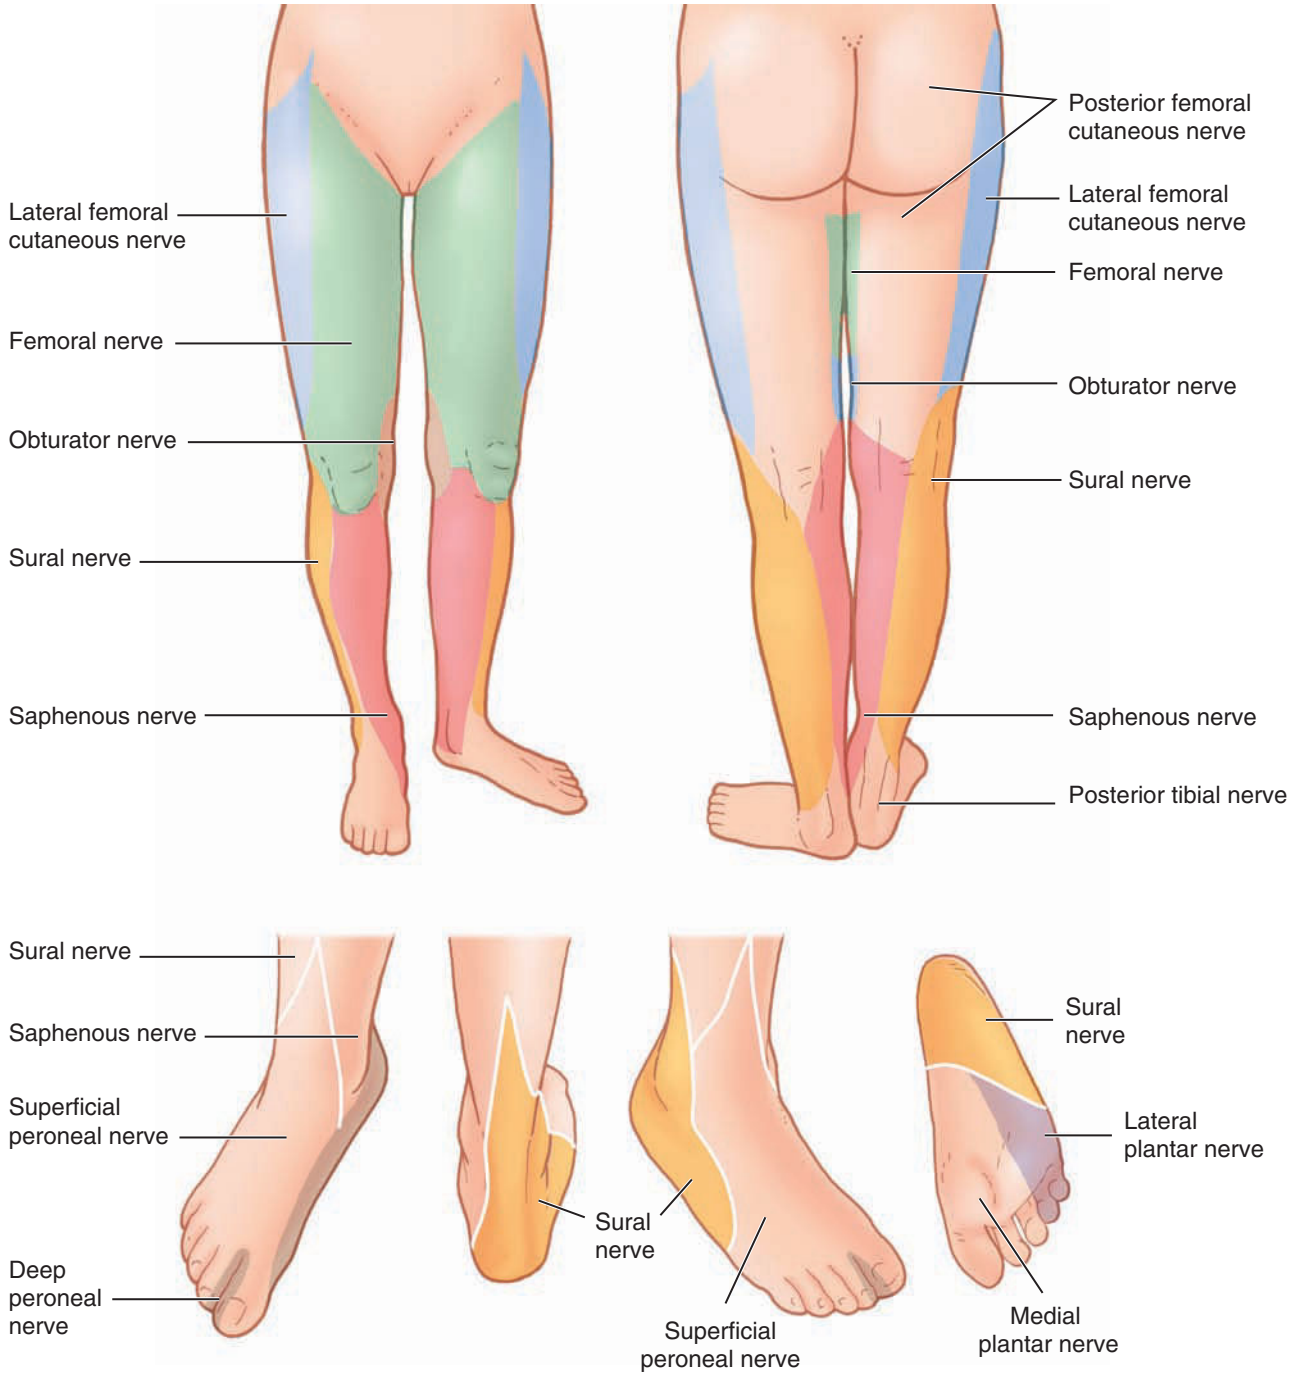

FIGURE 126-27. The sensory distribution of the cutaneous nerves of the lower extremity.

femoral nerve. Continue to advance the needle and penetrate the fascia lata and fascia iliaca so that the tip of the needle is adjacent to the femoral nerve. Aspirate to ensure that the needle tip is not in a blood vessel. Inject a test dose of 1 to 2 mL of local anesthetic solution. Watch the spread of local anesthetic solution around the femoral nerve. If satisfactory, inject the remainder of the local anesthetic solution to produce the "donut sign." If the test dose is not satisfactory, reposition the needle and inject another test dose.

Remarks The femoral nerve is contained within a fibrous sheath that is separate from the other contents (femoral artery and vein) of the femoral triangle (**Figure 126-28B**). **Paresthesias must be elicited to confirm the proper position of the tip of the needle before injecting the local anesthetic solution.** Deposition of the local anesthetic solution outside of the fibrous sheath will not result in any anesthesia except in the area of the injection.

SAPHENOUS NERVE BLOCK AT THE KNEE

Anatomy The saphenous nerve is the terminal branch of the femoral nerve. It travels across the anterior thigh in a medial direction to become superficial at the medial knee after emerging between the tendons of the gracilis and sartorius muscles (**Figure 126-29A**). It follows the great saphenous vein from above the knee to below the medial malleolus (**Figure 126-29B**). It provides sensory innervation

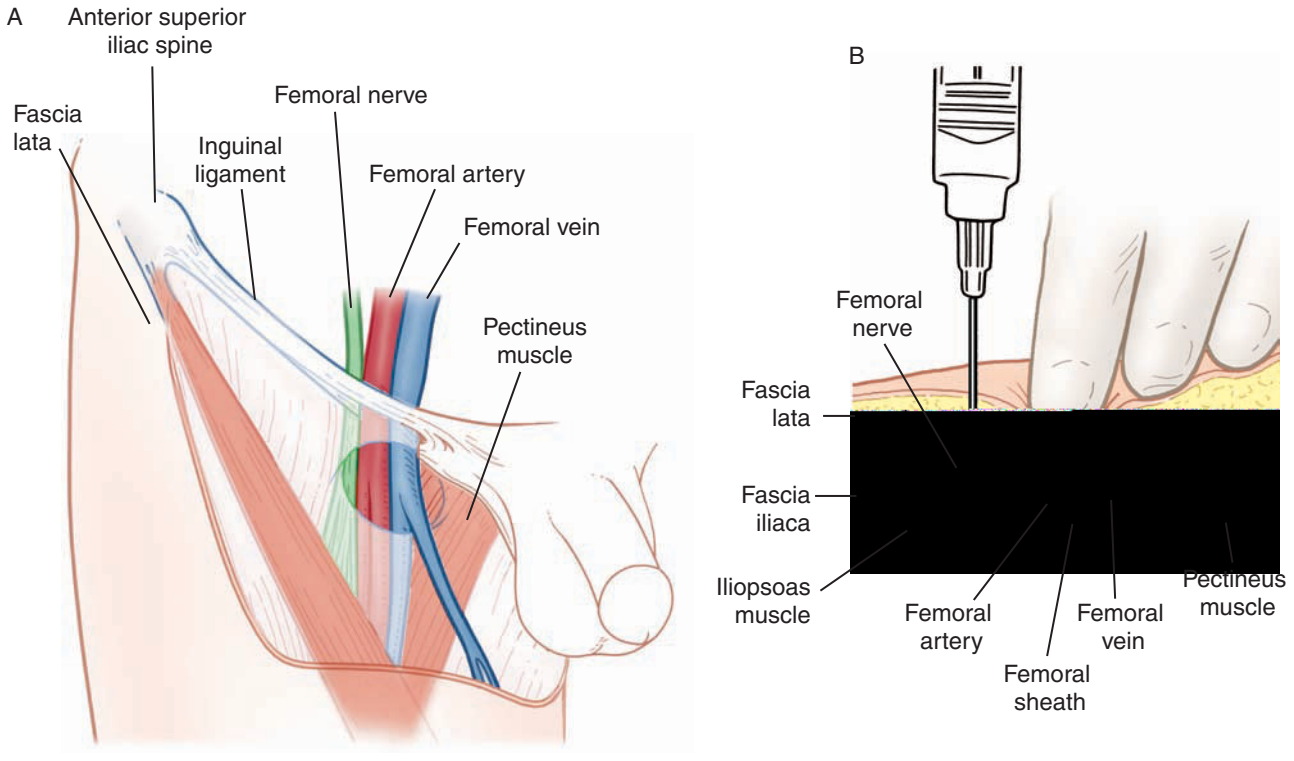

FIGURE 126-28. The femoral nerve block. **A.** The anatomy of the inguinal region. **B.** Blockade of the femoral nerve. **C.** US probe and needle placement. **D.** US image of the femoral neurovascular bundle. The femoral nerve is located within the crosshairs. (A–femoral artery, V–femoral vein)

to the anteromedial leg, medial leg, posteromedial leg, and medial border of the foot to the ball of the great toe (**Figure 126-27**). It has no motor component.

Patient Positioning Place the patient supine with their ankle supported on a pillow or blanket, the knee extended, and the leg externally rotated.

Landmarks Identify the femoral condyle above the knee or the tibial condyle below the knee by palpation.

Needle Insertion and Direction Place a skin wheal of local anesthetic solution over the posteromedial aspect of either condyle (femoral or tibial). Insert a 25 gauge needle through the skin wheal. Infiltrate 7 to 10 mL of local anesthetic solution subcutaneously in a transverse line from the posteromedial to the anteromedial aspect of either condyle (**Figure 126-29C**).

US-Guided Block Identify the femoral artery and femoral nerve at the inguinal crease (see femoral nerve block). Move the US probe

can be prevented by using appropriate techniques and care when delivering the infant.

SUMMARY

The Emergency Physician will occasionally be required to perform a delivery of a baby when the Obstetrician or Family Physician is not available or when delivery is imminent. Fortunately, births in the Emergency Department are rare and most proceed with good outcomes. Knowledge of the normal labor and delivery mechanics aids in a safe delivery and helps to identify complications. The Emergency Physician must develop strategies to treat potential complications and must be prepared to intervene.

132 Episiotomy

Francisco Orejuela

INTRODUCTION

An episiotomy is a surgical incision of the female perineum performed at the time of delivery to increase the diameter of the soft tissue pelvic outlet and facilitate a vaginal delivery. It is one of the most commonly performed surgical procedures in women in the United States, yet it is controversial.

For many decades the episiotomy was thought to provide protection to the female genital tract.[1,2] It is thought to prevent perineal tearing by substituting a straight surgical incision for a ragged spontaneous laceration that may have a worse outcome after repair. It was also believed that an episiotomy resulted in decreased postoperative pain and improved healing when compared to a tear. These original beliefs have been challenged. There is a growing body of evidence demonstrating increased injury to the pelvic floor with the routine use of an episiotomy.[3–6] A recent Cochrane database review of eight randomized controlled trials concluded that there is less posterior perineal trauma, less suturing, and fewer complications with a restrictive use versus the liberal use of an episiotomy.[7] Currently, the evidence does not support a liberal or routine use of an episiotomy.[8] These practice patterns are reflected in a steady decline in the use of an episiotomy from 1.6 million in 1992 to 716,000 in 2003.[9,10]

Nonetheless, there is a place for the episiotomy in modern obstetrics. The indications for an episiotomy today are based primarily on the clinical situation at the time of delivery. Another important reason to make an episiotomy is the prevention of a long and irregular spontaneous perineal laceration. The repair of a controlled surgical incision might be easier to repair, and the anatomical planes easier to recognize. Good clinical judgment is still the best guide to proceed or not with an episiotomy.[11]

ANATOMY AND PATHOPHYSIOLOGY

ANATOMY OF THE PERINEUM

The most critical area of the perineum is the distance from the vestibular fossa to the anus. This area is known as the pudenda, or more commonly as the perineal body. It is usually 3 to 4 cm in length in the nonpregnant woman.[10,11] The perineal body is a complex fibromuscular mass into which many structures insert. It is bordered cephalad by the rectovaginal septum (Denonvilliers' fascia), caudad by the perineal skin, anteriorly by the posterior wall of the vagina, posteriorly by the anterior wall of the anorectum, and laterally by the ischial rami.[12]

The perineal body is the center of the hub of a wheel that includes the transverse perineal muscles, the capsule of the external anal sphincter muscle, and the bulbospongiosus muscle (**Figure 132-1**). The perineal body attaches to the ischial

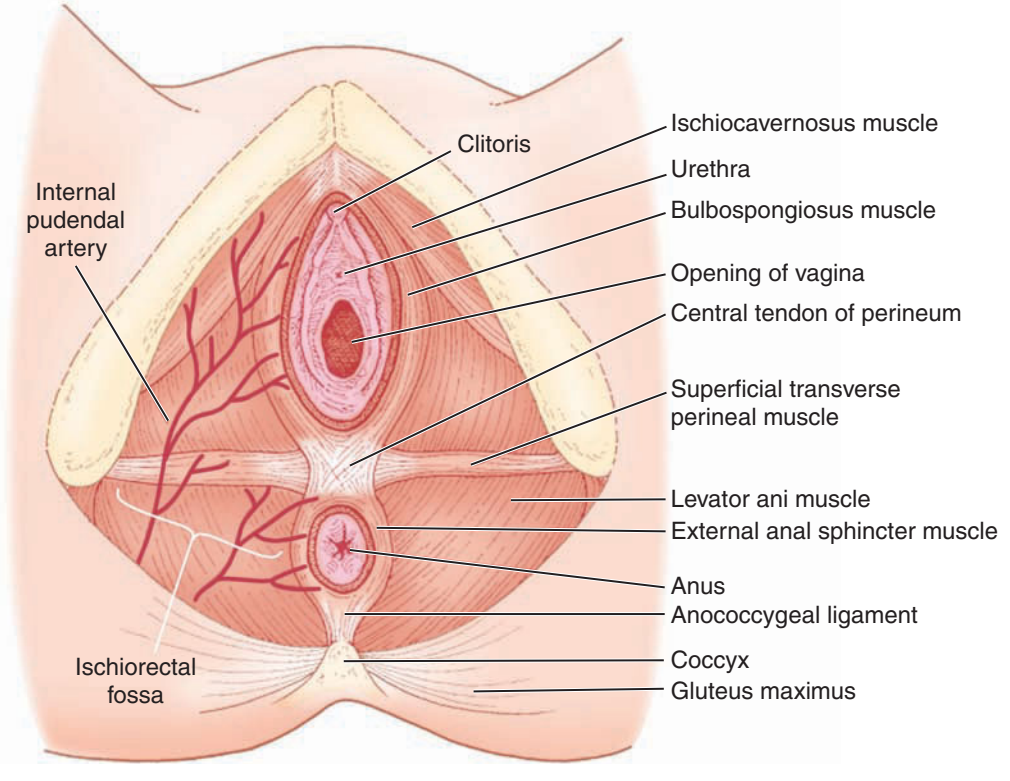

FIGURE 132-1. The anatomy of the perineum. The skin and subcutaneous tissues have been removed.

tuberosities and to the inferior pubic rami through the perineal membrane and superficial transverse perineal muscles. The bulbospongiosus muscles are located laterally to the introitus and deep to the labia majora. They insert into the inferior limit of the perineal body with the superficial transverse muscles and the subcutaneous portion of the external anal sphincter. Laterally, the bulbospongiosus muscle is attached to the muscles of the pelvic diaphragm. It is anchored posteriorly to the coccyx by the anal sphincter and anococcygeal ligament. The mediolateral episiotomy transects the superficial muscles of the perineum whereas the midline episiotomy does not.

The pudendal nerve supplies most of the innervation to the perineal body. This nerve is formed from the ventral rami of sacral spinal nerves two through four. The arterial supply is primarily derived from the internal pudendal artery, one of the branches of the anterior trunk of the internal iliac artery.[11]

TYPES OF EPISIOTOMY

An episiotomy may be performed in the midline or mediolaterally (**Figure 132-2**).[13–16] The choice between the two types of episiotomy is largely dependent upon the experience of the practitioner. Factors that influence type of episiotomy include, but are not limited to, the site of prior episiotomies, position of the presenting fetal part, the thickness or rigidity of the patient's perineum, and the obstetric perception of an impending severe laceration that risks a fourth-degree extension. A mediolateral incision may be prudent when an extended episiotomy is required or when the risk of a fourth-degree laceration is significant.[17–19] **Never perform a lateral (Figure 132-2A) or a Schuchardt (Figure 132-2D) episiotomy in the Emergency Department.** These are associated with significant complications.[13]

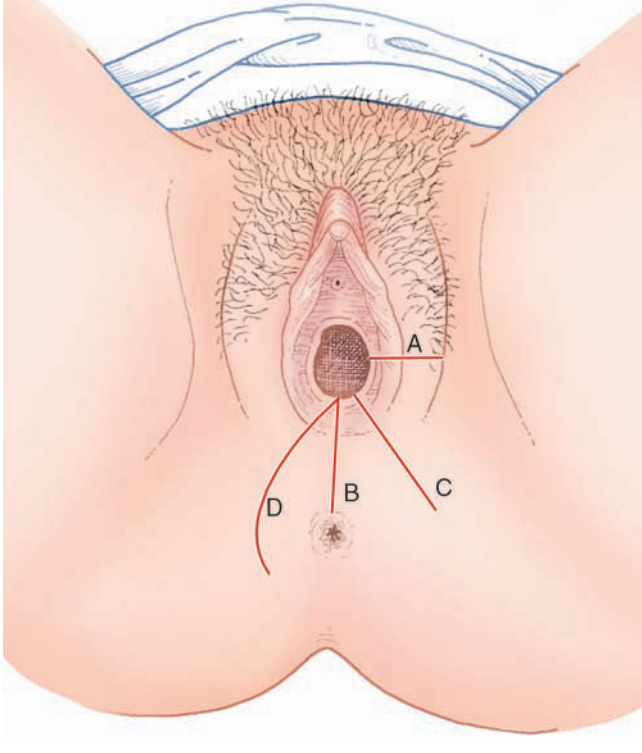

FIGURE 132-2. The types of episiotomies. **A.** Lateral. **B.** Midline. **C.** Mediolateral. **D.** Schuchardt.

MIDLINE EPISIOTOMY

The midline episiotomy is a surgical incision made in the midline of the perineal body, starting from the vaginal orifice toward the anus (**Figure 132-2B**). The incision transects the central tendinous portion of the perineal body and usually extends to the level of the transverse perineal muscle (**Figure 132-1**). This is the most common type of episiotomy performed in the United States. The midline episiotomy is easy to perform and to repair. It is associated with quicker healing, less pain and postpartum discomfort since no muscle belly is transected, and less blood loss than the other types of episiotomies. Compared to mediolateral episiotomies, there is an increased risk of third-degree and fourth-degree extensions with the midline episiotomy.

MEDIOLATERAL EPISIOTOMY

The mediolateral episiotomy is preferred outside the United States.[20] The mediolateral episiotomy is a surgical incision made from the midline of the posterior vaginal orifice obliquely toward the ischial tuberosity (**Figure 132-2C**). The anatomic structures transected from superficial to deep are the skin, the subcutaneous tissues, the bulbospongiosus muscle, the superficial transverse perineal muscle, and a portion of the levator ani muscle and fascia.

The mediolateral episiotomy is the preferred technique as it is associated with a decreased risk of extension to the anal sphincter (third-degree laceration) and the rectum (fourth-degree laceration), especially when combined with an operative vaginal delivery.[21] The disadvantages of the mediolateral episiotomy are the increased blood loss, higher degree of difficulty to repair, and increased postpartum discomfort.[6,17,22,23] It may also result in faulty healing, anatomical deformities, and dyspareunia. The adequate surgical repair of these structures requires a good understanding of the anatomy of the perineum, and is technically more challenging.

EXTENSION OF AN EPISIOTOMY

The classification of perineal lacerations most often used in the United States is quite simple.[24] A first-degree laceration is a superficial laceration of the vaginal mucosa or perineal body not requiring suturing. A second-degree laceration or episiotomy involves the vaginal mucosa and/or perineal skin and subcutaneous tissue. It requires suture closure. The third-degree laceration or episiotomy is an extension of the laceration to involve any part of the capsule or anal sphincter muscle. Finally, the fourth-degree laceration or episiotomy is an extension to include involvement of the rectal mucosa.

INDICATIONS

The rate of episiotomy decreases as one travels the continuum from Obstetrician to Family Practitioner to Certified Nurse Midwife to lay Midwife. The indications for episiotomy are more largely based on expert consensus than in evidence-based criteria. The indications depend on the clinical picture at the time of delivery. Most practitioners consider the performance of an episiotomy to be appropriate in situations of fetal distress or maternal disease requiring urgent delivery.[8] Deliveries necessitating greater space accommodation for effective delivery are also indications for an episiotomy. These situations include shoulder dystocia, breech delivery, forceps or vacuum extractions, occiput posterior positions, and cases of imminent perineal rupture.[25] Other indications include too small of a perineal body with a high likelihood of a large spontaneous laceration, contracted outlet syndrome, face presentations, and extensive fetal head extension. It is commonly believed

that an episiotomy safely aids in shortening the second stage of labor and reduces trauma to the pelvic floor musculature.[4] More perineal and pelvic tissue injury is noted with a precipitous labor; thus a timely episiotomy is critical.[1]

CONTRAINDICATIONS

Contraindications to performing an episiotomy include rectal or perineal lesions, prior or concurrent fistulae, inflammatory bowel disease, prior rectal surgery, or prior anal surgery.[26] Maternal diseases that impair healing such as autoimmune disorders (e.g., SLE, rheumatoid arthritis), HIV, pregestational diabetes mellitus, and immunosuppression are relative contraindications to an episiotomy. Some authors suggest that coagulation disorders may be contraindications.[13] However, a vaginal delivery with an episiotomy is preferable to a cesarean delivery.[13] Relative contraindications specific to the midline episiotomy are a short perineum, fetal macrosomia, vaginal operative deliveries, and abnormal fetal presentation.

EQUIPMENT

- Local anesthetic solution, lidocaine or bupivacaine
- Alcohol wipes
- 16 to 18 gauge needle
- 10 mL syringe
- 22 to 25 gauge needle
- Straight Mayo scissors
- #10 scalpel blade on a handle
- Povidone iodine solution
- Sterile drapes
- Sterile gown and gloves
- Chromic or polyglycolic acid suture, 2-0 or 3-0
- Vicryl suture, 4-0 and 5-0
- Needle driver
- 23 gauge spinal needle

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient. Clean the perineum of any dirt, debris, stool, and urine. Apply povidone iodine or chlorhexidine solution and allow it to dry. Place sterile drapes beneath the buttocks, over the legs, and on the abdomen to prevent contamination from nonsterile areas.

Anesthetize the perineal body (**Figure 132-3**). Infiltrate 10 to 20 mL of local anesthetic solution directly into the perineal body, from the posterior base of the vaginal fourchette to the anus (**Figure 132-3A**). This provides safe and effective anesthesia. It may be carefully performed if the baby's head is within the vagina or crowning.

A bilateral pudendal nerve block will also provide excellent pain control (**Figure 132-3B**). It requires more time to perform and cannot be done if the baby's head is in the vagina. Arm a 10 mL syringe with a 23 gauge spinal needle and filled with local anesthetic solution. Place the nondominant index finger in the vagina and palpate the ischial spine. The ischial spines are identified as the bony protrusions located in the posterolateral region of the vaginal side wall. The sacrospinous ligament is a firm band that runs from the ischial spine to the sacrum. The pudendal nerve and artery lie between the ischial spine and ischial tuberosity. Palpate the ischial tuberosity with the nondominant thumb.

To perform the block on the maternal right side, use the right index and middle fingers to palpate the right ischial spine and guide

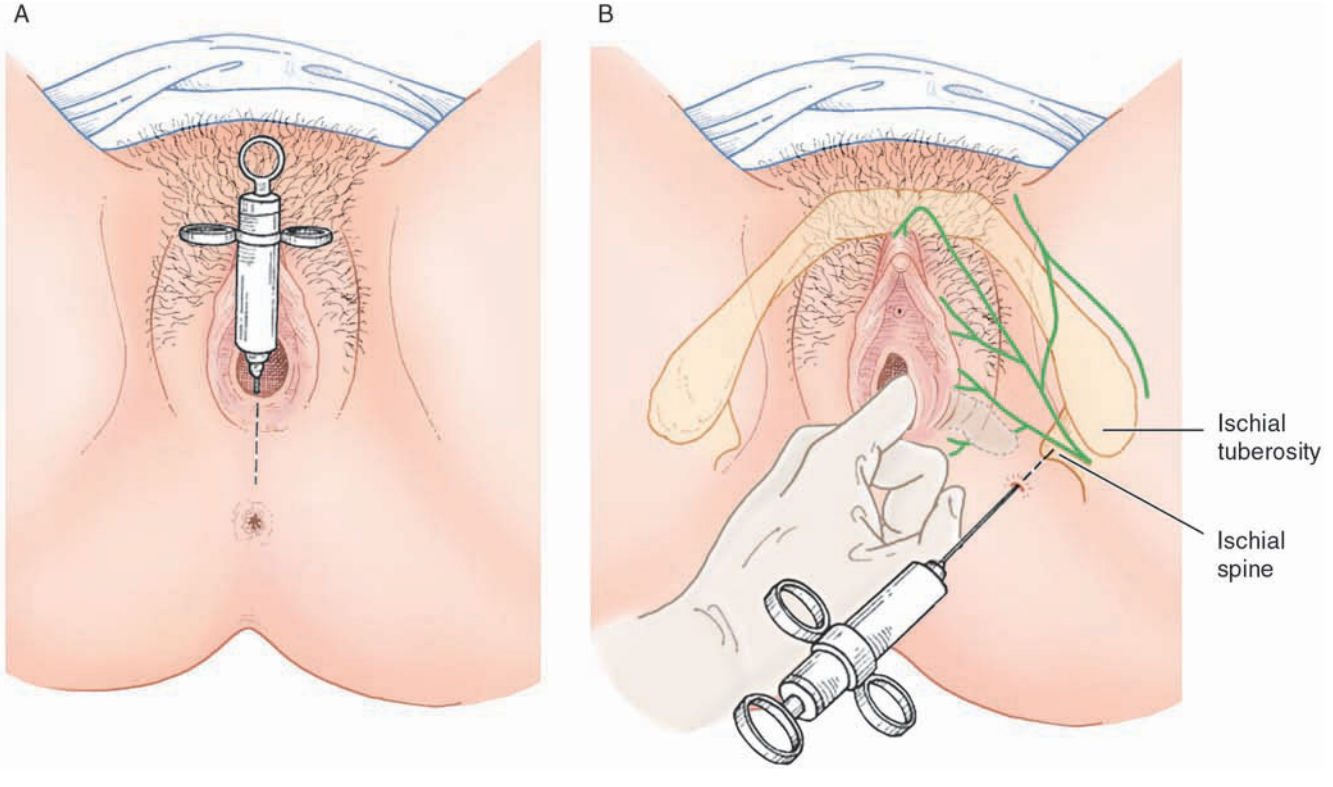

FIGURE 132-3. Anesthesia of the perineum. **A.** Local anesthetic infiltration subcutaneously from the posterior fourchette to the anus. **B.** The pudendal nerve block.

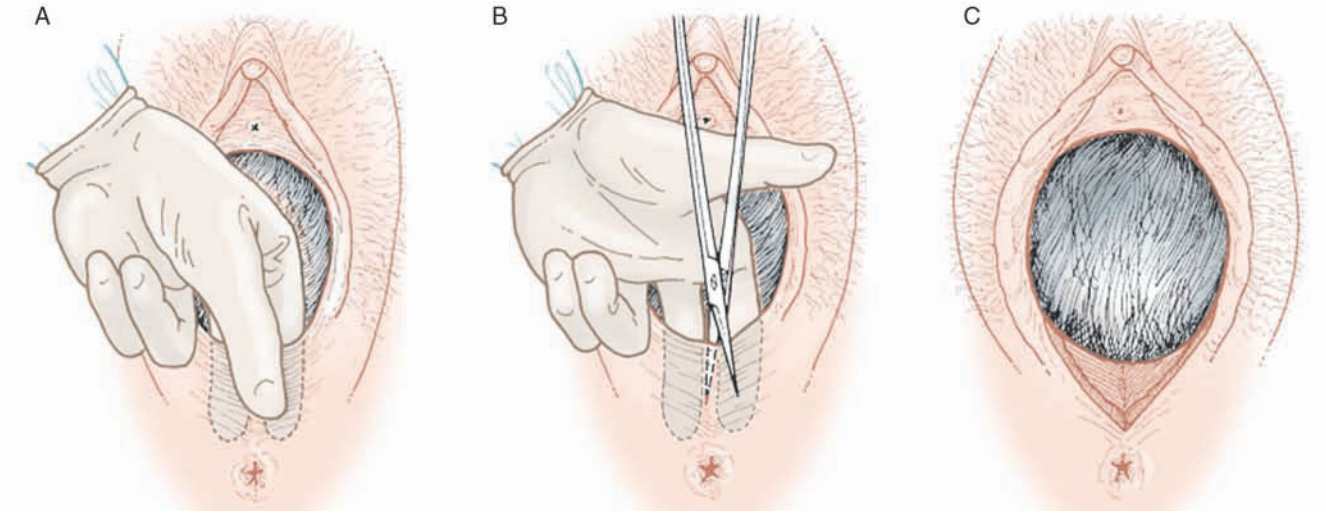

FIGURE 132-4. Performing a midline episiotomy. **A.** Place the nondominant index and middle fingers inside the introitus with the palm facing outward. **B.** Pull the perineal body away from the fetus and insert the straight Mayo scissors. Note that the blades of the Mayo scissors are positioned between the fingers. **C.** The introitus readily opens after making the episiotomy.

the spinal needle. Use the left hand to introduce the needle. Insert the tip of the needle 1 cm medial and 1 cm posterior to the ischial spine. Advance the needle through the sacrospinous ligament. Aspirate to ensure that the injection will not be intravascular. Inject 3 to 4 mL of local anesthetic solution. Advance the needle a few millimeters and inject another 3 to 5 mL of local anesthetic solution. Repeat the procedure on the contralateral side.

Occasionally, a cutaneous branch of the inferior anal nerve can innervate the area surrounding the anus. The infiltration of a local anesthetic solution will be required.[11]

TECHNIQUES

Place the index and middle fingers of the nondominant hand into the patient's introitus, with the palm of the hand facing outward (**Figure 132-4A**). Pull the perineal body away from the fetal presenting part to protect the fetus from injury (**Figure 132-4B**). Use a #10 scalpel blade, a #15 scalpel blade, or a straight Mayo scissors to make the incision. **The editor recommend using only the Mayo scissors. A scalpel can cause significant injury to the fetus, the mother, and/or the Emergency Physician.**

Insert the Mayo scissors so that one blade lies along the skin and the other is inside the introitus, between the index and middle fingers, and against the vaginal mucosa (Figure 132-4B). Allow the maximum descent of the fetal presenting part and moderate distension of the perineum before making the incision to avoid a third-degree or fourth-degree laceration. **Make the incision** when the perineum is bulging and when approximately 4 cm of fetal scalp is visible during a contraction unless early delivery is indicated.[1,22] Extend the incision 2 to 3 cm vertically up the vaginal mucosa. The introitus will readily open after making the episiotomy (**Figure 132-4C**).

MIDLINE EPISIOTOMY

Make the incision vertically in the midline of the perineal body, from the midpoint of the posterior vaginal orifice to the capsule of the anal sphincter (**Figure 132-4**). The incision length depends upon the perineal length. **Make it of sufficient length to increase the area of the introitus for successful delivery of the presenting part without compromising the anal sphincter. The incision must include the tendinous central portion of the perineal body.** This involves (in order of progression from anterior to posterior) the muscular attachments of the bulbospongiosus muscle, the superficial transverse perineal muscle, a portion of the levator ani muscle, and the capsule of the anal sphincter muscle.[8] **The most important aspect of the midline episiotomy is extension of the incision upward into the vaginal mucosal and past the hymenal ring.** This releases any constriction and allows maximal room for the presenting part of the fetus.

MEDIOLATERAL EPISIOTOMY

Make an incision at a 45° angle to the midline of the posterior vaginal orifice, from the inferior portion of the hymenal ring toward the ischial tuberosity (**Figure 132-2C**). The length of the incision is less critical than that for a median episiotomy. Longer incisions require a more extensive repair. The side to which the episiotomy is performed is generally the same as the handedness of the operator.[1] Make the incision at approximately 5 o'clock for left-handed dominants or at 7 o'clock for right-handed dominants. If the incision is not deep enough, there will be too little tissue relaxation and a second incision will be necessary. This second incision increases the risk of a zigzag line after healing.[11] The anatomic structures incised and requiring repair (in progression from superficial to deep) are the skin and subcutaneous tissues, the bulbospongiosus muscle, the superficial transverse perinei muscle, and a portion of the levator ani muscle and its fascia.

ASSESSMENT

Carefully examine the vagina, cervix, and lower uterine segment for any signs of injury or laceration immediately following delivery of the infant and placenta. Do not begin repairing the episiotomy until after the delivery of the placenta. The repair may be compromised if manual removal of the placenta or intravaginal procedures must be performed after the episiotomy is reconstructed. Assess the incision for extension (third-degree or fourth-degree). Identify any site of excessive bleeding and immediately control it with a Vicryl ligature. Perform a digital rectal examination to rule

out a fourth-degree extension or button-holing (a laceration through to the rectal mucosa which is not contiguous with the episiotomy).

MIDLINE EPISIOTOMY REPAIR TECHNIQUES

The midline episiotomy repair is an easier approximation than the mediolateral episiotomy as the incision is symmetrically situated in the perineal tissue.[21,27,28] The choice of suture is physician-dependent.[28] There are several options for episiotomy closure with limited data to suggest the superiority of one single type of material. The principal disadvantage of chromic is the rapid loss of tensile strength, increased wound breakdown, and increased initial pain.[24] The derivatives of polyglycolic acid, Vicryl and Dexon, have about a 20% reduction in short-term pain but causes perineal irritation. They frequently require removal during the puerperium. There are now monofilament absorbable sutures or more rapidly absorbable polyglactin derivates that combine both desirable characteristics of strength and rapid disappearance.[8] Use a round needle to close all layers except the capsule and skin to minimize the risk of a subcutaneous hematoma.

VAGINAL MUCOSA REPAIR

Repair the vaginal mucosa first (**Figure 132-5**). Use 3-0 suture on a noncutting needle. Place the initial suture superior to the apex of the vaginal incision to incorporate any retracted vessels. Tie the suture at the apex of the incision securely. Approximate the wound edges with a running subcuticular stitch (**Figure 132-5A**) or a running simple stitch (**Figure 132-5B**). Place a running locked stitch (**Figure 132-5C**) if there are any concerns about hemostasis. Continue the suture to the hymenal ring. **Do not allow the needle to enter through the rectal mucosa as this can result in the formation of a rectovaginal fistula.**

Place each stitch to bring together the mucous membrane of the vagina and the tissue between the vagina and rectum. This method of suturing provides for hemostasis, eliminates dead space, and decreases the risk of subsequent infection. Extend the continuous suture by one to two stitches past the hymenal ring and to the edge of the skin. Place the final suture to incorporate the subcutaneous tissue but not the skin. Finish reapproximating the skin incision with a buried knot.

The second suture is the so-called "crown suture." It is placed at the base of the sutured vaginal wound. Insert the needle into the immediate subcutaneous tissue, perpendicular to the skin, and angled deeply to approximate the edges of the bulbospongiosus muscle and its fascia. It is important to evaluate the perineal body at this time. If there is a big defect, close it with interrupted sutures to prevent leaving any open dead space. Close the remainder of the incision with the one-suture (**Figure 132-6**) or the two-suture technique (**Figure 132-7**).

ONE-SUTURE TECHNIQUE

The one-suture technique utilizes one strand of suture to close the entire episiotomy (**Figure 132-6**). Close the vaginal mucosa, as described previously, with a running stitch (**Figure 132-6A**). Approximate the hymeneal ring. Continue the running stitch to approximate the perineal body (**Figure 132-6B**). Continue the running stitch until the bottom of the episiotomy is reached. Place a running subcuticular stitch from the bottom of the episiotomy upward to the hymenal ring (**Figure 132-6C**). Finish approximating the skin incision with a buried knot at the hymenal ring.

TWO-SUTURE TECHNIQUE

This technique utilizes two strands of suture to close the episiotomy (**Figure 132-7**). Close the vaginal mucosa, as described

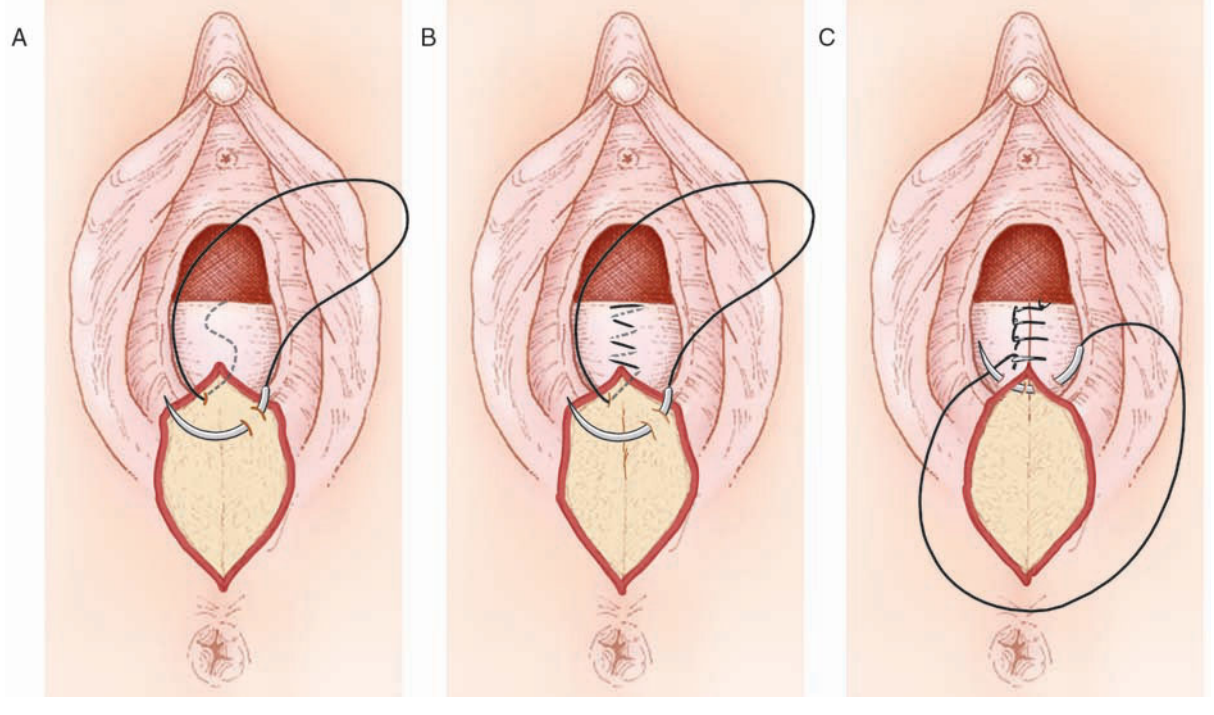

FIGURE 132-5. Methods of closing the vaginal mucosa. **A.** The running subcuticular stitch. **B.** The running simple stitch. **C.** The running locked stitch.

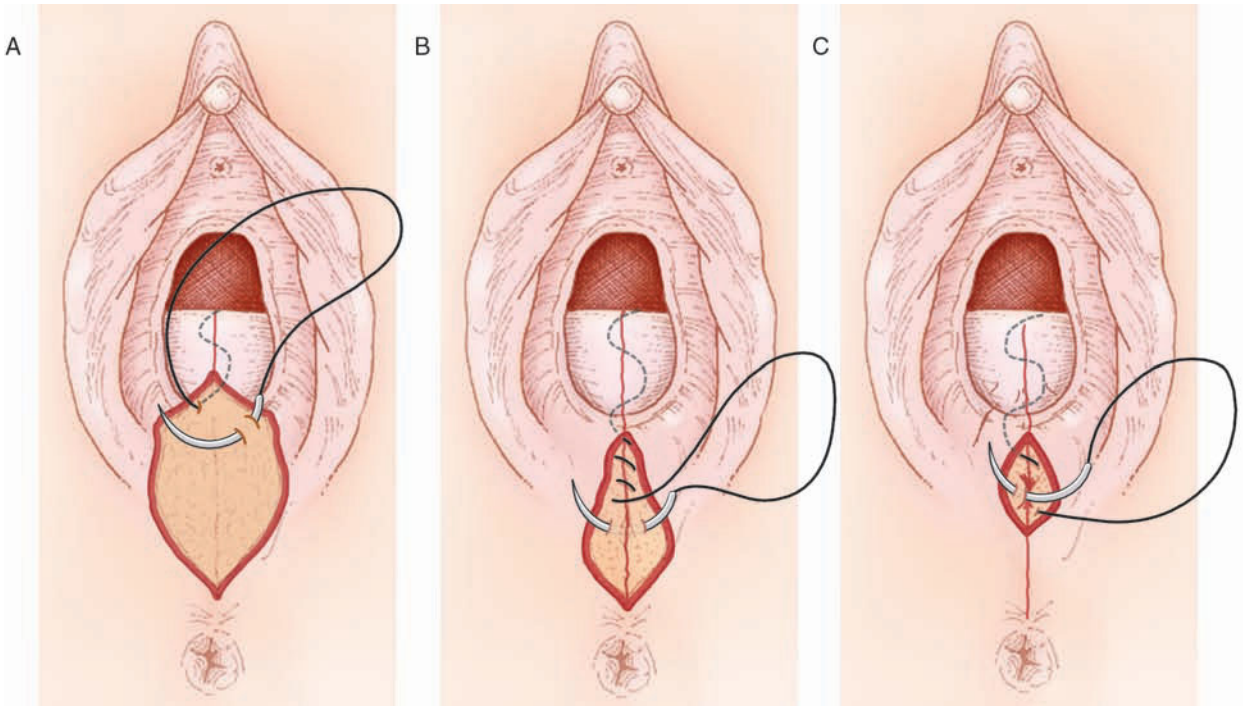

FIGURE 132-6. The one-suture technique to close an episiotomy. **A.** Approximate the vaginal mucosa with a running stitch. **B.** Approximate the hymenal ring followed by a running stitch to approximate the perineal body. **C.** Reverse the suture direction with a running subcuticular stitch to approximate the skin.

previously, with a running stitch (**Figure 132-7A**). Approximate the hymenal ring with this first strand of suture (**Figure 132-7B**). Close the perineal body using a second strand of suture material. Place running or interrupted stitches (**Figure 132-7B**). After the perineal body is closed, use the first strand of suture to place a subcuticular running stitch to approximate the skin (**Figure 132-7C**). Finish approximating the skin incision with a buried knot.

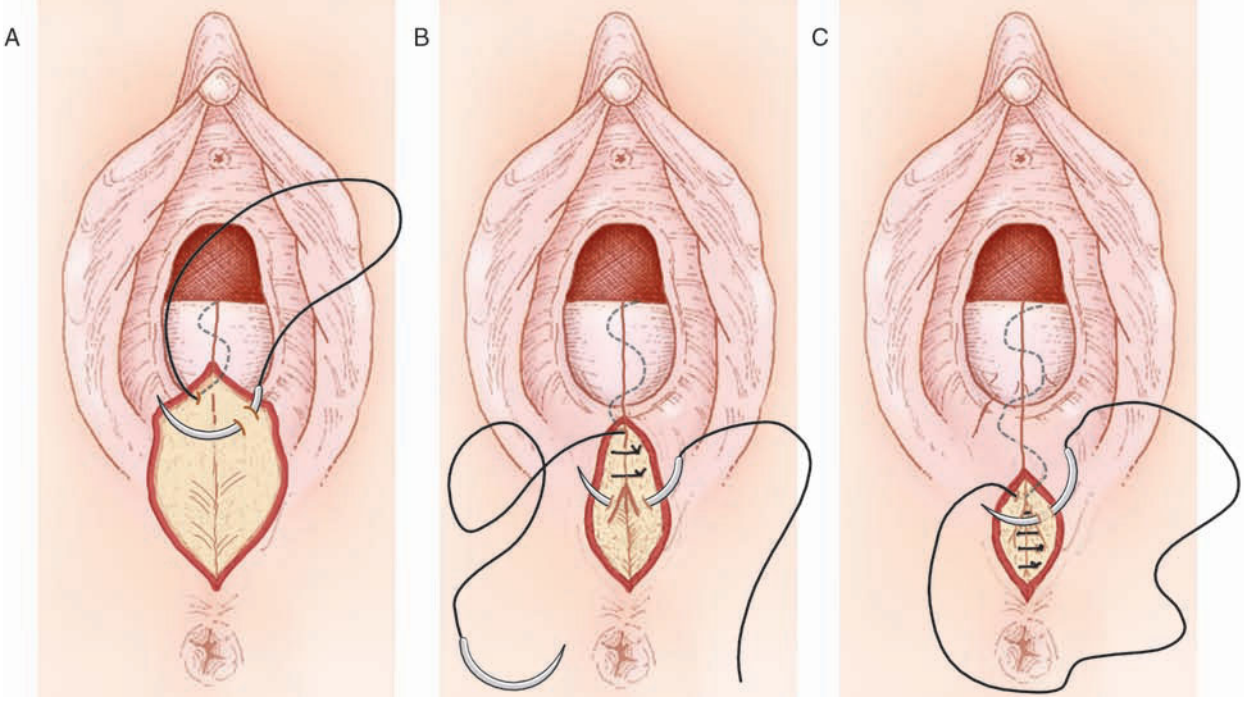

FIGURE 132-7. The two-suture technique to close an episiotomy. **A.** Approximate the vaginal mucosa with a running stitch. **B.** The hymenal ring is approximated with the first suture. The perineal body is approximated with a second suture utilizing an interrupted stitch. **C.** The first suture is continued subcutaneously to approximate the skin.

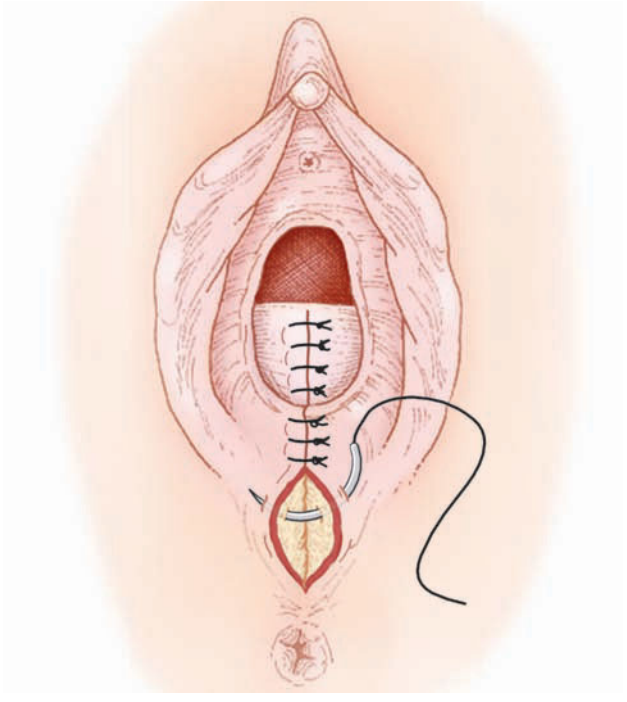

FIGURE 132-8. An alternative technique to close an episiotomy. Place simple interrupted stitches to approximate the mucosa, skin, and perineal body.

ALTERNATIVE TECHNIQUE

Approximation of an episiotomy with one or two sutures can be time consuming and difficult. An alternative is to close the episiotomy using a simple interrupted stitch (**Figure 132-8**). Take deep bites of tissue with the needle to ensure that the stitches close the subcutaneous tissues and perineal body along with the overlying vaginal mucosa and skin.

THIRD-DEGREE LACERATION REPAIR

A third-degree laceration involves the anal sphincter muscle and spares the anal mucosa. Visually inspect the anal sphincter muscle for partial lacerations. **A patient can have normal anal sphincter tone and a partial anal sphincter muscle laceration.** Repair any anal sphincter muscle lacerations as described in the following section on fourth-degree laceration repair.

FOURTH-DEGREE LACERATION REPAIR

Fourth-degree lacerations may occur as a result of a tearing of the tissues with or without an episiotomy. **These lacerations involve the anal sphincter muscle and the anal mucosa. They must be repaired to restore the normal anatomy and decrease the chance of fecal incontinence.**

A suture is placed 1 cm above the apex of the laceration, and extended through the submucosal tissue, but not through the mucosa. The mucosa is closed in a continuous running or subcuticular fashion. The suture should not penetrate the rectal mucosa, and the suture carried down to the perineal body (**Figure 132-8A**). 4-0 or 5-0 chromic gut sutures are usually used for this step, but synthetic material can also be used. A second layer over the rectal mucosa is placed, in order to reinforce the initial suture. Additionally, this suture will close the dead space between the vaginal mucosa and the rectum.

Identify both ends of the anal sphincter. They are usually retracted laterally. Use Allis clamps to grasp the edges and pull them together in the midline (**Figure 132-9A**). It is very important to incorporate the capsule of the anal sphincter in the repair and not just the muscle fibers (**Figure 132-9B**). We recommend the use of the pneumonic "**PISA**" when repairing the anal sphincter.

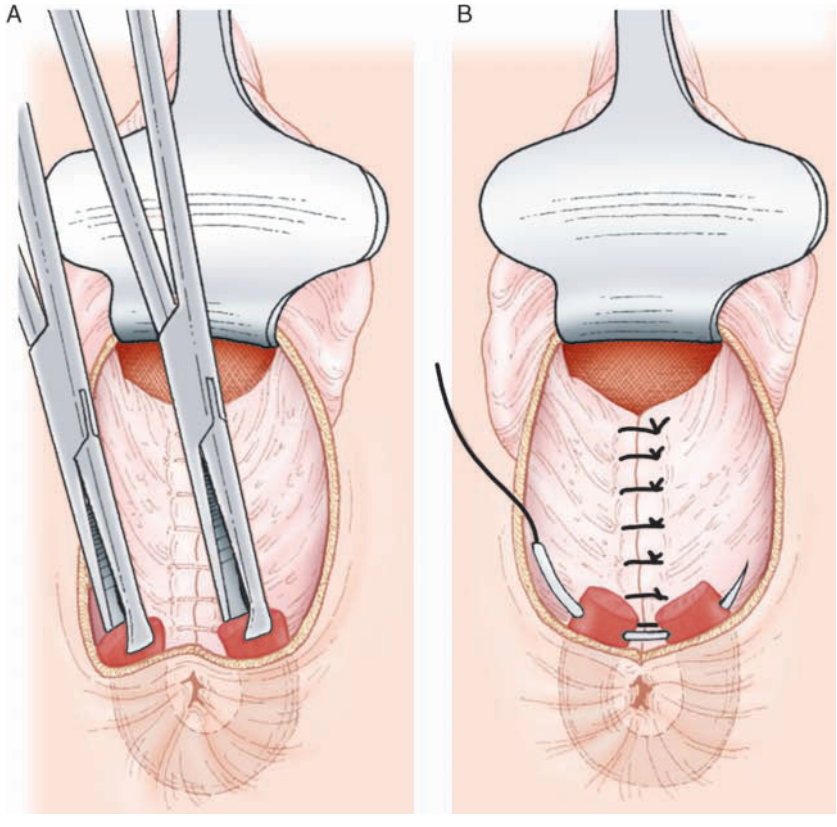

FIGURE 132-9. Repair of a fourth-degree laceration or episiotomy. **A.** Approximate the rectal submucosa and muscularis with simple interrupted sutures. Grasp the cut edges of the anal sphincter muscle with Allis clamps. **B.** Approximate the ends of the anal sphincter muscle with transfixion stitches.

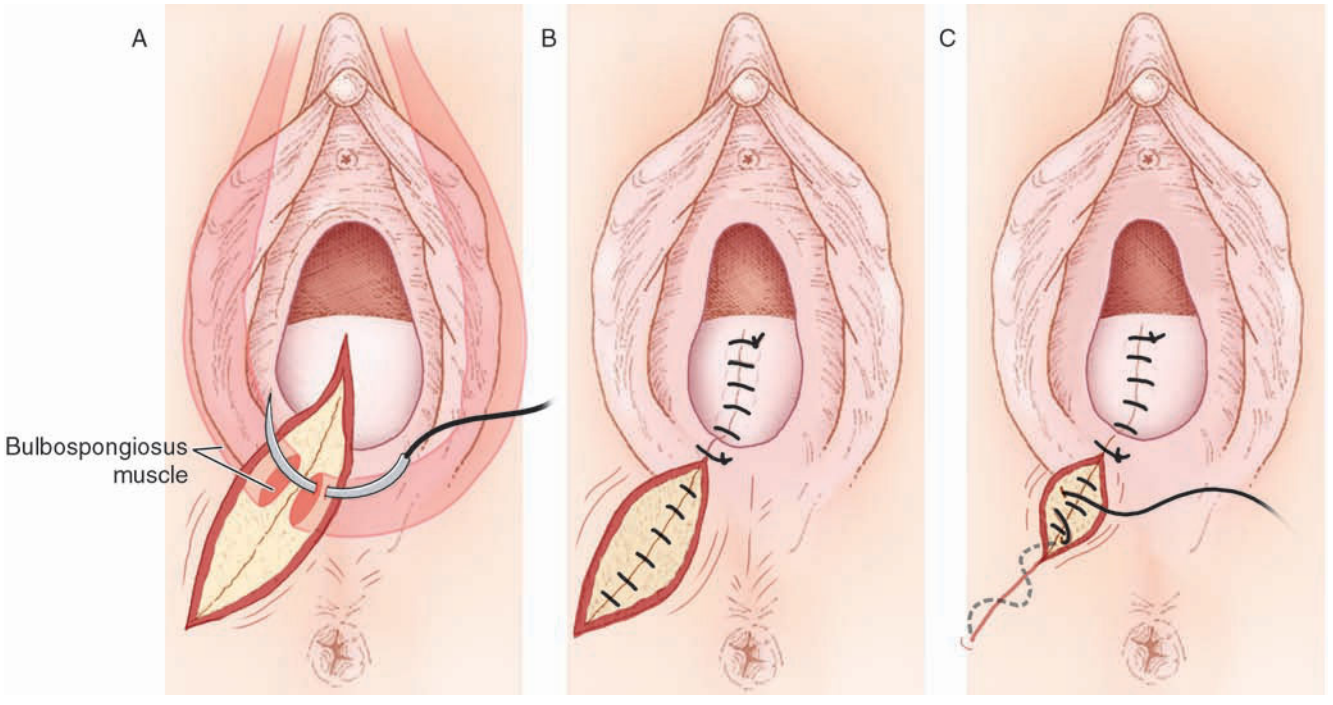

FIGURE 132-10. Repair of a mediolateral episiotomy. **A.** Find and approximate the ends of the transected bulbospongiosus muscle. **B.** Approximate the vagina and deep peroneal tissues using the one-suture or two-suture technique. **C.** Approximate the skin with running subcuticular stitches.

The use of a 2-0 polygalactic acid suture (e.g., Vicryl) on a taper needle is recommended. Initiate the repair with the **P**osterior aspect of the sphincter, which has the structure of a cylinder, at the 9 o'clock position. Next, place the most **I**nferior suture at the 6 o'clock position. Follow this with a stitch in the **S**uperior aspect at the 12 o'clock position. Finish the repair with a suture at the 3 o'clock position on the **A**nterior aspect of the sphincter.

MEDIOLATERAL EPISIOTOMY REPAIR TECHNIQUE

It is extremely important to locate and repair the transected bulbospongiosus muscle. Find and grasp the transected ends of the bulbospongiosus muscle with Allis clamps. Approximate it using 4-0 and 5-0 Vicryl sutures (**Figure 132-10A**). Approximate the vagina and deep perineal tissues using the one-suture or the two-suture technique (**Figure 132-10B**). Approximate the skin of the perineum using a running subcuticular stitch (**Figure 132-10C**).

AFTERCARE

The aftercare for a perineal incision involves perineal hygiene and adequate analgesia. The use of warm sitz baths three to four times a day in concert with the use of ice packs to the perineum will decrease inflammation and the risk of infection. Routine use of prophylactic antibiotics has never been proven effective to prevent infections after an episiotomy. Prescribe stool softeners to decrease the pain of defecation and the risk of episiotomy disruption, especially if it was associated with a third-degree or fourth-degree extension. Nonsteroidal anti-inflammatory drugs or acetaminophen provide adequate analgesia in most patients. Narcotic analgesics may be required for 24 to 72 hours, especially in cases of mediolateral episiotomies. Many Obstetricians prefer oxycodone or acetaminophen with codeine as they are not as constipating as the other narcotic analgesics. This is especially important in patients with third-degree or fourth-degree lacerations.

COMPLICATIONS

The most common complications are hemorrhage, infection, and dehiscence. Most hemorrhage can be controlled by the application of direct pressure with a sterile gauze. Place a figure-of-eight stitch in the tissues if direct pressure fails. The mediolateral episiotomy has an increased risk of hemorrhage compared to the midline episiotomy. Therefore, adequate hemostasis must be assured during the repair. Vaginal hematomas can easily form. Large or expanding vaginal hematomas usually require the incision to be opened, the hematoma drained, and the hemorrhage controlled. Small hematomas can be managed with analgesics and ice packs.
